In this way, application designers can choose a configuration that maximises performance within the limitations of available memory. Clearly, the more constrained the memory, the greater the potential for adverse consequences for performance, or the number of supported connections. However, it should be realised that even with copious quantities of memory resources available to lwIP, it cannot be expected that a stack intentionally designed from the outset to be sparing with memory will perform as well as a stack intentionally designed from the outset for high performance. Nevertheless careful tuning of lwIP almost always results in significant performance improvements.

A simple real-world test application, from a target platform with only a total of 128K of RAM, would when performing a simple test transmitting multiple 1400-byte packets obtain a throughput of >1000k/s. However, the same platform configuration sending multiple 8192-byte packets would see the throughput drop to <100k/s since fragmentation and buffer availability now impact the lwIP performance. System designers need to consider how the application makes use of the available lwIP APIs in conjunction with the resources available to maximise application network throughput.

Limitations

As already mentioned, lwIP does not seek to provide a complete implementation of a TCP/IP stack providing the same level of functionality provided in large OSes such as Linux, Windows, *BSD, etc. While some aspects are controlled by configuration, in other cases functionality is intentionally limited to fit the design requirements of a compact footprint.

While a complete list of the limitations would be too numerous to enumerate, here are some of the most relevant ones to be aware of:

- Retransmission and windowing algorithms are implemented simply, at the expense of some performance.
- Routing is simplified - one gateway per interface. IP forwarding follows the same rules as the host itself.
- No support for NAT, nor packet filtering.
- The TCP, DHCP and IP protocols can contain options in their packets. Relatively few of these options are supported by lwIP.
- IPv4 Path MTU discovery (from RFC1191) is not supported. Ordinarily it is used to avoid fragmentation of packets resulting from the maximum MTU of an intermediate link between source and destination being smaller than the packet sizes actually transmitted. lwIP does however allow the TCP Maximum Segment Size (MSS) to be configured.
- No complex data structures, caches and search trees to optimise speed. Generally simple lists are used.
- Thread safety (for the sequential and BSD compatibility API) is implemented in a very simple form. Individual connections should not be operated on by multiple threads simultaneously. The mutual exclusion that is provided is at a very coarse grain - the network processing operations themselves are not multi-threaded.
- Most ICMP packet types are ignored.
- If IP fragmentation and reassembly support is enabled then a limited sequence of IP fragments can be reassembled at one time (controlled by lwIP configuration options). If the number of active sequences supported is exceeded then packet fragments for new sequences are simply dropped, with the hope that a subsequent retransmission may be successful. Received IP fragments are allowed to be reassembled out of order however.
- The BSD sockets compatibility API does not implement all socket options, API functions, nor API semantics.
- Error handling for application errors is frequently only handled with asserts - used only during debug builds during development, allowing for smaller production code in release builds.

- The TCP persist timer is not implemented. If a remote peer has filled its receive window and as a result lwIP stops sending, then when the remote peer processes more data it sends an ACK to update the window. However if that ACK is lost, then if data is entirely unidirectional (lwIP to remote host), the connection could stall. In practice, this has not been something people have experienced really.
- TCP data is not split in the unsent queue, resulting in somewhat inefficient use of receiver windows.
- The DNS client support only returns IPv4 addresses.
- The SNMP agent only provides traps to IPv4 addresses.
- The SNTP client provides a minimal `SNTPv4` implementation.
- The lwIP IPv6 implementation does not currently track router advertisement routeinfo information. The IPv6 routing simply uses the normal /64 prefix for matching destination addresses against acquired (source) addresses for each indivdual lwIP network interface. If a destination address cannot be matched against an acquired source /64 address then the routingerror (`ERR_RTE`) code is returned. This is not normally a limitation when using link-local or global addresses, but if an organisation is using unique-local addressing the lwIP stack by default will limit addressing to destinations on the same subnet (i.e. the matching /64 prefix). However, an eCos specific extension exists for supporting unique-local addresses, where the CDL option `CYGNUM_LWIP_IPV6_UNIQUELOCAL_MASK` can define the number of global prefix bits which are matched (from /48 to /64). This option can be configured to allow destination addresses for other unique-local subnets to be matched against the specific /64 interface unique-local address.

There are many more examples.

If a lwIP Direct device driver is being used then see the section called “GDB/RedBoot” regarding limitation of remote network GDB/RedBoot debugging.

Quick Start

Incorporating lwIP into your application is straightforward. The essential starting point is to incorporate the lwIP eCos package (`CYGPKG_NET_LWIP`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool. If you wish to support Ethernet devices, you will also need to include the Common Ethernet Support (`CYGPKG_IO_ETH_DRIVERS`) eCos package. For SLIP/PPPoS support, you will need to enable the Hardware serial device drivers (`CYGPKG_IO_SERIAL_DEVICES`) configuration option within the Serial device drivers (`CYGPKG_IO_SERIAL`) eCos package.

Note

When using serial devices it is important to ensure the I/O driver configuration provides the necessary buffers and/or hardware flow-control to avoid the possibility of PPPoS/SLIP RX data loss.

Alternatively, as a convenience, configuration templates have been provided to permit an easy starting point for creating a configuration incorporating lwIP. Two templates are provided: `lwip_eth` for those intending to use lwIP with Ethernet; and `lwip_ppp` for those intending to use lwIP with PPP. These may be used either by providing the template name as an extra argument on the command line to **ecosconfig new**; or with the **Build->Templates…** menu item within the eCos Configuration Tool. Both these templates are basic, incorporating only those packages which are essential for lwIP operation.

At this stage it would be appropriate to tailor the lwIP package configuration to the application requirements. At a minimum it would be appropriate to consider whether a static IP address, or a dynamic IP address served from a DHCP server, is required. Note that if RedBoot is used on the target and incorporates network support, then you must not give lwIP and RedBoot the same IP address. For the same reason, you must not configure both lwIP and RedBoot to obtain an IP address via DHCP.

Prior to coding your application to perform lwIP stack operations using its APIs, the stack must be initialised. This does not happen automatically, and instead a C function must be called:

```
int cyg_lwip_init ();
```

The function declaration can be obtained by including the `network.h` header file:

```
#include <network.h>
```

`cyg_lwip_init` returns 0 on success and non-zero on failure. Note that 0 may be returned even if no network interfaces were successfully initialised. This is because in some cases interfaces are brought up asynchronously in any case, devaluing such an error indication; and because an interface not coming up may be expected. If the application needs to determine the status of interfaces, it should query the stack using the `netif_*` functions using the `<lwip/netif.h>` header file.

The `cyg_lwip_init` function **must** be called from a thread context. Raw API users need not call this function, although they instead will be required to perform their own stack initialization. Consult the raw API documentation for more information.

Note

The `cyg_lwip_init` function, depending on the configuration, may block for some time waiting for interfaces to acquire network addresses. Alternatively the:

```
int cyg_lwip_init_nowait ();
```

function can be called to perform just the necessary low-level initialisation, without the extra addresswait functionality. The `cyg_lwip_init` function itself uses the `cyg_lwip_init_nowait` routine prior to waiting for network addresses to be assigned.

Alternatively, the (weak) helper function:

```
void init_all_network_interfaces ();
```

is provided. By default it just calls the lwIP specific `cyg_lwip_init` initialisation, but it may be overridden by drivers or run-time support if alternative initialisation strategies are required.

Note

The `init_all_network_interfaces` name is the same as used by the alternative `CYGPKG_NET` BSD networking world.

If obtaining an address via DHCP it can be convenient to enable the network interface debugging configuration option within lwIP (`CYGDBG_LWIP_DEBUG_NETIF`). This will allow the IP address which was set to be viewed on the diagnostic output console. Similarly the helper function:

```
int cyg_lwip_netif_print_info (netif, pf);
```

can be called after `cyg_lwip_init` to output specific interface address information via the supplied `printf`-alike routine. For example using `diag_printf` for the *`pf`* parameter will display the address information on the diagnostic output console without having to enable the network interface debugging feature.

Chapter 162. Port

Port status

The eCos port of lwIP in eCosPro is based on the main lwIP Savannah git code base, with modifications consisting of both bug fixes and feature enhancements being made to the lwIP core code by eCosCentric.

The port requires the eCos kernel (`CYGPKG_KERNEL`) for now. The main reasons for this are because the ethernet driver and serial driver implementations have dependencies on interrupts and non-kernel interrupt support is tricky; and that it is only really feasible in the lwIP core code to avoid a multi-thread OS if solely using the raw API. And when using the raw API, the application would have to be responsible for polling the underlying device driver (e.g. Ethernet) in any case.

Some eCos Ethernet drivers may have alignment constraints on packet data. This is usually not a problem, however it can affect PBUF_ROM packets, whose alignment is dictated by the application. Therefore the application must ensure only appropriately aligned PBUF_ROM packets are passed to lwIP, as appropriate for the hardware-specific Ethernet device driver.

lwIP's BSD sockets compatibility API is completely separate from the socket and file descriptor interface provided by the eCos File I/O (`CYGPKG_IO_FILEIO`) package. As such, network packages which rely on semantics such as being able to read and write both files and sockets with that API, cannot work with lwIP at the present time. This includes the httpd, DNS, SNTP and FTP client packages. The NET-SNMP package uses BSD stack-specific APIs and so also cannot work with lwIP, though lwIP can be configured with its own internal SNMP agent providing MIB-2 support. Note that an example httpd server written using the lwIP raw API is included in the `tests/` subdirectory of the lwIP eCos package.

For convenience when using the BSD sockets compatibility API, including the `network.h` header file:

```
#include <network.h>
```

This allows access to the API. This also has the benefit of potentially allowing interchangeable application code if switching between the lwIP BSD socket compatibility API and the real BSD stack port in eCos.

lwIP does not attempt to provide a cleanly delineated namespace for lwIP functions. This could make it difficult to port legacy code where there is a chance of conflicting names and symbols, both functions and data. Care is required here.

Note

The serial-based SLIP and PPP protocols should be functional, however they have not been well tested, and so are not supported under the terms of incident support in eCosPro.

There is only convenient configuration for a single SLIP and/or PPP interface. Multiple interface support is planned for some future point.

Implementation

The following sections provide an overview of how the port is structured regarding the interface between eCos and the core lwIP implementation.

System Configuration

The normal lwIP approach of the user supplying a `lwipopts.h` header file that provides manifests to override the standard lwIP `opt.h` header file is used to configure the main stack features. For eCos the `lwipopts.h` is provided as part of the `CYGPKG_NET_LWIP` package along with the lwIP generic sources. Note: For eCos the `lwipopts.h` also contains definitions for some lwIP features that do not yet have defaults defined within `opt.h`.

The eCos `lwipopts.h` implementation itself sets the majority of the lwIP feature control options based on the standard eCos CDL (`.ecc`) configuration world.

System Source

The `CYGPKG_NET_LWIP` package provides some eCos specific functionality in the `src/ecos/` directory.

- `lwip_ecos_init.cxx`

  This source file provides two functions that are normally called by the application. The function cyg_lwip_init is needed to initialize the lwIP network stack, and cyg_lwip_netif_print_info can optionally be called to output network interface address information.

  If `CYGINT_IO_ETH_DRIVERS_PHY_EVENTS` is configured to provide PHY event notification support then the functions cyg_net_eth_phy_ctx_acquireand cyg_net_eth_phy_dsr are available for network device drivers to manage per-interface event notification between the driver and lwIP TCP/IP stack layers.

- `sys_arch.cxx`

  This source file implements the majority of the run-time support needed by lwIP to execute under eCos, which mainly covers:

  - Mailbox support, mapping lwIP sys_mbox_t to eCos Cyg_Mbox objects.
  - Semaphore support, mapping lwIP sys_sem_t to eCos Cyg_Counting_Semaphore objects.
  - Thread support, mapping lwIP sys_thread_t to eCos Cyg_Thread objects.
  - Mutex support, mapping lwIP sys_mutex_t to eCos Cyg_Mutex objects.
  - Timer conversion support for converting between real-time-clock and millisecond ticks. The cyg_lwip_tick_to_msecand cyg_lwip_msec_to_tick functions may be useful to applications.

- `sio.c`

  Some serial I/O utility routines for SLIP and PPPoS support.

  Only a single serial interface is support and is accessed via a named serial I/O device (either `CYGDAT_LWIP_PPP_DEV` for PPPoS, or `CYGDAT_LWIP_SLIP_DEV` for SLIP). The I/O device is configured with non-blocking RX, and blocking TX as per the requirements of the lwIP APIs. The lwIP package CDL does not enforce any specific serial configuration (due to the varied differences between architectures and driver feature sets), so the developer is responsible for ensuring a suitable serial I/O driver configuration.

Threads

The lwIP network stack is mostly thread-safe for sockets and the sequential API, but not for the raw API. The most important caveat is that even for the sequential API it is **NOT** thread-safe to access the **same** BSD-style socket, or netconn, from multiple threads.

The default for eCos is for the run-time support to provide the TCP/IP helper thread, which is enabled via the lwIP `NO_SYS=0` manifest definition. The lwIP API thread will be created even if the `CYGFUN_LWIP_SEQUENTIAL_API` option is not enabled, unless over-ridden by the `CYGFUN_LWIP_NO_SYS` option.

Note

Disabling the sequential API option does not disable the TCP/IP helper thread for backwards compatibility with previous eCos configurations where the helper thread is expected even if the option `CYGFUN_LWIP_SEQUENTIAL_API` is disabled.

When the TCP/IP helper thread is required, the eCos lwIP run-time support will call the lwIP `tcpip_init()` function as part of the initialization sequence. The created eCos thread is named with the configured `CYGDAT_LWIP_TCPIP_THREAD_NAME` value, and with the priority as configured by `CYGNUM_LWIP_NETWORK_THREAD_PRIORITY`.

Providing this thread allows simple raw API applications to interact with the eCos ethernet device drivers.

Note

The, mutually exclusive, SLIP and PPPoS features require the `CYGFUN_LWIP_SEQUENTIAL_API` support, and hence cannot be used with a `CYGFUN_LWIP_NO_SYS` configuration.

Caution

If the option `CYGFUN_LWIP_NO_SYS` is enabled then the system overhead required for suitably configured raw API applications will be minimised. It is the responsibility of the application to implement the necessary thread or polled model as desired for its specific, required, functionality.

If SLIP support is configured then a handler thread is also created during the system initialization. As with the main lwIP thread the name and the priority of the thread can be set in the eCos configuration.

The current PPPoS implementation does not use a seperate helper thread, with the required RX work being done as part of the normal TCP/IP helper thread.

Note: At some points within the lwIP network stack the eCos scheduler is locked. Whilst this is only for short sections of code, this could disrupt real-time behaviour.

Thread-safety considerations regarding lwIP:

- the network stack is thread-safe in general

  However, individual sockets should **not** be shared between different eCos threads simultaneously (e.g. two threads doing overlapping `recv()`s).

- uses semaphores

  So priority inversion is possible.

- coarse locking granularity

  The whole lwIP network stack can remain locked for a long time whilst an operation is processed. This could exacerbate any priority inversion issues.

- core lwIP code (and hence the raw API) is not thread-safe

- mailboxes are used extensively

  Mailboxes are used to funnel all threads' API requests into the lwIP context to avoid synchronisation problems, but this can cause priority inversion.

  Also the effects of `CYGNUM_KERNEL_SYNCH_MBOX_QUEUE_SIZE` should be considered, since a very shallow mailbox depth could lead to client threads blocking waiting to post requests.

For eCos the timer support has been extended to provide absolute timeout functionality to provide consistent timeout behaviour. The manifset setting `SYS_TIMEOUT_ENDTIME=1` is enforced for eCos builds. If the previous lwIP functionality is required then `SYS_TIMEOUT_ENDTIME=0` and `SYS_TIMEOUT_DELTA=1` should be manually configured in the `lwipopts.h` header file.

Caution

If the older SYS_TIMEOUT_DELTA=1 support is enabled then be aware that the default lwIP sources do not work on absolute times, and as such the lwIP idea of what time is will go wrong if the single lwIP thread is pre-empted for too long. In this case the lwIP code should really be executed in a high priority thread, but this is not enfored by default, as there may be application threads in the system which must run at a higher priority. This laxness of time management within lwIP can lead to problems with some sub-systems. For example, accuracy of DHCP lease-time renewal requests

Extensions

When creating a deeply-embedded network application some features of lwIP can be used by the general application code to save on the code footprint of duplicating similar support. One major area that can easily be made use of in such a way is the lwIP memory allocation support.

If the CDL option CYGFUN_LWIP_MEMP_USE_CUSTOM_POOLS is enabled then the user can supply the lwippools.h header file accessible to the lwIP build. This header file is included by lwIP when defining the memory pool structures, and can include application specific *custom* pools. The following example implementation provides a new application specific 16 entry memory pool containing 64-byte buffers:

```
/*> lwippools.h <*/

/* NOTE: We do NOT have the standard header file one-time inclusion conditional
   checks since this source file is referenced multiple-times, with different
   macro definitions, depending on the part of the memory pool support being
   instantiated. */

LWIP_MEMPOOL(APP_BUFFER, 16, 64, "APP_BUFFER")

/*> EOF lwippools.h <*/
```

The custom memory pool space is located within the configured lwIP memory pool space. The pool can then be accessed via the memp_malloc() and memp_free() as normal:

```
pointer = (someptr *)memp_malloc(MEMP_APP_BUFFER);
/* Do some work with the buffer … */
memp_free(MEMP_APP_BUFFER, pointer);
```

For eCos the memory pool allocation support is protected using the SYS_ARCH_PROTECT (DSR) serialization support code, allowing the calls to be made from any thread.

Similarly if lwIP is configured with CYGFUN_LWIP_MEM_USE_POOLS then it will use fixed size memory pools instead of a heap for the mem_malloc() calls. The lwippools.h header file can then be used to define the specific fixed size memory pools to be used by including suitable LWIP_MALLOC_MEMPOOL() macro calls. For example the following fragment will define a set of fixed size pools:

```
/* Define three pools with buffer sizes of 256, 512, and 1512 bytes  respectively. */
LWIP_MALLOC_MEMPOOL_START
LWIP_MALLOC_MEMPOOL(20,  256)
LWIP_MALLOC_MEMPOOL(10,  512)
LWIP_MALLOC_MEMPOOL( 5, 1512)
/* More pools can be added as required. */
LWIP_MALLOC_MEMPOOL_END
```

eCos API reference

Name

cyg_lwip_init — Initialise lwIP network stack

Synopsis

#include <arch/cc.h>

`int` **`cyg_lwip_init`** `();`

Description

This function should be called by the eCos application at startup. It performs the initialization of the lwIP network stack and any configured network device drivers.

If either of the IPv4 DHCP `CYGSEM_LWIP_DHCP_WAIT_DHCP_COMPLETE` or IPv6 stateless autoconfiguration `CYGSEM_LWIP_IPV6_AUTOCONFIG_WAIT_COMPLETE` options are enabled then this initialization routine will wait for up to the maximum of the configured timeouts for the network interfaces to acquire the relevant addresses. If the network services are slow in providing a required address then it is possible that this function will exit with the interface not yet reachable from the network, so applications should always validate interfaces after calling this initialization routine. The wait support is provided by this routine to ensure a common implementation. If required the function can be called again to re-wait for the configured timeouts, but it should be noted that subsequent calls do **not** re-initialize the lwIP stack.

Return value

The value 0 is returned on completion of the initialization. The value 1 is returned if the routine has previously been called, and is **not** an indication of a failure to initialise.

Name

cyg_lwip_netif_print_info — Output network interface address information

Synopsis

#include <arch/cc.h>

```
int cyg_lwip_netif_print_info (iface, pf);
```

Description

This helper function provides a common method for applications to output network address information for the specified *iface* interface. It can be used (see the section called "Quick Start") to provide user feedback of acquired addresses. It can easily be used with test programs by supplying `diag_printf()` as the *pf* output function. Supplying an application specific routine however can allow for the fixed format address string to be output via an alternative user interface.

The network interface pointer for passing to this function in the *iface* parameter can be obtained from the lwIP function:

```
struct netif *netif_find(char *name)
```

The *name* passed is the registered two-character interface name. Alternatively if the default network interface is required it can be directly referenced via the exported struct netif *netif_default variable.

Return value

The value 0 is returned on success. The value 1 is returned if there was a problem with the interface, e.g. the link is not up, or the address associated with the interface has not yet been set.

Name

cyg_net_eth_phy_ctx_acquire — Allocate PHY event context

Synopsis

#include <cyg/io/eth/eth_drv.h>

`void *`**`cyg_net_eth_phy_ctx_acquire`**` (`*`priv`*`);`

Description

To allow per-interface PHY notification, the client network driver will call this function to register the passed *`priv`* reference, and to be given an abstract handle which is subsequently passed to the cyg_net_eth_phy_dsr function when the driver needs to notify the lwIP stack of a PHY event. For lwIP this passed value **MUST** be a structnetif*netif (network interface) reference.

Return value

A `NULL` value indicates a system error, otherwise it is the abstract handle used in the driver->lwIP PHY event notification. The caller of this function does not need to interpret the returned value. Internal to the lwIP stack the value returned depends on whether the lwIP world is configured to use a helper thread. For `NO_SYS` (true raw) configurations without a helper thread this function will just return the passed *`netif`* parameter since that is all that is needed for the driver->lwIP support. When a helper thread is being used (e.g. sequential API) then it will be a pointer to the message used to communicate the PHY event information in a thread-safe manner.

Name

cyg_net_eth_phy_dsr — Notify lwIP stack of PHY event

Synopsis

#include <cyg/io/eth/eth_drv.h>

```
void cyg_net_eth_phy_dsr (ctx);
```

Description

This function is called when the underlying network device driver needs to notify the lwIP TCP/IP stack of a link (PHY) event. Primarily this would be used to report link up or down events as appropriate, since certain TCP/IP operations may need to occur when a network connection is re-established (e.g. ARP packets, address negotiation, etc.).

The *ctx* parameter should be the pointer returned by the cyg_net_eth_phy_ctx_acquire call.

Name

cyg_lwip_tick_to_msec — Convert eCos kernel clock ticks to millisecond count

Synopsis

#include <arch/sys_arch.h>

`u32_tcyg_lwip_tick_to_msec (ticks);`

Description

Convert eCos kernel clock *ticks* value to a millisecond count.

Return value

The number of milliseconds corresponding to the supplied *ticks* value.

Name

cyg_lwip_msec_to_tick — Convert millisecond count to eCos kernel clock ticks

Synopsis

#include <arch/sys_arch.h>

`cyg_tick_countcyg_lwip_msec_to_tick (msecs);`

Description

Convert millisecond count to eCos kernel clock ticks.

Return value

The eCos kernel clock ticks corresponding to the supplied *msecs* millisecond count.

Name

cyg_lwip_statistics — Statistics output

Synopsis

#include <arch/cc.h>

```
void cyg_lwip_statistics (outfn);
```

Description

This function is provided mainly for debugging and development tuning, since it may be useful to monitor lwIP resource usage over various test scenarios when tuning an eCos lwIP configuration.

The function is a NOP unless the lwIP statistics gathering support is configured. The main configuration option `CYGDBG_LWIP_STATS` controls the availability of the statistics feature, with sub-options then being available to control specific sub-section statistics gathering.

The *`outfn`* is the printf-style varargs routine used to output the human-readable information. For example, a simple usage would be to pass the `diag_printf` function so that the statistics are output on the same diagnostic channel as any other test/debug information.

Chapter 163. Configuration

This chapter shows how to include the lwIP networking support into an eCos configuration, and how to configure it once installed. This subject was briefly covered in the section called “Quick Start”.

Configuration Overview

The lwIP networking stack is contained in a single eCos package `CYGPKG_NET_LWIP`. However, it depends on the services of a collection of other packages for complete functionality:

CYGPKG_KERNEL

> The main eCos kernel package. This provides the main run-time infrastructure as needed by the lwIP stack. For example, support for threads, semaphores, mailboxes, etc.

CYGPKG_ISOINFRA

> ISO C and POSIX standards infrastructure package. This provides access to many run-time utility routines. For example `rand_r()`.

CYGPKG_ERROR

> Error package. This provides access to the common eCos error and status codes.

CYGPKG_LIBC_STDLIB

> General support library. This provides general ISO C utility functions to the lwIP system.

CYGPKG_LIBC_STRING

> Strings library. This provides the string and memory move and compare routines used by the lwIP system.

CYGPKG_LIBC_I18N

> Internationalization library. This provides character interpretation support routines.

CYGPKG_IO_ETH_DRIVERS

> The common ethernet device driver support package. This is only required when lwIP is being configured for ethernet support.

CYGPKG_IO_SERIAL_DEVICES

> The serial device driver support package. This is only required when lwIP is being configured for SLIP or PPPoS support.

To add the lwIP support to a configuration, it is necessary to add the packages listed above as appropriate. This is best done by using a template file. Two examples of such templates files are provided:

lwip_eth   Provides a `current.ect` file containing the packages necessary to add ethernet lwIP support to any configuration.

lwip_ppp   Provides a `current.ect` file containing the packages necessary to add lwIP serial-based interface support to any configuration.

In addition to the packages listed above, hardware-specific device driver packages will be needed for ethernet devices to be used. These device drivers are usually part of the target description in the eCos database and will be enabled if the `CYGPKG_IO_ETH_DRIVERS` package is included.

For some target platforms a choice of device driver will be available. The lwIP driver model section of the CYGPKG_IO_ETH_DRIVERS_LWIP option may allow either a Direct or Standard driver to be selected. Direct are lwIP only device drivers designed for better performance on lower resource systems, but with some limitations on features supported (for example remote network debugging as mentioned in the section called "GDB/RedBoot"). The Standard drivers use the eCos standard ethernet driver interface allowing the device driver to be used for configurations using other TCP/IP stacks (e.g. FreeBSD) as well as for lwIP configurations.

Note: If lwIP is being configured to provide POSIX-style names for some socket support operations then the eCos package CYGPKG_IO_FILEIO should not normally be enabled in the eCos configuration at the same time, since care needs to be taken to avoid name-space clashes.

Configuring the lwIP stack

Note: For a low-level brief overview of how the lwIP source accesses the configured features see the section called "System Configuration".

Once added to the configuration, the lwIP package has a large number of configuration options. There are too many configuration options to go into full detail in this section, though the major eCos port specific options and fundamental support options are detailed. The configuration tool can be used to examine the hierarchy of the complete set of lwIP configuration options.

Stack size for system threads (CYGNUM_LWIP_THREAD_STACK_SIZE)

> The eCos lwIP implementation uses this fixed value as the stack size for all the lwIP system threads.
>
> If this value is set too low then incorrect operation can result due to stack overflow. The value should be configured to be large enough to cover the target platform worst-case stack requirement. The Thread Information documentation provides an overview of the `cyg_thread_measure_stack_usage()` that can be used to monitor and tune the stack requirements of the network application.

Network thread priority (CYGNUM_LWIP_NETWORK_THREAD_PRIORITY)

> This value defines the main lwIP network thread priority, and also, if the feature is used, the default thread priority assigned to lwIP system threads.

Loop interface (CYGFUN_LWIP_LOOPIF)

> This option controls whether support is included for the standard loopback network interface. The interface is created with the IPv4 address `127.0.0.1` and the IPv6 address `::1`. The interface can be used for testing purposes, or where compatibility with existing code is required.

Ethernet support (CYGPKG_LWIP_ETH)

> This boolean option defines whether support for ethernet interfaces is enabled, and if enabled provides access to a variety of configuration options for the ethernet interfaces.
>
> By default the eCos configuration provides support for defining up to 3 ethernet network interfaces. If more interfaces are required then the CDL source in `cdl/lwip_net.cdl` will need to be manually edited. For the following descriptions the *n* suffix should one of `0`, `1` or `2`.
>
> Interface *n* config (CYGPKG_LWIP_ETH_DEV*n*)
>
> > If this boolean option is enabled then it provides the set of configuration options for the specific ethernet network interface. The following STATIC, DHCP, AUTOIP and MANUAL options are mutually exclusive, with only one being actively configured at any point.

Static IPv4 address (`CYGPKG_LWIP_ETH_DEV_ADDR_STATIC*n*`)

If this boolean option is enabled then the ethernet interface will be configured during initialization to use the supplied IPv4 addresses.

IP address (`CYGPKG_LWIP_ETH_DEV_ADDR_STATIC_IP*n*`)

This option provides the hard-coded IPv4 address for the interface.

Netmask (`CYGPKG_LWIP_ETH_DEV_ADDR_STATIC_NETMASK*n*`)

This option provides the hard-coded subnet IPv4 netmask for the interface.

Gateway (`CYGPKG_LWIP_ETH_DEV_ADDR_STATIC_GW*n*`)

This option provides the hard-coded gateway router IPv4 address to be used for the default route for packets sent via the interface that are not destined for the directly connected subnet.

IPv4 address from DHCP (`CYGPKG_LWIP_ETH_DEV_ADDR_DHCP*n*`)

If the lwIP DHCP (Dynamic Host Configuration Protocol) support is configured then this option can be enabled for the interface to obtain its IPv4 address, netmask and gateway values from a suitable DHCP server present on the network.

IPv4 address from AutoIP (`CYGPKG_LWIP_ETH_DEV_ADDR_AUTOIP*n*`)

This option if enabled configures the interface to obtain a link-local IPv4 address using the AutoIP feature.

Set address manually (`CYGPKG_LWIP_ETH_DEV_ADDR_MANUAL*n*`)

This option if enabled indicates that the application code will itself be calling the lwIP functions required to configure the interface addresses.

The application will **need** to supply a `cyg_lwip_eth_init_manual()` function implementation, which will be called from the common IO layer lwIP Ethernet initialisation.

Set as default interface (`CYGPKG_LWIP_ETH_IS_DEFAULT*n*`)

This option, if enabled, selects the respective interface as the default to be used when the network stack needs to communicate with an address which is not part of a network directly associated with a specific interface.

TCP (`CYGPKG_LWIP_TCP`)

This option controls whether the TCP protocol is supported by the lwIP configuration. If enabled, a set of configuration options are available to tune the lwIP TCP implementation.

IPv4 (`CYGFUN_LWIP_IPV4`)

This option enables the IPv4 support. If enabled, a set of configuration options are available to control IPv4 specific features.

IPv6 (`CYGFUN_LWIP_IPV6`)

This option enables the IPv6 support. If enabled, a set of configuration options are available to control IPv6 specific features.

UDP (`CYGPKG_LWIP_UDP`)

This option controls whether the UDP protocol is supported by the lwIP configuration. If enabled, a set of configuration options are available to tune the lwIP UDP implementation.

SNMP Agent (`CYGFUN_LWIP_SNMP`)

If enabled the lwIP world will provide a SNMP (Simple Network Management Protocol) MIB-II agent.

Due to the stated lightweight and simple nature of lwIP, with it mainly being targeted at resource limited embedded targets, the SNMP features available are constrained (e.g. lwIP has a limited notion of IP routing, only pre-compiled MIBs, etc.). Objects located above the `.iso.org.dod.internet` hierarchy are not supported. By default only the `.mgmt` sub-tree is available, though if the CDL option `CYGFUN_LWIP_SNMP_PRIVATE_MIB` is enabled then the `.private` sub-tree becomes available too via the application supplied `private_mib.h` header file.

The supplied `private_mib.h` must contain a struct mib_array_node mib_private definition which is referenced by the lwIP SNMP agent, and describes the private MIB hierarchy. As an example the main struct min_array_node mgmt provided in the source file `src/core/snmp/mib2.c` can be referenced.

Note: The SNMP agent has a sizeable code and data footprint, so may not be suitable for targets with limited resources.

SLIP (`CYGPKG_LWIP_SLIP`)

If enabled lwIP will provide support for the SLIP (Serial Line IP) subsystem. This will provide a network interface to encapsulate IP packets and to send and receive them to a remote system using eCos serial drivers. This option enables a set of SLIP specific configuration options. Note: Though basic functionality has been tested, the SLIP functionality is not supported under the terms of the incident support in eCosPro.

PPP (`CYGPKG_LWIP_PPP`)

If enabled lwIP will provide support for the PPP (Point-to-Point Protocol) subsystem. This option enables a set of PPP specific configuration options.

PPP-over-Ethernet (`CYGPKG_LWIP_PPPOE_SUPPORT`)

If this PPP sub-option is enabled then support for PPPoE (PPP-over-Ethernet) is provided. This provides support for encapsulating PPP frames inside ethernet frames, and is mainly used where a secure point-to-point connection is required, for example, to avoid IP, MAC and DHCP issues.

Note

Support for PPPoE is not yet tested or supported for eCosPro.

PPP-over-Serial (`CYGPKG_LWIP_PPPOS_SUPPORT`)

If this PPP sub-option is enabled then support is provided to encapsulate IP packets and to send and receive them to a remote system using eCos serial drivers.

Note: PPP is more sophisticated than SLIP, and is therefore larger. It does however provide extra features, such as authentication, better link management, option negotion and header compression.

Note: Though basic PPPoS functionality has been tested, the PPPoS functionality is not supported under the terms of the incident support in eCosPro.

RAW sockets (`CYGPKG_LWIP_RAW`)

This option enables support for raw sockets. These allow the transmission or reception of packets over IP but using protocols other than TCP or UDP; or in order to construct packets that cannot be constructed with the lwIP API directly. Raw sockets can be used by selecting a connection type of NETCONN_RAW with the lwIP sequential API. This support is also used by the BSD socket API when creating a socket of type SOCK_RAW

Provide sequential API (CYGPKG_LWIP_SEQUENTIAL_API)

> This option enables support for the lwIP sequential API (see the section called “Application Programming Interfaces (APIs)” for an overview).

Provide BSD-style socket API (CYGFUN_LWIP_COMPAT_SOCKETS)

> This option enables the lwIP support for BSD-style socket operations. This can be useful for adapting existing software to be able to use the lwIP stack.
>
> The socket functions in the API have the form `lwip_accept()`, `lwip_bind()`, `lwip_listen()` etc. Enabling this option causes macros to be defined to map these functions to the BSD function names (`accept()`, `bind()`, `listen()`, etc.). If this causes naming conflicts for the application, then you may wish to disable this option. Particular care is required if this option is enabled at the same time as the File I/O CYGPKG_IO_FILEIO package is used since a single source file will be unlikely to be able to use the File I/O APIs and the lwIP BSD compatible socket API.

Provide POSIX-style socket API (CYGFUN_LWIP_POSIX_SOCKETS_IO_NAMES)

> This option enables the lwIP support for POSIX-style socket operations, useful for adapting existing software to be able to use the lwIP stack. The socket functions in the API have the form `lwip_read()`, `lwip_write()`, etc. Enabling this option causes macros to be defined to map the POSIX function names (`read()`, `write()`, etc.) to these lwIP functions. If this causes naming conflicts for the application you may want to disable this option.

Generate *proto* checksums (CYGIMP_LWIP_CHECKSUM_GEN_*proto*)
Verify *proto* checksums (CYGIMP_LWIP_CHECKSUM_CHECK_*proto*)

> There are a set of configuration options to control checksum generation and calculation support. The IP suffix deals with the generic ethernet IP packet checksum, and the UDP and TCP suffixes with the specific protocol packet checksums. The ICMP6 suffix (CHECK only) performs verification of IPv6 ICMPv6 packets.
>
> See the section called “Checksums” for more information regarding the implications of these options.

Checksum on copy (CYGIMP_LWIP_CHECKSUM_ON_COPY)

> This option if enabled implements code to calculate checksums when copying data from application buffers to packet buffers.

Internal lwIP callback hook definition header (CYGBLD_LWIP_HOOK_H)

> This option allows a specific configuration (i.e. application) to provide its own optional lwIP hook callback definitions if required. Some hooks extend functionality (e.g. LWIP_HOOK_VLAN_SET) whilst others are useful for diagnostics or tracking (e.g. LWIP_HOOK_IP4_INPUT). If enabling this functionality the developer should be conversant with the internals of lwIP and understand how to declare the specific hook macros as well as how they will be called.
>
> One caveat to be aware of is that since the hooks are compiled-into the lwIP stack they may be called from the very beginning of the network stack startup, which may be before the main application code is fully initialised. Care should be taken in the called hooks to ensure a valid state exists. This also means that any hooks that are defined to call application code, the relevant functions need to be available to all code linked against the lwIP stack built with the hooks included.
>
> Any private state needed must be referenced via the `netif` descriptor. However we currently use the `netif->state` pointer internally for eCos. The exact interpretation of the `state` field depends on the actual eCos configuration. For standard driver worlds it is normally a reference to the driver `struct eth_drv_sc` descriptor.
>
> So for any other private application context that needs to be referenced we can use the `client_data` vector held in each `netif` descriptor. The lwIP stack internally has fixed slots allocated for its internal functionality, so we need to ensure that CYGNUM_LWIP_NETIF_CLIENT_DATA is configured with the number of extra slots needed by any application code. The application is responsible for managing the indexing from LWIP_NETIF_CLIENT_DATA_INDEX_MAX onwards.

Hardware driver override header (CYGBLD_LWIP_HW_DRIVER_OVERRIDE_HEADER)

> This option is not normally set by the user, but is provided to allow device drivers to specify a target specific header file that can be used to influence the lwIP configuration.
>
> For example, the lwIP direct ethernet drivers use a header file configured via this option to influence the way the lwIP packet buffer pool is created.

ALTCP abstraction layer (CYGFUN_LWIP_ALTCP)

> This option enables the TCP abstraction layer that replaces the internal TCP function references with indirect calls allowing the support for SSL/TLS or proxy-connect support to applications written against the lwIP TCP callback API without the application layer requiring knowledge of the underlying protocol details.
>
> When the ALTCP functionality is enabled the option CYGFUN_LWIP_ALTCP_TLS controls whether the ALTCP TLS API is available.
>
> For eCos, in conjunction with the Mbed TLS (CYGPKG_MBEDTLS) package, the CYGFUN_LWIP_MBEDTLS configuration option uses the lwIP Mbed TLS wrapper for the lwIP CYGFUN_LWIP_ALTCP_TLS controlled TLS API.

Note

If the CYGFUN_LWIP_ALTCP_TLS option is enabled, but the CYGFUN_LWIP_MBEDTLS option is **not** enabled, then the developer is responsible for providing the ALTCP wrapper functions required. The lwIP package sub-directory src/apps/altcp_tls/altcp_tls_mbedtls contains the Mbed TLS wrapper which can be used as a reference if required.

Memory pool sizes (CYGNUM_LWIP_MEMP_NUM_*pool*)

> The lwIP configuration contains the ability to set many memory related options. The major configuration being the number of pool entries for the different types of memory buffer and descriptors used within the various lwIP subsystems, and these are prefixed CYGNUM_LWIP_MEMP_NUM_ with a usage specific *pool* suffix.
>
> See the section called “Memory Footprint” for more information about tuning the lwIP memory footprint.

Normally the configuration options should be left at their default values unless you have a specific need to change them, e.g. memory requirements. Once the configuration has been created, it should be possible to compile eCos and link it with the application without any errors.

Performance and Footprint Tuning

Performance

There are many changes in configuration that can affect performance. For example, the number and size of buffers, how checksum calculations are implementated, etc.

The CYGDBG_LWIP_STATS option can be enabled to allow for a variety of statistics counts to be gathered during execution. The various options are all prefixed with CYGDBG_LWIP_STATS_, and a sub-system specific suffix.

These statistics can help with the tuning of the lwIP world during development, since monitoring the minimum and maximum usage counts of resources along with the error counts can indicate resource starvation issues. Note: Some error counts are indicative of a temporary inability to claim a resource, and are not necessarily a fatal error for the stack, just a potential slowdown.

In order to determine the number of resources used in practice, during development it is recommended that testing is performed under the expected maximum load expected to need to be handled, in order to understand the resource requirements at that load. To get useful information for this, temporarily configure lwIP with a higher number of resources than would be expected to be needed, memory permitting. Then the application should be tested under the expected network load, at the end of which, the statistics can be inspected, and attention paid to the "max" fields which show the maximum number of each resource used in practice in that sample scenario. This can then be used to inform decisions into the appropriate allocation of reduced resources set in the configuration of lwIP for the final product, without unduly compromising performance.

If CYGDBG_LWIP_STATS is enabled then the function:

#include <lwip/stats.h>

```
void stats_display ();
```

can be used to dump all of the statistics gathered via the output routine defined by the LWIP_PLATFORM_DIAG function wrapper (currently defined to use diag_printf() in the eCos specific arch/cc.h header file).

See the section called “Memory Footprint” for more information about tuning the lwIP memory footprint.

TCP

If the CYGPKG_LWIP_TCP option is configured then various TCP specific options are available for tuning the performance. The main options are covered in the subsections below.

Receive Window

The CYGNUM_LWIP_TCP_WND option defines the maximum TCP receive window size. This size is advertised to remote peers to indicate how much data they can send. While larger values are faster, you should not advertise more than you can receive, which means you must have sufficient capacity in the pbuf pool used for received data for **all** your connections.

Maximum Segment Size

The CYGNUM_LWIP_TCP_MSS option defines the Maximum Segment Size (MSS) advertised to peers to constrain the amount of TCP data they send in each packet. This is recommended not to be more than the interface MTU less 40 bytes. The 40 bytes are the sum of a TCP header and IP header, neither with any options. If any options are used regularly, this value should be reduced further.

If the MSS has been set too large, it will result in IP fragmentation and consequent inefficient network operation. If the MSS is too large and IP fragmentation has been disabled (CYGFUN_LWIP_IP_FRAG), incorrect stack operation will likely result including oversize packets never getting sent, or even a failure in the ethernet driver. The most common MTU size is 1500 bytes (leading to a recommended MSS of up to 1460 bytes) but is certainly not universal: some routers, and especially VPNs, can have lower MTUs and will in turn fragment packets leading to lower efficiency. For best resource utilisation by lwIP, it is a good idea for the MSS to be set so that incoming packets can fit into a whole number of pbufs from the packet buffer pool. As such the default MSS is that of the pbuf pool packet buffer size (CYGNUM_LWIP_PBUF_POOL_BUFSIZE), less 40 bytes to allow room for TCP and IP headers without options.

Sending Data

The CYGNUM_LWIP_TCP_SND_BUF option defines the amount of buffer space in bytes allowed for outstanding (unacked) sent data for each TCP connection. This option is complementary to CYGNUM_LWIP_TCP_SND_QUEUELEN which defines the number of packet buffers allowed for outstanding (unacked) sent data for each TCP connection. The TCP layer will refuse to queue a buffer to be sent if either the total quantity of data in bytes waiting to be sent would then exceed CYGNUM_LWIP_TCP_SND_BUF, or there are already at least CYGNUM_LWIP_TCP_SND_QUEUELEN buffers in the queue waiting to be sent.

Optimizations

The following sections detail some optimization hints that could be useful on certain target platforms to maximise lwIP data throughput.

Checksums

A major performance bottle-neck for lwIP is the software checksum code, since it is executed frequently. If the underlying ethernet device driver provides hardware checksum support then the appropriate CHECKSUM_GEN_* and CHECKSUM_CHECK_* options can be disabled. However if software checksums are needed then you may want to override the standard checksum implementation. This can be achieved by adding a LWIP_CHKSUM definition to a header file included by lwIP, e.g. adding the following to lwipopts.h:

```
#define LWIP_CHKSUM your_checksum_routine
```

The standard lwip_standard_chksum() implementations from src/core/inet_chksum.c provide some C examples, though you might want to craft an assembly function for this specific case. RFC#1071 is a good introduction to this subject. A highly optimized assembler routine will provide the greatest improvement in overall lwIP performance for software checksum based systems.

If the CYGIMP_LWIP_CHECKSUM_ON_COPY functionality is enabled then support for calculating checksums when data is copied into the stack (from application buffers into packet buffers) and can result in fewer checksum calculations if a packet buffer is going to be used multiple times, or if pre-calculated checksums are available for pre-built packets.

The memcpy()-alike function:

```
u16_t lwip_chksum_copy (dest, src, len);
```

can be used to copy data, and return the checksum of the data copied. The extra TCP TF_SEG_DATA_CHECKSUMMED flag is used internally by the lwIP TCP support to track whether a checksum has been set on the payload data.

Network-vs-Host

Since network byte order is big-endian, other significant improvements can be made by supplying assembly or inline replacements for htons() and htonl() if you're using a little-endian architecture.

```
#define LWIP_PLATFORM_BYTESWAP 1
#define LWIP_PLATFORM_HTONS(x) your_htons
#define LWIP_PLATFORM_HTONL(x) your_htonl
```

If the lwIP CYGIMP_LWIP_HAL_BYTESWAP configuration option is enabled then lwIP will use the HAL supplied support. The CYGIMP_LWIP_HAL_BYTESWAP option is enabled by default if the architecture indicates that optimised byte-swap implementations are available, otherwise the option is disabled by default and for little-endian architectures lwIP will provide byte-swap functions.

Device Driver

The ethernet MAC device driver should ideally use interrupts and DMA to avoid busy loops wherever possible. Hardware support for scatter-gather DMA should be used if available, since multiple packet buffers can then be used to hold the different sections of a frame, allowing for zero-copy of payload data.

Release Builds

For a production release it is highly recommended to disable CYGDBG_LWIP_STATS.

Memory Footprint

The setting of the CYGNUM_LWIP_THREAD_STACK_SIZE configuration option and the memory configuration options described in the section called “Performance” will all affect the overall RAM footprint required by lwIP.

However, as long as the option to use the standard run-time allocator (`CYGFUN_LWIP_MEM_LIB_MALLOC`) is **NOT** enabled, the memory footprint of lwIP is deterministic and fixed by the selected configuration.

The major memory configuration options are listed below. Setting these configuration values is usually a compromise between the amount of physical RAM available on the target platform, and the lwIP throughput (performance) requirements.

Heap size (`CYGNUM_LWIP_MEM_SIZE`)

> This option defines the size of the heap that lwIP maintains separate from the system heap so that the resource requirements of one do not affect the other. It is primarily (although not exclusively) used as the memory pool from which packet buffers for transmission are allocated, when the data to be sent needs to be copied (type PBUF_RAM). It is also used to allocate space for dynamically created messages boxes and semaphores. This option can be increased to improve performance when sending large amounts of data.

Packet buffer size (`CYGNUM_LWIP_PBUF_POOL_BUFSIZE`)

> This option specifies the maximum size of data which a single packet buffer (pbuf) allocated from the packet buffer pool for incoming packets can contain. The overall memory footprint of each packet buffer is slightly larger to account for metadata. Incoming packets larger than this size are chained together, using additional packet buffers. If only short packets are usually received, memory efficiency may be improved by reducing the packet buffer size, even if this is accompanied by an increase in the number of packets in the pool using the `CYGNUM_LWIP_PBUF_POOL_SIZE` option. If larger packets tend to be received, the converse is true.
>
> Note: Some network drivers set constraints on the value of this option, in order to better integrate with hardware properties.

Incoming packet messages (`CYGNUM_LWIP_MEMP_NUM_TCPIP_MSG`)
API messages (`CYGNUM_LWIP_MEMP_NUM_API_MSG`)

> When using the sequential API these options define the simultaneous number of, respectively, the packet input and API messages. These messages are used for communicating between external threads and the core lwIP network stack.

Netbufs (`CYGNUM_LWIP_MEMP_NUM_NETBUF`)

> This option defines the maximum number of netbuf structures which may be in use simultaneously with the sequential API (which in turn are used by the BSD sockets API). Each netbuf structure corresponds to a chain of packet buffers to be used for sending or receiving data. This option may be set to 0 if the application will only be using the raw API.

Netconns (`CYGNUM_LWIP_MEMP_NUM_NETCONNS`)

> This option defines the maximum number of netconn structures which may be in use simultaneously with the sequential API. Each netconn structure corresponds to a connection, whether active or inactive. This option may be set to 0 if the application will only be using the raw API.

Packet buffer pool size (`CYGNUM_LWIP_PBUF_POOL_SIZE`)

> This option specifies the number of packet buffers (pbufs) present in the packet buffer pool. This pool is used to provide space for incoming data packets, and so this option limits the number of incoming data packets being processed, or pending (including those not yet read out from the stack by the application). It is also used to hold packet fragments if the option `CYGFUN_LWIP_IP_REASS` is enabled, and so must be large enough to cover the `CYGNUM_LWIP_IP_REASS_MAX_PBUFS` requirement. Note that additional buffers are used in a chain when incoming packets are received which exceed the maximum size of each packet buffer. This option may be adjusted depending on the anticipated peak network traffic. Incoming packets are dropped when the pool is depleted.

Number of memp packet buffers (`CYGNUM_LWIP_MEMP_NUM_PBUF`)

> The lwIP API allows packets to be transmitted which only contain a reference to the data being sent, instead of copying the data into a separate buffer. This can be useful when sending a lot of data out of ROM (or other static memory). This option

specifies the number of such packets that can be used simultaneously. You may wish to increase the value of this option if the application sends a lot of such data, or reduce if not sending any of this form. These buffers are also used when IP fragmentation support is enabled, but a static buffer is not used (`CYGIMP_LWIP_IP_FRAG_USES_STATIC_BUF` disabled), so may also need increasing if fragmentation is common.

RAW protocol control blocks (`CYGNUM_LWIP_MEMP_NUM_RAW_PCB`)

This option defines the number of RAW protocol control blocks that may be used simultaneously. One is required for each active RAW connection.

UDP control blocks (`CYGNUM_LWIP_MEMP_NUM_UDP_PCB`)

This option defines the number of UDP protocol control blocks that may be used simultaneously. One is required for each active UDP connection.

TCP control blocks (`CYGNUM_LWIP_MEMP_NUM_TCP_PCB`)

This option defines the number of TCP protocol control blocks that may be used simultaneously. One is required for each TCP connection. Hence this option defines the maximum number of TCP connections that may be open simultaneously. Increase the value of this option if more simultaneous TCP connections are required.

Listening TCP control blocks (`CYGNUM_LWIP_MEMP_NUM_TCP_PCB_LISTEN`)

This option defines the number of protocol control blocks dedicated to listening for incoming TCP connection requests. This corresponds to the maximum number of TCP ports which may be simultaneously listened on.

Queued TCP segments (`CYGNUM_LWIP_MEMP_NUM_TCP_SEG`)

This option defines the maximum number of TCP segments which may be simultaneously queued. This option may need to be adjusted if the stack reports memory failure errors when attempting to send large quantities of data through TCP connections simultaneously, or when individual TCP writes are so large that the number of MSS-sized segments exceeds the value of this option. If the option to allow out-of-order incoming packets (`CYGIMP_LWIP_TCP_QUEUE_OOSEQ`) is enabled, then such segments may also be dropped if the maximum number of TCP segments specified in this option has been reached.

Queued packets for ARP resolve (`CYGNUM_LWIP_MEMP_NUM_ARP_QUEUE`)

The number of simultaneously queued outgoing packet buffers that are waiting for an ARP request to finish to resolve their destination address.

Queued IP reassembly packets (`CYGNUM_LWIP_MEMP_NUM_REASSDATA`)
Simultaneous IP fragments (`CYGNUM_LWIP_MEMP_NUM_FRAG_PBUF`)

These options provide respectively the number of packets that can simultaneously be queued for reassembly, and the number of fragments (not packets) that can be simultaneously queued for sending.

System timeouts (`CYGNUM_LWIP_MEMP_NUM_INTERNAL_TIMEOUTS`)
User timeouts (`CYGNUM_LWIP_MEMP_NUM_USER_TIMEOUTS`)

The `INTERNAL` value is the number of timeout objects required to support the configured lwIP features. The `USER` value defines the maximum number of user timeouts that may be pending simultaneously. The value of this option may need to be increased if there are more threads using the raw API, or if there are more threads calling the `select()` BSD compatibility function.

Multicast group members (`CYGNUM_LWIP_MEMP_NUM_IGMP_GROUP`)

This option defines the number of multicast groups whose network interfaces can be members at the same time. This value must be at least twice the number of active network interfaces active in the configuration.

Active `lwip_addrinfo()` calls (`CYGNUM_LWIP_MEMP_NUM_NETDB`)
Local host list entries (`CYGNUM_LWIP_MEMP_NUM_LOCALHOSTLIST`)

> If DNS support is enabled then these options respectively control the number of concurrent `lwip_addrinfo()` calls supported, and the number of host entries in the dynamic local host list.

Simultaneous PPP connections (`CYGNUM_LWIP_MEMP_NUM_PPP_PCB`)
Concurrent PPPoE interfaces (`CYGNUM_LWIP_MEMP_NUM_PPPOE_INTERFACES`)

> These options respectively control the number of simultaneously active PPP connections, and the number of concurrently active PPPoE connections.

lwIP Footprint

The following size information was gathered from a CortexM3 targeted configuration using the eCosCentric GNU tools (version 4.4.5c) with gcc *-O2* optimization selected. The byte sizes are provided to give an *example* overview of the lwIP footprint that can be expected, and are purely for informational purposes.

In the following builds *Basic* refers to a sequential API configuration with UDP and TCP support, but with most options disabled (no fragmentation or reassembly support, static address, no SNMP agent, no IGMP, etc.). The builds marked *Reassembly* refers to the addition of fragmented packet reassembly code to the *Basic* builds. The *Full* entry is a configuration with all the lwIP ethernet features enabled (excluding SNMP, SLIP and PPP) to give an idea of the upper footprint for a fully-featured ethernet build.

The values given are for the complete lwIP library package, so specific application linkage (due to the eCos use of *-ffunction-sections*) means that not all of the code and data measured in the sizes given below may actually be included in the final executable. The footprint can be made even smaller by explicit use of the raw API.

Note: The *bss* values below do **NOT** include the stack requirement for the sequential API thread, nor the main configurable lwIP heap space. This is because the aim is to present an example of the base lwIP requirement, independent of the configured heap and stack space required for a particular application or target environment.

CortexM3 (STM32F2xx)	text + rodata	data	bss
Basic IPv4 static	40224	16	516
Basic IPv4 AutoIP	41660	16	516
Basic IPv4 DHCP	46712	16	520
Basic IPv4 IPv6	58680	24	613
Reassembly IPv4 static	41928	16	526
Reassembly IPv4 IPv6	60488	24	627
Full IPv4 IPv6	80512	24	1843

Note: Configurations built with the options `CYGDBG_LWIP_DEBUG`, `CYGDBG_LWIP_ASSERTS` or `CYGDBG_LWIP_STATS` enabled will have a significantly larger code footprint. Similarly configurations built with the `CYGPKG_INFRA_DEBUG` option or the compiler *-O0* optimisation flag will also have a significant effect on the footprint.

Example "small" footprint

The example described in this section targets the STM3220G-EVAL platform, but similar figures have also been obtained for other platforms (e.g. AT91SAM7XEK).

With careful tuning it is possible to implement a simple raw API webserver using the httpd2 test example in ~32K of ROM and ~10K of RAM. This is for the complete application, thread stacks, network buffers, etc.

Even though httpd2 is a simple application it does provide a real-world useful working data point for a minimal footprint system. Note: For this example build the `httpd2.c` source was modified to use the minimal `STACK_SIZE` definition.

The `small_rom_stm3220g_httpd2.ecm` example template used is provided in the lwIP package `doc` directory. The steps needed to build the minimal example binary are:

```
$ mkdir small_httpd2
$ cd small_httpd2
$ ecosconfig new stm3220g_eval
[  ecosconfig output elided  ]
$ ecosconfig import $ECOS_REPOSITORY/net/lwip_tcpip/VERSION/doc/small_rom_stm3220g_httpd2.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make tests
[  make output elided  ]
$ arm-eabi-objcopy -O binary install/tests/net/lwip_tcpip/VERSION/tests/httpd2 httpd2.bin
```

The produced `httpd2.bin` binary can then be loaded into the flash of the STM3220G-EVAL at address `0x08000000`.

Chapter 164. Sequential API

Overview

As described earlier, the lwIP sequential API provides a straightforward and easy-to-use method of interfacing to the stack. Unlike the raw API, which requires event-driven callbacks, an application can simply call the API functions as needed to perform stack operations such as sending data, receiving data, or manipulating packet buffers or connections. While the raw API may allow for more efficient operation, the sequential API typically allows for simpler application design.

Comparison with BSD sockets

In design, it is not unlike the BSD sockets API. Some of the terminology differs however: in the sequential API, the term *connection* is used for any communication link between network peers, and the handle for a connection is termed a *netconn*. A netconn can be considered analogous to a socket, albeit specific to networking - BSD sockets traditionally represent both network connections and files.

The main reason for superiority over the socket API occurs with buffer management. The BSD socket API was designed to manage the fact that the user and the operating system kernel operate in different address spaces and data must always be copied regardless. This results in not only decreased performance, but also increased footprint as buffers must be allocated to hold the copied data.

BSD API Restrictions

By default the eCos lwIP configurations enable the option `CYGFUN_LWIP_COMPAT_SOCKETS` which means normally you cannot include both the lwIP headers `<lwip/sockets.h>` or `<network.h>`, and the `CYGPKG_IO_FILEIO` package (i.e. POSIX-alike) headers from the same file.

Netbufs

Instead of the BSD approach of generic buffers, the sequential API uses *netbufs*, which are based on pbufs. This allows users to manage buffers directly, including even allowing data to come from ROM. Since pbufs, and hence netbufs, can be chained, this also allows the application and lwIP to avoid the need for large regions of entirely contiguous memory in order to hold data. Instead data can be constructed in chunks, and chained together.

When the application wishes to send data, it can send a netbuf directly with UDP. TCP is different as it is intrinsically a buffering, streaming protocol, which requires data to be kept aside to allow for retransmissions. As a result data is sent using just a pointer to memory and a length. However since TCP data can also reside in ROM, it is possible to indicate that the data does not need copying, and so will persist even if the stack needs to queue the data. This can lead to huge savings of memory. For example, static web page content can reside in ROM, and never need to be copied to RAM.

For both TCP and UDP, incoming data is passed to the application as netbufs. The application can use API functions to extract the data from the netbufs - care must be taken as the received data may in fact be a chain. A convenience function exists to copy out the entirety of data across the whole chain into a single contiguous region of memory. Otherwise the application can process data in each netbuf in the chain in turn. The functions `netbuf_first()` and `netbuf_next()` can be used to iterate throught the chain.

TCP/IP thread

When interacting with the network stack using the sequential API, all operations are not handled by the calling thread, but instead are passed to the lwIP network processing (TCP/IP) thread. Inter-thread communication is used inside lwIP to ensure that at the point the API function returns, operation is either complete, or for asynchronous operations, under way.

For example, to register a timeout callback the `tcpip_timeout()` function can be used from client threads to cross the thread boundary into the sequential TCP/IP thread. However, since the actual timeout callback handler registered will be executed within the sequential TCP/IP thread context, it can subsequently directly call the lwIP internal `sys_timeout()` if it needs to re-schedule its callback.

Usage

API declarations

Declarations for all sequential API types and functions may be obtained by including the `<lwip/api.h>` header file:

```
#include <lwip/api.h>
```

Types

Objects of type struct netconn and struct netbuf are intended to be used as opaque types and the structure contents are intended to be maintained and viewed only by lwIP itself. User applications accessing internal members do so at their own risk, and future API compatibility is not guaranteed, nor is thread synchronization since lwIP is entitled to change structure contents at any time.

IP address representation

Depending on the lwIP configuration some API functions take an IP address, which can either be an IPv4 or an IPv6 address.

The IPv4 type struct ip_addr may be accessed as if it has the following structure:

```
struct ip_addr {
  u32_t addr;
};
```

The IPv6 type struct ip6_addr may be accessed as if it has the following structure:

```
struct ip6_addr {
  u32_t addr[4];
};
```

⚠ **Caution**

API users must use the declarations of these structures from the header file `<lwip/ip_addr.h>` which is included implicitly by `<lwip/api.h>`. These types must not be declared by the application itself.

To make it easier to work with either IPv4 or IPv6 addresses the type ipX_addr_t is provided. This is a union of the IPv4 and IPv6 address structures, and may be accessed as if it has the following structure:

```
typedef union {
  ip_addr_t ip4;
  ip6_addr_t ip6;
} ipX_addr_t;
```

See the section called “ipX Helpers” for an overview of the IP version neutral address support. As with the caveat regarding the declarations of the specific IPv4 and IPv6 address structures, the `ipX` declarations should be accessed via including the `<lwip/ip_addr.h>` header file.

IPv4 Addresses

For convenience, predefined struct ip_addr instances are provided for the special cases of "any" IP address (0.0.0.0), and the global broadcast address (255.255.255.255). These instances can be accessed with the macro defines `IP_ADDR_ANY` and `IP_ADDR_BROADCAST` which return values of type struct ip_addr *.

The *`addr`* field is a 32-bit integral value representing the IP address in network byte order (not host byte order).

A variety of convenience function-like macros exist for manipulation or evaluation of IP addresses:

`IP_ADDR_ANY`

> This macro evaluates to an expression of type struct ip_addr * identifying an IP address structure which can be used to represent the special "any" IP address `0.0.0.0`.

`IP_ADDR_BROADCAST`

> This macro evaluates to an expression of type struct ip_addr * identifying an IP address structure which can be used to represent the special global IP address `255.255.255.255`.

`IN_CLASSA(a)`

> An expression which evaluates to non-zero if *`a`* (of type u32_t and in host byte order) is a class A internet address.

`IN_CLASSB(a)`

> An expression which evaluates to non-zero if *`a`* (of type u32_t and in host byte order) is a class B internet address.

`IN_CLASSC(a)`

> An expression which evaluates to non-zero if *`a`* (of type u32_t and in host byte order) is a class C internet address.

`IN_CLASSD(a)`

> An expression which evaluates to non-zero if *`a`* (of type u32_t and in host byte order) is a class D internet address.

`IP4_ADDR(ipaddr, a, b, c, d)`

> Sets ipaddr (of type struct ip_addr *) to the internet address a.b.c.d. For example:

```
struct ip_addr host;
    …
    IP4_ADDR(host, 192, 168, 1, 1);
```

`ip_addr_cmp(addr1, addr2)`

> Returns non-zero if the arguments *`addr1`* and *`addr2`*, both of type struct ip_addr * are identical. Zero if they differ.

`ip_addr_netcmp(addr1, addr2, mask)`

> Returns non-zero if the arguments *`addr1`* and *`addr2`*, both of type struct ip_addr * are on the same network, as indicated by the network mask *`mask`* which is itself also of type struct ip_addr *. Zero if they are on different networks.

`htons(s)`

> Portably converts *`s`* of type u16_t from host byte order to a u16_t in network byte order.

`ntohs(s)`

> Portably converts *`s`* of type u16_t from network byte order to a u16_t in host byte order.

`htonl(l)`

> Portably converts *`l`* of type u32_t from host byte order to a u32_t in network byte order.

`ntohl(l)`

Portably converts *`l`* of type u32_t from network byte order to a u32_t in host byte order.

Some further potentially useful macro definitions can be viewed in `<lwip/ip_addr.h>`.

IPv6 Addresses

The header file `<lwip/ip6_addr.h>` (which is included by default from `<lwip/api.h>`) contains definitions for many IPv6 address convenience function-like macros, as well as utility function prototypes.

The following is not an exhaustive list, so the reader is recommended to inspect the header file to get a complete overview of the IPv6 address support macros and functions.

`IP6_ADDR_ANY`

This macro evaluates to an expression of type struct ip6_addr * identifying an IP address structure which can be used to represent the special "any" IPv6 address `::/128`. It actually just returns the address of the exported `ip6_addr_any` variable.

`ip6_addr_copy(dest, src)`

This implements a fast (no `NULL` check) address copy.

`ip6_addr_set(dest, src)`

Set the *`dest`* address from the supplied *`src`*. If *`src`* is `NULL` the destination is written with zeroes.

`ip6_addr_set_zero(ip6addr)`

Sets the *`ip6addr`* address to all zeroes.

`ip6_addr_set_any(ip6addr)`

This explicitly sets the `IP6_ADDR_ANY` address value.

`ip6_addr_set_loopback(ip6addr)`

This sets the destination *`ip6addr`* parameters to the `::1` loopback address.

`ip6_addr_set_hton(dest, src)`

Copy the *`src`* address to the *`dest`* address converting from host to network byte order.

`ip6_addr_netcmp(addr1, addr2)`

An expression which evaluates to non-zero if the supplied *`addr1`* and *`addr2`* parameters are on the same network, by comparing the most-significant 64-bits of the addresses.

`ip6_addr_cmp(addr1, addr2)`

An expression which evaluates to non-zero if there is an exact match between the supplied *`addr1`* and *`addr2`* parameters.

`ip6_get_subnet_id(ip6addr)`

This returns in host byte order the 16-bit subnet identifier.

`ip6_addr_isany(ip6addr)`

An expression which evaluates to non-zero if *`ip6addr`* matches the `IP6_ADDR_ANY` address (all zeroes).

`ip6_addr_isglobal(ip6addr)`

An expression which evaluates to non-zero if the supplied *`ip6addr`* is a valid global address.

`ip6_addr_islinklocal(ip6addr)`

An expression which evaluates to non-zero if the *`ip6addr`* parameter is a valid link-local address.

`ip6_addr_issitelocal(ip6addr)`

An expression which evaluates to non-zero if the *`ip6addr`* parameter is a valid site-local address.

`ip6_addr_isuniquelocal(ip6addr)`

An expression which evaluates to non-zero if the *`ip6addr`* parameter is a valid unique link-local address.

`ip6_addr_ismulticast(ip6addr)`

An expression which evaluates to non-zero if the supplied *`ip6addr`* is a valid multicast address.

There are various other function-like macros provided to further decode whether the multicast address is a loopback, link-local, admin-local, global, etc. address. The definitions for these variants can be found by inspecting the `<lwip/ip6_addr.h>` header file.

`ip6_addr_isallnodes_iflocal(ip6addr)`

An expression which evaluates to non-zero if the supplied *`ip6addr`* matches the IPv6 `ff01::1` loopback "all nodes" address.

`ip6_addr_isallnodes_linklocal(ip6addr)`

An expression which evaluates to non-zero if the supplied *`ip6addr`* matches the IPv6 link-local "all nodes" address.

`ip6_addr_isallrouters_linklocal(ip6addr)`

An expression which evaluates to non-zero if the supplied *`ip6addr`* matches the IPv6 link-local "all routers" address.

`ip6_addr_set_allnodes_linklocal(ip6addr)`

Sets the given *`ip6addr`* to the `ff02::1` link-local "all nodes" multicast address.

`ip6_addr_set_allrouters_linklocal(ip6addr)`

Sets the given *`ip6addr`* to the `ff02::2` link-local "all routers" multicast address.

`ip6_addr_isinvalid(addr_state)`

An expression which evaluates to non-zero if the supplied *`addr_state`* parameter is `IP6_ADDR_INVALID`.

`ip6_addr_isvalid(addr_state)`

An expression which evaluates to non-zero if the supplied *`addr_state`* parameter denotes a valid address state, where the `IP6_ADDR_VALID` bitmask is set.

`ip6_addr_istentative(addr_state)`

An expression which evaluates to non-zero if the supplied *`addr_state`* parameter has the `IP6_ADDR_TENTATIVE` bitmask set.

`ip6_addr_ispreferred(addr_state)`

An expression which evaluates to non-zero if the supplied *`addr_state`* parameter is `IP6_ADDR_PREFERRED`.

`ip6_addr_isdeprecated(addr_state)`

An expression which evaluates to non-zero if the supplied *`addr_state`* parameter is `IP6_ADDR_DEPRECATED`.

`int ip6addr_aton(const char *cp, ip6_addr_t *addr)`

Checks whether *`cp`* is a valid ASCII representation of an IPv6 address, and if valid converts it to the binary IPv6 address destination *`addr`*. The function returns 1 on successful conversion, or 0 on failure.

`char *ip6addr_ntoa_r(const ip6_addr_t *addr, char *buf, int buflen)`

Converts the binary IPv6 address *`addr`* into an ASCII representation written into the supplied *`buf`* buffer of *`buflen`* bytes.

Returns the *`buf`* parameter on success if the buffer has been updated to hold the ASCII address representation, or `NULL` if the buffer was too small.

ipX Helpers

Instead of directly referencing the IPv4 or IPv6 versions of the utility routines, applications should ideally use the common `ipX_*` variants. These functions, and function-like macros, take as their first parameter a boolean *`is_ipv6`* value denoting when zero that the referenced addresses are IPv4 structures, or when non-zero that the referenced addresses are IPv6 structures. Note: If IPv6 support is not enabled for lwIP then the `ipX_*` implementations default to only using IPv4 addresses.

`ipX_addr_copy(is_ipv6, dest, src)`

This implements a fast (no `NULL` check) address copy.

`ipX_addr_set(is_ipv6, dest, src)`

Set the *`dest`* address from the supplied *`src`*. If *`src`* is `NULL` the destination is written with zeroes.

`ipX_addr_set_ipaddr(is_ipv6, dest, src)`

Sets the *`dest`* address parameter from the specified *`src`*. If *`src`* is `NULL` the destination is written with zeroes.

`ipX_addr_set_zero(is_ipv6, ipaddr)`

Sets the address to all zeroes. This is normally the `ANY` address.

`ipX_addr_set_any(is_ipv6, ipaddr)`

This explicitly sets the `ANY` address.

`ipX_addr_set_loopback(is_ipv6, ipaddr)`

This sets the destination *`ipaddr`* to the respective loopback interface address. For IPv4 this is `127.0.0.1` and `::1` for IPv6.

`ipX_addr_set_hton(is_ipv6, dest, src)`

Copy the *`src`* address to the *`dest`* address converting from host to network byte order.

`ipX_addr_cmp(is_ipv6, addr1, addr2)`

An expression which evaluates to non-zero if there is an exact match between the supplied *`addr1`* and *`addr2`* parameters.

`ipX_addr_isany(is_ipv6, ipaddr)`

An expression which evaluates to non-zero if *ipaddr* is NULL or points at the ANY address value.

`ipX_addr_ismulticast(is_ipv6, ipaddr)`

An expression which evaluates to non-zero if *ipaddr* references a valid multicast address value.

`ipX_addr_debug_print(is_ipv6, debug, ipaddr)`

This debugging helper macro will output the raw IPv4 or IPv6 address via the printf-alike debug support calls if the relevant lwIP debugging option specified by the *debug* parameter is enabled.

Error codes

While the BSD sockets API uses POSIX standard error codes (ENOMEM, EINVAL, etc.) the lwIP sequential API has its own separate set of error code definitions.

These error definitions are used by any API function that returns a value of type err_t. The following table indicates possible error code values and their meaning:

Table 164.1. lwIP sequential API error codes

Code	Meaning
ERR_OK	No error, operation successful.
ERR_MEM	Out of memory error.
ERR_BUF	Buffer error.
ERR_ABRT	Connection aborted.
ERR_RST	Connection reset.
ERR_CLSD	Connection closed.
ERR_CONN	Not connected.
ERR_VAL	Illegal value.
ERR_ARG	Illegal argument.
ERR_RTE	Routing problem.
ERR_USE	Address in use.
ERR_IF	Low-level network interface error.
ERR_ISCONN	Already connected.
ERR_TIMEOUT	Timeout.
ERR_INPROGRESS	Operation in progress.
ERR_WOULDBLOCK	Operation would block.

API reference

Name

netbuf_new() — Allocate a netbuf structure

Synopsis

```
struct netbuf *netbuf_new ();
```

Description

Allocates a netbuf structure. No buffer space is allocated when doing this, only the top level structure. After use, the netbuf must be deallocated with `netbuf_delete()`.

Name

netbuf_delete() — Deallocate a netbuf structure

Synopsis

```
void netbuf_delete ();
```

Description

Deallocates a netbuf structure previously allocated by a call to the `netbuf_new()` function. Any buffer memory allocated to the netbuf by calls to `netbuf_alloc()` is also deallocated.

Example

Example 164.1. This example shows the basic mechanisms for using netbufs.

```
int
main()
{
    struct netbuf *buf;
    buf = netbuf_new();     /* create a new netbuf */
    netbuf_alloc(buf, 100); /* allocate 100 bytes of buffer */

    /* do something with the netbuf */
    /* […] */
    netbuf_delete(buf); /* deallocate netbuf */
}
```

Name

netbuf_alloc() — Allocate space in a netbuf

Synopsis

```
void *netbuf_alloc (buf, size);
```

Description

Allocates buffer memory with *size* number of bytes for the netbuf *buf*. The function returns a pointer to the allocated memory. Any memory previously allocated to the netbuf *buf* is deallocated. The allocated memory can later be deallocated with the `netbuf_free()` function. Since protocol headers are expected to precede the data when it should be sent, the function allocates memory for protocol headers as well as for the actual data.

Name

netbuf_free() — Deallocate buffer memory associated with a netbuf

Synopsis

```
void netbuf_free (buf);
```

Description

Deallocates the buffer memory associated with the netbuf *buf*. If no buffer memory has been allocated for the netbuf, this function does nothing.

Name

netbuf_ref() — Associate a data pointer with a netbuf

Synopsis

```
err_t netbuf_ref (buf, data, size);
```

Description

Associates the external memory pointed to by the *data* pointer with the netbuf *buf*. The size of the external memory is given by *size*. Any memory previously allocated to the netbuf is deallocated. The difference between allocating memory for the netbuf with `netbuf_alloc()` and allocating memory using, e.g., `malloc()` and referencing it with `netbuf_ref()` is that in the former case, space for protocol headers is allocated as well which makes processing and sending the buffer faster.

The result returned will be `ERR_OK` if the data is referenced successfully, or the error `ERR_MEM` if the data could not be referenced due to lack of memory.

Example

Example 164.2. This example shows a simple use of the `netbuf_ref()`

```
int
main()
{
    struct netbuf *buf;
    char string[] = "A string";

    /* create a new netbuf */
    buf = netbuf_new();

    /* reference the string */
    if (netbuf_ref(buf, string, sizeof(string)) == ERR_OK) {
        /* do something with the netbuf */
        /* […] */
    }

    /* deallocate netbuf */
    netbuf_delete(buf);
}
```

Name

netbuf_len() — Obtain the total length of a netbuf

Synopsis

```
u16_t netbuf_len (buf);
```

Description

Returns the total length of the data in the netbuf *buf*, even if the netbuf is fragmented. For a fragmented netbuf, the value obtained by calling this function is not the same as the size of the first fragment in the netbuf.

Name

netbuf_data() — Obtain a pointer to netbuf data

Synopsis

```
err_t netbuf_data (buf, data, len);
```

Description

This function is used to obtain a pointer to and the length of a block of data in the netbuf *buf*. The arguments *data* and *len* are result parameters that will be filled with a pointer to the data and the length of the data pointed to. If the netbuf is fragmented, this function gives a pointer to one of the fragments in the netbuf. The application program must use the fragment handling functions `netbuf_first()` and `netbuf_next()` in order to reach all data in the netbuf. See the example under `netbuf_next()` for an example of how use `netbuf_data()`.

Name

netbuf_next() — Traverse internal fragments in a netbuf

Synopsis

`s8_t` **`netbuf_next`** `(`*`buf`*`);`

Description

This function updates the internal fragment pointer in the netbuf *`buf`* so that it points to the next fragment in the netbuf. The return value is zero if there are more fragments in the netbuf, > 0 if the fragment pointer now points to the last fragment in the netbuf, and < 0 if the fragment pointer already pointed to the last fragment.

Example

Example 164.3. This example shows how to use the `netbuf_next()` function

We assume that this is in the middle of a function and that the variable `buf` is a netbuf.

```
/* […] */
do {
    char *data;
    int len;

    /* obtain a pointer to the data in the fragment */
    netbuf_data(buf, data, len);

    /* do something with the data */
    do_something(data, len);
} while(netbuf_next(buf) >= 0);
/* […] */
```

Name

netbuf_first() — Reset fragment pointer to start of netbuf

Synopsis

```
void netbuf_first (buf);
```

Description

Resets the internal fragment pointer in the netbuf *buf* so that it points to the first fragment.

Name

netbuf_copy() — Copy all netbuf data to memory pointer

Synopsis

`void` **`netbuf_copy`** `(`*`buf`*`,` *`data`*`,` *`len`*`);`

Description

Copies all of the data from the netbuf *`buf`* into the memory pointed to by *`data`* even if the netbuf buf is fragmented. The *`len`* parameter is an upper bound of how much data that will be copied into the memory pointed to by data.

Example

Example 164.4. This example shows a simple use of `netbuf_copy()`

Here, 200 bytes of memory is allocated on the stack to hold data. Even if the netbuf buf has more data that 200 bytes, only 200 bytes are copied into `data`.

```
void
example_function(struct netbuf *buf)
{
    char data[200];
    netbuf_copy(buf, data, 200);

    /* do something with the data */
}
```

Name

netbuf_copy_partial() — Copy some netbuf data to memory pointer

Synopsis

```
void netbuf_copy_partial (buf, data, len, offset);
```

Description

This function is similar to `netbuf_copy()` except that it takes an extra parameter, *`offset`*, which can be used to set an offset from the start of the packet to start copying the *`len`* bytes.

Name

netbuf_chain() — Chain two netbufs together

Synopsis

```
void netbuf_chain (head, tail);
```

Description

Chains the two netbufs *head* and *tail* together so that the data in tail will become the last fragment(s) in *head*. The netbuf *tail* is deallocated and should not be used after the call to this function.

Name

netbuf_fromaddr() — Obtain the sender's IPv4 address for a netbuf

Synopsis

```
struct ip_addr *netbuf_fromaddr (buf);
```

Description

Returns the IPv4 address of the host the netbuf *buf* was received from. If the netbuf has not been received from the network, the return value of this function is undefined. The function `netbuf_fromport()` can be used to obtain the port number of the remote host.

Name

netbuf_fromaddr_ip6() — Obtain the sender's IPv6 address for a netbuf

Synopsis

```
struct ip6_addr *netbuf_fromaddr (buf);
```

Description

Returns the IPv6 address of the host the netbuf *buf* was received from. If the netbuf has not been received from the network, the return value of this function is undefined. The function `netbuf_fromport()` can be used to obtain the port number of the remote host.

Name

netbuf_fromport() — Obtain the sender's port number for a netbuf

Synopsis

```
u16_t netbuf_fromport (buf);
```

Description

Returns the port number of the host the netbuf *buf* was received from. If the netbuf has not been received from the network, the return value of this function is undefined. The function `netbuf_fromaddr()` can be used to obtain the IP address of the remote host.

Name

netconn_new() — Create a new connection structure

Synopsis

```
struct netconn *netconn_new (type);
```

Description

Creates a new connection abstraction structure. The argument usually one of either `NETCONN_TCP` or `NETCONN_UDP`, yielding either a TCP or a UDP connection. No connection is established by the call to this function and no data is sent over the network.

For more advanced use, it is also possible to specify different connection types: `NETCONN_UDPLITE`, `NETCONN_UDPNOCHKSUM` or `NETCONN_RAW`.

If IPv6 support is configured then the type can be suffixed with `_IPV6` to specify an IPv6 connection. e.g. `NETCONN_TCP_IPV6`.

Name

netconn_new_with_callback() — Create a new connection structure with a callback

Synopsis

```
struct netconn *netconn_new_with_callback (type, (*callback));
```

Description

This function is similar to `netconn_new()` except that an additional function pointer *`callback`* is passed. The function pointed to by *`callback`* will be called when data is sent or received. Specifically, the *`netconn_evt`* parameter to the callback is used to indicate the event type. This enum can have the following values:

NETCONN_EVT_RCVPLUS

> Used when new incoming data from a remote peer arrives. The amount of data received is passed in *`len`*. If *`len`* is 0 then a connection event has occurred: this may be an error, the acceptance of a connection for a listening connection (called for the listening connection), or deletion of the connection.

NETCONN_EVT_RCVMINUS

> Used when new incoming data from a remote peer has been received and accepted by higher layers. The amount of data accepted is passed in *`len`*. If *`len`* is 0 then this indicates the acceptance of a connection as a result of a listening port (called for the newly created accepted connection).

NETCONN_EVT_SENDPLUS

> Used when data has been sent to a remote peer and received by it. This only occurs for TCP connections, and specifically is only triggered when, as a consequence of TCP acknowledgements from the remote peer, the free TCP send buffer size now exceeds the configured send buffer low water mark (configured with the `CYGNUM_LWIP_TCP_SNDLOWAT` CDL configuration option). The amount of data sent in the most recent transaction is passed in *`len`*. If *`len`* is 0 then this indicates the connection has been deleted.

NETCONN_EVT_SENDMINUS

> This is only used for TCP connections, and is triggered when a sufficient amount of data has been sent on the connection that the amount of free send buffer space is now under the send buffer low water mark (configured with the `CYGNUM_LWIP_TCP_SNDLOWAT` CDL configuration option). The amount of data sent in the most recent transaction is passed in *`len`*.

NETCONN_EVT_ERROR

> This is only used for TCP connections, and is triggered when an error has occurred or a connection is being forced closed. It is used to signal `select()`.

Name

netconn_new_with_proto_and_callback() — Create a new connection structure with a callback for a specific protocol

Synopsis

```
struct netconn *netconn_new_with_callback(type, proto, (*callback));
```

Description

This function is similar to `netconn_new_with_callback()` except that an additional parameter *`proto`* may be used to indicate the IP protocol number to use. If *`proto`* is non-zero, it must only be used with the *`type`* set to `NETCONN_RAW`.

The most common use of this function is the creation of connections suitable for generating ICMP packets.

Name

netconn_delete() — Deallocate a netconn

Synopsis

```
err_t netconn_delete (conn);
```

Description

Deallocates the netconn *conn*. If the connection is open, it is closed as a result of this call.

Name

netconn_type() — Obtain the type of netconn

Synopsis

```
enum netconn_type netconn_type (conn);
```

Description

Returns the type of the connection *conn*. This is the same type that is given as an argument to netconn_new() (and its variants) and can be one of `NETCONN_TCP`, `NETCONN_UDP`, `NETCONN_UDPLITE`, `NETCONN_UDPNOCHKSUM` or `NETCONN_RAW`.

If IPv6 support is configured then it can also be one of `NETCONN_TCP_IPV6`, `NETCONN_UDP_IPV6`, `NETCONN_UDPLITE_IPV6` or `NETCONN_UDPNOCHKSUM_IPV6`.

Name

netconn_peer() — Obtain the remote host IP address/port of a netconn

Synopsis

```
err_t netconn_peer (conn, addr, port);
```

Description

This function is used to obtain the IPv4 address and port of the remote end of the connection indicated by *conn*. The parameters *addr* and *port* are result parameters that are set by the function. If the connection *conn* is not connected to any remote host, the results are undefined.

Name

netconn_addr() — Obtain the local host IPv4 address/port of a netconn

Synopsis

```
err_t netconn_addr (conn, addr, port);
```

Description

This function is used to obtain the local IPv4 address and port number of the connection *conn*.

Name

netconn_bind() — Set local IP address/port of a netconn

Synopsis

```
err_t netconn_bind (conn, addr, port);
```

Description

Binds the connection *conn* to the local IP address *addr* and TCP or UDP port *port*. If *addr* is `NULL`, the local IP address is determined by the networking system.

The *addr* is defined as a pointer to an IPv4 address, though the routine will accept a suitably cast IPv6 address structure pointer. However the `netconn_bind_ip6()` function provides explicit IPv6 address support.

Name

netconn_bind_ip6() — Set local IPv6 address/port of a netconn

Synopsis

```
err_t netconn_bind (conn, addr, port);
```

Description

Binds the connection `conn` to the local IPv6 address `addr` and TCP or UDP port `port`. If `addr` is `NULL`, the local IP address is determined by the networking system.

Name

netconn_connect() — Connect netconn to remote peer

Synopsis

```
err_t netconn_connect (conn, remote_addr, remote_port);
```

Description

In case of UDP, sets the remote receiver as given by *remote_addr* and *remote_port* of UDP messages sent over the connection. For TCP, `netconn_connect()` opens a connection with the remote host.

Solely for UDP, it is possible to call `netconn_connect()` repeatedly to set a new remote destination to use for UDP packets, rather than having to create and delete netconns for each destination.

Name

netconn_connect_ip6() — Connect netconn to remote peer

Synopsis

```
err_t netconn_connect (conn, remote_addr, remote_port);
```

Description

If IPv6 is configured then this provides similar functionality to the IPv4 function `netconn_connect()`, but with the *`remote_addr`* referencing an IPv6 addresss.

Name

netconn_disconnect() — Disconnect UDP connection

Synopsis

```
err_t netconn_disconnect (conn);
```

Description

This function is only relevant for UDP connections. It unsets any previously set (using `netconn_connect()`) remote peer address and port associated with connection *`conn`*.

Name

netconn_listen() — Make a listening TCP netconn

Synopsis

```
err_t netconn_listen (conn);
```

Description

Puts the TCP connection *conn* into the TCP LISTEN state. This means its purpose will become listening for incoming connections from remote peers. `netconn_accept()` is required to establish a connection resulting from incoming connection requests.

Name

netconn_accept() — Wait for incoming connections

Synopsis

`err_t` **`netconn_accept`** `(`*`conn`*`, `*`new_conn`*`);`

Description

This function blocks the process until a connection request from a remote host arrives on the TCP connection *`conn`*. The connection must be in the LISTEN state so `netconn_listen()` must be called prior to `netconn_accept()`. When a connection is established with the remote host, a new connection structure is returned in the *`new_conn`* parameter.

Example

Example 164.5. This example shows how to open a TCP server on port 2000 [*]

```
int
main()
{
    struct netconn *conn, *newconn;

    /* create a connection structure */
    conn = netconn_new(NETCONN_TCP);

    /* bind the connection to port 2000 on any local IP address */
    netconn_bind(conn, NULL, 2000);

    /* tell the connection to listen for incoming connection requests */
    netconn_listen(conn);

    /* block until we get an incoming connection */
    if (netconn_accept(conn, newconn) == ERR_OK) {
        /* do something with the connection */
        process_connection(newconn);

        /* deallocate both connections */
        netconn_delete(newconn);
    }
    netconn_delete(conn);
}
```

[*] This is only an example for illustrative purposes, and a complete version should perform comprehensive error checking.

Name

netconn_recv() — Wait for data

Synopsis

`err_t` **`netconn_recv`** `(`*`conn`*`,` *`new_buf`*`);`

Description

This function blocks the process while waiting for data to arrive on the connection *`conn`*. The return value will be `ERR_OK` on success. On error, for example if the connection has been closed by the remote host, NULL is returned in *`new_buf`*, otherwise a netbuf containing the received data is returned in *`new_buf`*.

Example

Example 164.6. This example demonstrates usage of the `netconn_recv()` function

In the following code, we assume that a connection has been established before the call to `example_function()`.

```
voidexample_function(struct netconn *conn)
{
    struct netbuf *buf;
    err_t err;

    /* receive data until the other host closes the connection */
    while((err = netconn_recv(conn, buf)) == ERR_OK) {
        do_something(buf);
    }

    /* the connection has now been closed by the other end, so we close our end */
    netconn_close(conn);
}
```

Name

netconn_recv_tcp_pbuf() — Wait for data

Synopsis

```
err_t netconn_recv_tcp_pbuf (conn, new_buf);
```

Description

This function is similar to the `netconn_recv()` function, with the difference that the received data is placed in a pbuf instead of a netbuf.

Name

netconn_recved() — Update receive window

Synopsis

`void` **`netconn_recved`** `(`*`conn`*`, `*`length`*`);`

Description

The application can call this function to notify the stack that it has processed the received data and is able to accept new data.

Warning

This function is primarily for use with sockets, and should be used with care. It can only be used when `netconn_set_noautorecved(conn,1)` has been used to disable the automatic receive window updating.

Name

netconn_write() — Send data on TCP connection

Synopsis

```
err_t netconn_write (conn, data, len, copy);
```

Description

This function is only used for TCP connections. It puts the data pointed to by *data* on the output queue for the TCP connection *conn*. The length of the data is given by *len*. There is no restriction on the length of the data. This function does not require the application to explicitly allocate buffers, as this is taken care of by the stack. The *copy* parameter is a combination of the following bitmask flags:

```
#define NETCONN_NOFLAG 0x00
#define NETCONN_COPY 0x01
#define NETCONN_MORE 0x02
#define NETCONN_DONTBLOCK 0x04
```

When passed the flag `NETCONN_COPY` the data is copied into internal buffers which are allocated for the data. This allows the data to be modified directly after the call, but is inefficient both in terms of execution time and memory usage. If the flag is not set then the data is not copied but rather referenced, and the `NETCONN_NOCOPY` manifest is provided for backwards compatibality. The data must not be modified after the call, since the data can be put on the retransmission queue for the connection, and stay there for an indeterminate amount of time. This is useful when sending data that is located in ROM and therefore is immutable. If greater control over the modifiability of the data is needed, a combination of copied and non-copied data can be used, as seen in the example below.

The flag `NETCONN_MORE` can be used for TCP connections and indicates that the PSH (push) flag will be set on the last segment sent. The flag `NETCONN_DONTBLOCK` tells the stack to only write the data if all the data can be written at once.

Example

Example 164.7. This example demonstrates basic usage of the `netconn_write()` function [*]

Here, the variable data is assumed to be modified later in the program, and is therefore copied into the internal bufiers by passing the flag `NETCONN_COPY` to `netconn_write()`. The text variable contains a string that will not be modified and can therefore be sent using references instead of copying.

```
int
main()
{
    struct netconn *conn;
    char data[10];
    char text[] = "Static text";
    int i;

    /* set up the connection conn */
    /* […] */

    /* create some arbitrary data */
    for(i = 0; i < 10; i++)
        data[i] = i;

    netconn_write(conn, data, 10, NETCONN_COPY);
    netconn_write(conn, text, sizeof(text), NETCONN_NOFLAG);
```

[*] This is only an example for illustrative purposes, and a complete version should perform comprehensive error checking.

```
    /* the data can be modified */
    for(i = 0; i < 10; i++)
        data[i] = 10 - i;

    /* take down the connection conn */
    netconn_close(conn);
}
```

Name

netconn_send() — Send data on UDP connection

Synopsis

`err_t **netconn_send**(*conn*, *buf*);`

Description

Send the data in the netbuf *`buf`* on the UDP connection *`conn`*. The data in the netbuf should not be too large if IP fragmentation support is disabled. If IP fragmentation support is disabled, the data should not be larger than the maximum transmission unit (MTU) of the outgoing network interface, less the space required for link layer, IP and UDP headers. No checking is necessarily made of whether the data is sufficiently small and sending very large netbufs might give undefined results.

Example

Example 164.8. This example demonstrates basic usage of the `netconn_send()` function [*]

This example shows how to send some UDP data to UDP port 7000 on a remote host with IP address 10.0.0.1.

```
int
main()
{
    struct netconn *conn;
    struct netbuf *buf;
    struct ip_addr addr;
    char *data;
    char text[] = "A static text";
    int i;

    /* create a new connection */
    conn = netconn_new(NETCONN_UDP);

    /* set up the IP address of the remote host */
    addr.addr = htonl(0x0a000001);

    /* connect the connection to the remote host */
    netconn_connect(conn, addr, 7000);

    /* create a new netbuf */
    buf = netbuf_new();
    data = netbuf_alloc(buf, 10);

    /* create some arbitrary data */
    for(i = 0; i < 10; i++)
        data[i] = i;

    /* send the arbitrary data */
    netconn_send(conn, buf);

    /* reference the text into the netbuf */
    netbuf_ref(buf, text, sizeof(text));

    /* send the text */
    netconn_send(conn, buf);

    /* deallocate connection and netbuf */
    netconn_delete(conn);
```

[*] This is only an example for illustrative purposes, and a complete version should perform comprehensive error checking.

```
    netconn_delete(buf);
}
```

Name

netconn_close() — Close a connection

Synopsis

```
err_t netconn_close (conn);
```

Description

Close the connection *conn*.

Name

netconn_shutdown() — Shutdown a connection

Synopsis

```
err_t netconn_shutdown (conn, shut_rx, shut_tx);
```

Description

Shut down one, or both, sides of a TCP connection, but without deleting the connection. The *shut_rx* and *shut_tx* parameters are treated as boolean values with non-zero values indicating that the respective read or write side should be closed. Specifying that both RX and TX are to be shut is the same as closing the connection via calling `netconn_close()`.

Name

netconn_set_noautorecved() — Set the connection no-auto-recved state

Synopsis

```
void netconn_set_noautorecved (conn, val);
```

Description

If *val* equates to `true` then the `NETCONN_FLAG_NO_AUTO_RECVED` state is set for the connection, otherwise the flag is cleared.

Name

netconn_get_noautorecved() — Get the connection no-auto-recved state

Synopsis

```
cyg_bool netconn_get_noautorecved (conn);
```

Description

Returns a boolean state indicating the current `NETCONN_FLAG_NO_AUTO_RECVED` flag state for the connection.

Name

netconn_err() — Obtain connection error status

Synopsis

```
err_t netconn_err (conn);
```

Description

Obtain the stored error status of connection *conn*.

Chapter 165. Raw API

Much of the information in this chapter has been derived from lwIP's own raw API documentation, although additions, modifications and adaptations for eCos have been made.

Overview

While the high level lwIP sequential API is good for programs that are themselves sequential and can benefit from the blocking open-read-write-close paradigm, lwIP itself is event based by nature. If an application can be written with an event-based approach, then it becomes possible to integrate directly with the event-based design of the core lwIP code.

The *raw TCP/IP API* allows the application program to integrate better with the TCP/IP code. Program execution is event based by having callback functions being called from within the TCP/IP code. The TCP/IP code and the application program both run in the same thread. The sequential API has a much higher overhead and is not very well suited for small systems since it forces a multithreaded paradigm on the application.

The raw TCP/IP interface is not only faster in terms of code execution time but is also less memory intensive. The drawback is that program development is somewhat harder and application programs written for the raw TCP/IP interface are more difficult to understand. Still, this is the preferred way of writing applications that should be small in code size and memory usage.

Both APIs can be used simultaneously by different application programs. In fact, the sequential API is implemented as an application program using the raw TCP/IP interface.

An example of an application using the raw API can be found in the `tests/` subdirectory of the lwIP eCos package. This httpd2 test is built when the CDL configuration option `CYGBLD_NET_LWIP_BUILD_MANUAL_TESTS` is enabled. This raw API application acts as a simple HTTP server. For more information see the section called “httpd2”.

Usage

The raw API is a very direct interface, and is close to the metal. If the `CYGFUN_LWIP_NO_SYS` option is enabled then there still needs to be a single lwIP owner thread but an application can be constructed where the main processing loop of that thread performs lwIP support as well as other application event processing as required so that only a single stack footprint is required. The trueraw application is built when `CYGFUN_LWIP_NO_SYS` is configured, and the `CYGBLD_NET_LWIP_BUILD_MANUAL_TESTS` option is enabled. This provides a simple example of an application using the raw API without the overhead of the TCP/IP helper thread.

For true raw API applications the `cyg_lwip_init()` function can be used to initialise the lwIP stack (as for sequential or BSD API applications), but there is no support for waiting for the network to be brought up within that function call, since when using a true raw world the caller of the `cyg_lwip_init()` is also responsible for processing network packets that may be needed to bring up the network interface up. If required an application can perform its own lwIP stack initialization, and does not need to use the eCos default support.

Note that if you do decide to use `cyg_lwip_init()` with the configuration option `CYGFUN_LWIP_SEQUENTIAL_API` disabled, so that solely the raw API is available, bbut with the configuration option `CYGFUN_LWIP_NO_SYS` also disabled, then the application will need to provide its own alternative to the tcpip_input() function which had previously been used to inject received packets into the stack. This function must be declared as follows:

```
err_t tcpip_input (, );
```

See the section called “System initialization” for further details on initialization.

Declarations for the API functions are found in header files within the lwIP include tree. The TCP functions are found in `<lwip/tcp.h>`, and UDP in `<lwip/udp.h>`.

The raw API uses many of the same types and definitions used in the sequential API. In particular the raw API functions use struct ip_addr and err_t error codes.

Callbacks

The configuration option `CYGFUN_LWIP_EVENT_CALLBACK` defaults to enabled. If enabled then program execution is driven by callbacks. Each callback is an ordinary C function that is called from within the TCP/IP code. Every callback function is passed the current TCP or UDP connection state as an argument. Also, in order to be able to keep program specific state, the callback functions are called with a program specified argument that is independent of the TCP/IP state.

If the `CYGFUN_LWIP_EVENT_CALLBACK` option is disabled then a common user-supplied function is called from within the TCP/IP code instead of the respective callback routine:

```
err_t lwip_tcp_event (arg, pcb, lwip_event, p, size, err);
```

For the individual callbacks or the shared `lwip_tcp_event()` the `tcp_arg()` function is used for setting the private `arg` application connection state.

Name

tcp_arg() — Set the application connection state

Synopsis

```
void tcp_arg (pcb, arg);
```

Description

The `tcp_arg()` function specifies the program specific state that should be passed to all other callback functions, or if configured the `lwip_tcp_event()` function. The "pcb" argument is the current TCP connection control block, and the "arg" argument is the argument that will be passed to the callbacks.

TCP connection setup

The functions used for setting up connections are similar to those of the sequential API and of the BSD socket API. A new TCP connection identifier (i.e., a protocol control block - PCB) is created with the `tcp_new()` function. This PCB can then be either set to listen for new incoming connections or be explicitly connected to another host.

Name

tcp_new() — Create a new TCP PCB

Synopsis

```
struct tcp_pcb *tcp_new ();
```

Description

Creates a new TCP connection identifier (PCB).

Return value

Returns the new PCB. If memory is not available for creating the new PCB, `NULL` is returned.

Name

tcp_bind() — Bind PCB to local IP address and port

Synopsis

```
err_t tcp_bind (pcb, ipaddr, port);
```

Description

Binds `pcb` to a local IP address and port number. The IP address can be specified as `IP_ADDR_ANY` in order to bind the connection to all local IP addresses.

Return value

If another connection is bound to the same port, the function will return `ERR_USE`, otherwise `ERR_OK` is returned.

Name

tcp_listen() — Make PCB listen for incoming connections

Synopsis

```
struct tcp_pcb *tcp_listen (pcb);
```

Description

Commands *pcb* to start listening for incoming connections. When an incoming connection is accepted, the function specified with the `tcp_accept()` function will be called. *pcb* must have been bound to a local port with the `tcp_bind()` function.

Return value

The `tcp_listen()` function returns a new connection identifier, and the one passed as an argument to the function will be deallocated. The reason for this behavior is that less memory is needed for a connection that is listening, so `tcp_listen()` will reclaim the memory needed for the original connection and allocate a new smaller memory block for the listening connection.

`tcp_listen()` may return `NULL` if no memory was available for the listening connection. If so, the memory associated with *pcb* will not be deallocated.

Name

tcp_accept() — Set callback used for new incoming connections

Synopsis

```
void tcp_accept (pcb, (*accept));
```

Description

Specify the callback function that should be called when a new connection arrives for a listening TCP PCB.

Name

tcp_connect() — Open connection to remote host

Synopsis

```
err_t tcp_connect (pcb, ipaddr, port, (*connected));
```

Description

Sets up *pcb* to connect to the remote host indicated by *ipaddr* on port *port* and sends the initial SYN segment which opens the connection.

The tcp_connect() function returns immediately; it does not wait for the connection to be properly set up. Instead, it will call the *connected()* function specified as the fourth argument when the connection is established. If the connection could not be properly established, either because the other host refused the connection or because the other host didn't answer, the *connected()* function will be called with its *err* argument set accordingly.

Return value

The tcp_connect() function can return ERR_MEM if no memory is available for enqueueing the SYN segment. If the SYN indeed was enqueued successfully, the tcp_connect() function returns ERR_OK.

Sending TCP data

TCP data is sent by enqueueing the data with a call to tcp_write(). When the data is successfully transmitted to the remote host, the application will be notified with a call to a specified callback function.

Name

tcp_write() — Enqueue data for transmission

Synopsis

```
err_t tcp_write (pcb, dataptr, len, copy);
```

Description

Enqueues the data pointed to by *dataptr*. The length of the data is passed in *len*. The argument *copy* may be either 0 or 1 and indicates whether the new memory should be allocated for the data to be copied into. If the argument is 0, no new memory should be allocated and the data should only be referenced by pointer.

Return value

The `tcp_write()` function will fail and return `ERR_MEM` if the length of the data exceeds the current send buffer size (as defined by the `CYGNUM_LWIP_TCP_SND_BUF` CDL configuration option) or if the length of the queue of outgoing segment is larger than the upper limit defined by the `CYGNUM_LWIP_TCP_SND_QUEUELEN` CDL configuration option. The number of bytes available in the output queue can be retrieved with the `tcp_sndbuf()` function:

```
u16_t tcp_sndbuf (pcb);
```

The proper way to use this function is to call the function with at most `tcp_sndbuf()` bytes of data. If the function returns `ERR_MEM`, the application should wait until some of the currently enqueued data has been successfully received by the other host and try again. This can be achieved with a callback function previously provided to `tcp_sent()`.

Name

tcp_sent() — Set callback for successful transmission

Synopsis

```
void tcp_sent (pcb, (*sent));
```

Description

Specifies the callback function that should be called when data has successfully been received (i.e. acknowledged) by the remote host. The *len* argument passed to the *sent* callback function gives the number of bytes that were acknowledged by the last acknowledgment.

Receiving TCP data

TCP data reception is callback based - an application specified callback function is called when new data arrives. When the application has taken the data, it has to call the `tcp_recved()` function to indicate that TCP can advertise an increase in the receive window.

Name

tcp_recv() — Set callback for incoming data

Synopsis

```
void tcp_recv (pcb, (*recv));
```

Description

Sets the callback function that will be called when new data arrives on the connection associated with *pcb*. The callback function will be passed a `NULL` pbuf to indicate that the remote host has closed the connection.

Name

tcp_recved() — Indicate receipt of data

Synopsis

```
void tcp_recved (pcb, len);
```

Description

This function must be called when the application has received the data. *len* indicates the length of the received data.

Application polling

When a connection is idle (i.e., no data is either transmitted or received), lwIP will repeatedly poll the application by calling a specified callback function. This can be used either as a watchdog timer for killing connections that have stayed idle for too long, or as a method of waiting for memory to become available. For instance, if a call to `tcp_write()` has failed because memory wasn't available, the application may use the polling functionality to call `tcp_write()` again when the connection has been idle for a while.

Name

tcp_poll() — Set application poll callback

Synopsis

```
void tcp_poll (pcb, interval, (*poll));
```

Description

Specifies the polling interval and the callback function that should be called to poll the application. The interval is specified in number of TCP coarse grained timer shots, which typically occurs twice a second. An interval of 10 means that the application would be polled every 5 seconds.

Closing connections, aborting connections and errors

Name

tcp_close() — Close the connection

Synopsis

```
err_t tcp_close (pcb);
```

Description

Closes the connection. The pcb is deallocated by the TCP code after a call to tcp_close().

Return value

The function may return `ERR_MEM` if no memory was available for closing the connection. If so, the application should wait and try again either by using the acknowledgment callback or the polling functionality. If the close succeeds, the function returns `ERR_OK`.

Name

tcp_abort() — Abort the connection

Synopsis

```
void tcp_abort (pcb);
```

Description

Aborts the connection by sending a RST (reset) segment to the remote host. *pcb* is deallocated. This function never fails.

If a connection is aborted because of an error, the application is alerted of this event by the callback previously registered with `tcp_err()`. Errors that might abort a connection are when there is a shortage of memory.

Name

tcp_err() — Set callback for errors

Synopsis

```
void tcp_err (pcb, (*err));
```

Description

Set callback function to be used on connection errors. The error callback function does not get the connection's pcb passed to it as a parameter since the pcb may already have been deallocated.

Lower layer TCP interface

TCP provides a simple interface to the lower layers of the system. During system initialization, the function `tcp_init()` has to be called before any other TCP function is called. When the system is running, the two timer functions `tcp_fasttmr()` and `tcp_slowtmr()` must be called at regular intervals. The `tcp_fasttmr()` should be called every `TCP_FAST_INTERVAL` milliseconds (defined in tcp.h, and currently 250ms) and `tcp_slowtmr()` should be called every `TCP_SLOW_INTERVAL` milliseconds, currently 500ms.

UDP interface

The UDP interface is similar to that of TCP, but due to the lower level of complexity of UDP, the interface is significantly simpler.

Name

udp_new() — Create a new UDP pcb

Synopsis

```
struct udp_pcb *udp_new ();
```

Description

Creates a new connection identifier (PCB) which can be used for UDP communication. The PCB is not active until it has either been bound to a local address or connected to a remote address.

Return value

Returns the new PCB. If memory is not available for creating the new PCB, `NULL` is returned.

Name

udp_remove() — Remove a UDP pcb

Synopsis

```
void udp_remove (pcb);
```

Description

Removes and deallocates *pcb*.

Name

udp_bind() — Bind PCB to local IP address and port

Synopsis

```
err_t udp_bind (pcb, ipaddr, port);
```

Description

Binds *pcb* to the local address indicated by *ipaddr* and port indicated by *port*. *ipaddr* can be IP_ADDR_ANY to indicate that it should listen to any local IP address. Port may be 0 for any port.

Return value

This function can return ERR_USE if all usable UDP dynamic ports are used (only relevant if *port* is 0. Otherwise udp_bind() will always return ERR_OK.

Name

udp_connect() — Set remote UDP peer

Synopsis

```
err_t udp_connect (pcb, ipaddr, port);
```

Description

Sets the remote end of *pcb*. This function does not generate any network traffic, but only sets the remote address of the pcb.

Return value

This function can return `ERR_USE` if all usable UDP dynamic ports are used. Otherwise `udp_connect()` will always return `ERR_OK`.

Name

udp_disconnect() — Set remote UDP peer

Synopsis

```
void udp_disconnect (pcb);
```

Description

Remove the remote end of *pcb*. This function does not generate any network traffic, but only removes the remote address of the pcb.

Name

udp_send() — Send UDP packet

Synopsis

```
err_t udp_send (pcb, p);
```

Description

Sends the pbuf *p* to the remote host associated with *pcb*. The pbuf is not deallocated.

Return value

This function returns `ERR_OK` on success; but may return `ERR_MEM` if there is insufficient memory to prepend a UDP header, or `ERR_RTE` if no suitable outgoing network interface could be found to route the packet on.

Name

udp_recv() — Set callback for incoming UDP data

Synopsis

`void` **`udp_recv`** `(`*`pcb`*`, `*`(*recv)`*`, `*`recv_arg`*`);`

Description

Registers a callback function *`recv`* with the PCB *`pcb`* so that when a UDP datagram is received, the callback is invoked. The callback argument *`arg`* is set as the argument *`recv_arg`* to `udp_recv()`. The received datagram packet buffer is held in *`p`*. The source address of the datagram is provided in *`addr`*, and the source port in *`port`*. The callback is expected to free the packet.

System initialization

When performing manual initialization of lwIP for use with the raw API, the function `lwip_init()` can be called to perform the core setup. Depending on the actual `lwipopts.h` configuration `lwip_init()` will call the necessary routines to initialize the required lwIP sub-systems.

In this example, these functions must be called in the order of appearance:

`lwip_init()`

Calls the individual, as configured, low-level lwIP module initialization routines.

If `LWIP_ARP` is defined then `etharp_tmr()` must be called at the regular `ARP_TMR_INTERVAL` interval (default 5 seconds) after the system has been initialized by this call.

Similarly if `LWIP_TCP` is defined then you must ensure that `tcp_fasttmr()` and `tcp_slowtmr()` are called at the predefined regular intervals.

`struct netif *netif_add(struct netif *netif, struct ip_addr *ipaddr, struct ip_addr *netmask, struct ip_addr *gw, void *state, err_t (* init)(struct netif *netif), err_t (* input)(struct pbuf *p, struct netif *netif))`

Adds your network interface to the `netif_list`. Allocate a struct netif and pass a pointer to this structure as the first argument. Give pointers to cleared struct ip_addr structures when using DHCP, or fill them with sane numbers otherwise. The state pointer may be NULL.

The *`init`* function pointer must point to an initialization function for your ethernet netif interface. The following code illustrates an example use:

```
err_t netif_if_init(struct netif *netif)
{
    u8_t i;

    for(i = 0; i < 6; i++)
        netif->hwaddr[i] = some_eth_addr[i];
    init_my_eth_device();
    return ERR_OK;
}
```

Normally for ethernet devices the *`input`* function must point to the lwIP function `ethernet_input()`.

`netif_set_default(struct netif *netif)`

Registers *`netif`* as the default network interface.

`netif_set_up(struct netif *netif)`

When *`netif`* is fully configured, this function must be called to allow it to be used.

`dhcp_start(struct netif *netif)`

If `LWIP_DHCP` is configured then this function creates a new DHCP client for this interface the first time the routine is called. Note: you must call `dhcp_fine_tmr()` and `dhcp_coarse_tmr()` at the predefined regular intervals after starting the client.

You can peek in the `netif->dhcp` struct for the actual DHCP status.

Initialization detail

If required the manual raw API initialization could directly call the required lwIP sub-system module initialization functions (rather then calling the `lwip_init()` function).

The calls should be performed in the following order:

`stats_init()`

Clears the structure where runtime statistics are gathered.

Note: The statistics support is only included if `LWIP_STATS` is configured, and then some of the statistics code is only present if `LWIP_DEBUG` is also defined.

`sys_init()`

Not generally used with raw API, but can be called for ease of compatibility if using sequential API in addition, initialised manually. The `lwip_init()` implementation only calls this function if `NO_SYS` is **NOT** defined.

`mem_init()`

Initializes the dynamic memory heap defined by the CDL configuration option `CYGNUM_LWIP_MEM_SIZE`.

`memp_init()`

Initializes the memory pools defined by the CDL configuration options `CYGNUM_LWIP_MEMP_NUM_*`.

`pbuf_init()`

Initializes the pbuf (packet buffer) memory pool defined by the CDL configuration option `CYGNUM_LWIP_PBUF_POOL_SIZE`.

`netif_init()`

This function will call `netif_add()` as appropriate to create the `LWIP_HAVE_LOOPIF` configured loopback network interface.

`lwip_socket_init()`

If `LWIP_SOCKET` is configured then this function is called to initialise the BSD-alike API module. It does not do much at present, but it should be called to handle future changes.

`ip_init()`

This function does not do much at present, but it should be called to handle future changes.

`etharp_init()`

Called if `LWIP_ARP` is configured to initialize the ARP table and queue.

Note: you must regularly call the `etharp_tmr` function at the `ARP_TMR_INTERVAL` (default 5 seconds) interval after this initialization.

`raw_init()`

If `LWIP_RAW` is configured then this function is called. It does not do much at present, but it should be called to handle future changes.

`udp_init()`

If `LWIP_UDP` is configured then this function is called to initialize the required UDP support state.

`tcp_init()`

If `LWIP_TCP` is configured then this function is called to initialise the required TCP support state.

Note: you must call `tcp_fasttmr()` and `tcp_slowtmr()` at the predefined regular intervals after this initialization.

`snmp_init()`

If `LWIP_SNMP` is configured then this function is called to start the SNMP agent support. It allocates a UDP pcb and binds it to `IP_ADDR_ANY` for the `SNMP_IN_PORT` (default `161`) configured port, listening for SNMP The routine will also generate a SNMP coldstart trap if configured appropriately.

`autoip_init()`

If `LWIP_AUTOIP` is configured then this function is called for the IPv4 AutoIP support. It does not do much at present, but it should be called to handle future changes.

`igmp_init()`

If `LWIP_IGMP` is configured then this function is called for the IPv4 IGMP support. It configures the `allsystems` and `allroutes` multicast addresses.

`dns_init()`

If `LWIP_DNS` is configured then this function is called to allocate the UDP pcb for the client and initialise the default DNS server address.

`ip6_init()`

If `LWIP_IPV6` is configured then this function is called. It does not do much at present, but it should be called to handle future changes.

`nd6_init()`

If `LWIP_IPV6` is configured then this function is called. It does not do much at present, but it should be called to handle future changes.

`mld6_init()`

If `LWIP_IPV6` and `LWIP_IPV6_MLD` are configured then this function is called. It does not do much at present, but it should be called to handle future changes.

`sys_timeouts_init()`

If `LWIP_TIMERS` is configured then this function is called. It uses the `sys_timeout()` to register timeout callbacks for the configured lwIP features. Normally the raw API will not be providing the `sys_timeout` functionality, and will, as mentioned above, have to manually ensure the relevant timeout functions are called. e.g. ARP, TCP, etc.

Chapter 166. Debug and Test

Debugging

Some explicit lwIP configuration items exist to aid with debugging problems. These, along with some other suggestions, are documented in the sections below.

Asserts

An initial starting point for checking valid operation is to enable lwIP asserts. The `CYGDBG_LWIP_ASSERTS` option turns on run-time asserts that can usually detect problems before they reach a fatal target/platform exception.

The lwIP asserts are based on the standard eCos assertion support, so will normally stop the code in a busy loop if triggered. Normally when debugging it is usual to set a breakpoint on the entry to the `cyg_assert_fail()` function so that debugger access to application state can be performed.

Memory Allocations

Run-time validation of the memory pools can be enabled in the lwIP configuration by setting one or more of the following options:

Sanity check memory pools (`CYGDBG_LWIP_MEMP_SANITY_CHECK`)

> If enabled lwIP will perform extra sanity checking of the memory pools every time an item is released.

Memory pool overflow checks (`CYGDBG_LWIP_MEMP_OVERFLOW_CHECK`)

> This configuration option can currently be set to the value 0, 1 or 2.
>
> If set to 0 then the feature is disabled (the default configuration), with the non-zero values enabling code to perform MEMP under-/over-flow checking.
>
> If set to 1 then a buffer boundary check is performed when an item is released.
>
> If set to 2 then the code performs the buffer boundary check on every item, in every pool, every time an allocation or release operation is performed. This, obviously, will be slow. However, it will normally provide quicker detection of buffer problems.
>
> For the non-zero configurations the options `CYGDBG_LWIP_MEMP_SANITY_REGION_BEFORE` and `CYGDBG_LWIP_MEMP_SANITY_REGION_AFTER` respectively define the size (in bytes) of the *catch* areas placed before and after all allocations.

Statistics

The lwIP stack provides support for tracking statistics via enabling the Trafficstatistics `CYGDBG_LWIP_STATS` option. These statistics have been briefly covered in the section called “Performance”. For debugging the error count (normally the `err` field of the relevant statistics structure) can be useful in indicating resource issues, some of which will result in the stack failing to operate correctly.

GDB/RedBoot

Some standard platforms may, by default, provide the RedBoot debug monitor, which in turn may be configured to allow remote network GDB debugging connections. It should be noted that a limitation exists where an eCos application configured to use a lwIP Direct driver **CANNOT** be debugged via such a remote network GDB connection due to interaction between the RedBoot use of a Standard device driver and the application Direct device driver models. Using GDB via a UART or hardware debug connection is not affected.

In practice this is not normally an issue since low-level debugging, when developing for such low resource platforms that require the use of the lwIP Direct device driver, is normally performed via a hardware debug interface (e.g. JTAG).

Host Tools

An invaluable tool to aid debugging of both network protocol stack problems and application level network interaction is WireShark. It can be used to log packets, and to trace connection streams, whilst providing human readable data dumps.

The eCos synthetic ethernet target support can be a useful aid in separating application level networking problems from issues with the under-lying network transport stack (e.g. lwIP). It can usefully be used to debug higher-level network applications in a resource rich environment, before tuning the code for the resource-restricted lwIP target platform.

Testing

Some test applications are built if the active eCos lwIP configuration is suitable:

- **lwipsnmp**
- **lwipsntp**
- **lwiperf**
- **unitwrap**

If the configuration option `CYGBLD_NET_LWIP_BUILD_MANUAL_TESTS` is enabled then a further set of simple tests are built. Note: The option is disabled by default. These manually executed are just basic verification tests and are not designed to be an exhaustive test of all lwIP or TCP/IP networking features.

For the manual tests frag and udpecho the host tool nc (netcat) can be used to interface with the test. In the following sections any examples given of using the tests assume that the Unit Under Test (UUT) is at the local network IPv4 address `192.168.1.200`. The actual local addresses for the UUT should be ascertained and substituted accordingly.

Note

Most of the manual tests are currently limited to accepting IPv4 connections. The exceptions are socket and tcpecho which will accept IPv4 or IPv6 connections.

lwipsnmp

This is a simple test to exercise the SNMP agent when enabled via the `CYGFUN_LWIP_SNMP` option. It relies on the `hostsnmp.sh` script being executed on a host system to exercise a set of SNMP operations agsinst the target executing this application.

lwipsntp

This application tests the use of the lwIP SNTP client implementation when enabled via the `CYGFUN_LWIP_SNTP` option. It initialises the SNTP client code and then waits to receive a valid time.

lwiperf

This test can be used to exercise the iPerf2 server provided by lwIP when it is enabled in the configuration using the `CYGFUN_LWIP_LWIPERF` option. It requests the test host to exercise a **iperf-c** against the target executing this application as a simple demonstration of measuring the achievable network bandwidth.

unitwrap

If the eCos lwip configuration meets the requirements (re. memory configuration, TCP options, etc.) for the standard lwIP check-framework unit tests then this test application is built. The application is a wrapper to support the lwIP unit tests and allows verification of some lwIP features.

socket

This is a very simple TCP protocol test using the BSD-alike socket API. The test will listen for two IPv4 or IPV6 connections on port 7. For each connection established the test will continue to echo the data received on the TCP stream until the particular connection is closed.

The nc utility can be used to communicate with the test program.

```
nc 192.168.1.200 7
```

After starting nc the UUT will acknowledge the connection by displaying:

```
PASS:<Received connection OK>
```

As this point it will wait for a line of text to be input and completed by pressing the **Enter** key. Multiple lines of text can be entered, and should be echoed back to indicate that the UUT has received and responded OK. Entering **Ctrl-D** will terminate the nc connection.

Another execution of nc as above will complete the test.

tcpecho

This is a very simple TCP protocol test. See the section called “socket” for a description of the test, since it has identical requirements to that example.

udpecho

This is a very simple UDP protocol test, listening for two connections on port 7 and echo-ing back the data received.

The nc utility can be used to communicate with the test program.

```
nc -u 192.168.1.200 7
```

After starting nc it will wait for a line of text to be input and completed by pressing the **Enter** key. The nc will then perform the necessary UDP connection to the specified port, transmit the data and output any reply. Another line of text can then be entered to complete the test. Unlike the tcpecho a single nc execution can be used for the test, since each line transmitted counts as a single UDP connection test.

frag

This is a simple test that should result in fragmented TCP packets being transmitted. The test can be exercised like the section called “udpecho” since it listens for two UDP connections on port 7.

The major difference being that after echoing the received data the UUT will transmit a large amount of data to the host nc.

nc_test_slave

This test provides a client for use with the host side `CYGPKG_NET` nc_test_master application. The host side test code must be manually built within the `packages/net/common/`*`vsn`*`/tests` directory.

When the UUT is started it will initially perform some slave performance calculations before it will start listening for connections.

httpd

This is a very simple HTTP daemon that will listen for two `HTTP GET` connections on port 80. Currently only IPv4 socket connections are listened for. The test when started will display some information on the diagnostic channel, including:

```
PASS:<Listening on TCP port 80>
INFO:<Will wait for two HTTP connections>
```

When it is has displayed the Will wait … message the UUT is ready to be accessed from the test host. The following example uses the host tool wget to perform such a page fetch, and can be executed twice to perform the test. e.g.

```
wget http://192.168.7.165/
```

After the second `GET` operation the test will exit.

httpd2

This is a slightly more realistic HTTP daemon test, that will execute indefinitely. This test is a useful example of using the raw API, and could form the basis of a simple, lightweight, webserver.

Currently it will only accept IPv4 socket connections on port 80. On startup it will not display any diagnostic output other than the `cyg_lwip_netif_print_info( netif_default, diag_printf )` output displaying the default network interface address information.

A standard web browser can be used to access the pages served by the daemon, returning a simple demonstration page as the root document. The test has been designed to be extendible to easily support multiple pages.

lookup

If IPv4 DNS support is configured then this test performs some simple verification using some known lookups against the locally configured DNS address (e.g. obtained via DHCP), and then again using a known fixed DNS server.

sys_timeout

This is a simple stand-alone test of the lwIP internal timeout handling. No external interaction is required.

lwiphttpd

This is a build of the standard lwIP example HTTPD application provided when the option `CYGFUN_LWIP_HTTPD` is enabled. It provides a static (built-in) web-page.

If the lwIP configuration option `CYGFUN_LWIP_MBEDTLS` is enabled then the test also provides a TLS daemon (port 443) using a built-in self-signed certificate as a basic example of the lwIP ALTCP TLS support.

Note

For eCos the `CYGFUN_LWIP_MBEDTLS` option is only available when the `CYGFUN_LWIP_ALTCP_TLS` option is enabled, in turn controlled by the support for the lwIP ALTCP being enabled by the `CYGFUN_LWIP_ALTCP` feature. The developer should be aware that you need to provide your own ALTCP wrapper functions if `LWIP_ALTCP_TLS` is defined but not the `CYGPKG_MBEDTLS` integration option `LWIP_ALTCP_TLS_MBEDTLS`.

Part XLV. Ethernet Device Support

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 167. Writing Ethernet Device Drivers

Generic Ethernet API

This section provides a simple description of how to write a low-level, hardware dependent ethernet driver. In eCos this is known as a “standard” driver.

There is a high-level driver (which is only code — with no state of its own) that is part of the stack. There will be one or more low-level drivers tied to the actual network hardware. Each of these drivers contains one or more driver instances. The intent is that the low-level drivers know nothing of the details of the stack that will be using them. Thus, the same driver can be used by the eCos supported TCP/IP stack, RedBoot, or any other, with no changes.

A driver instance is contained within a struct eth_drv_sc:

```
struct eth_hwr_funs {
    // Initialize hardware (including startup)
    void (*start)(struct eth_drv_sc *sc,
                  unsigned char *enaddr,
                  int flags);
    // Shut down hardware
    void (*stop)(struct eth_drv_sc *sc);
    // Device control (ioctl pass-thru)
    int  (*control)(struct eth_drv_sc *sc,
                    unsigned long key,
                    void *data,
                    int   data_length);
    // Query - can a packet be sent?
    int  (*can_send)(struct eth_drv_sc *sc);
    // Send a packet of data
    void (*send)(struct eth_drv_sc *sc,
                 struct eth_drv_sg *sg_list,
                 int sg_len,
                 int total_len,
                 unsigned long key);
    // Receive [unload] a packet of data
    void (*recv)(struct eth_drv_sc *sc,
                 struct eth_drv_sg *sg_list,
                 int sg_len);
    // Deliver data to/from device from/to stack memory space
    // (moves lots of memcpy()s out of DSRs into thread)
    void (*deliver)(struct eth_drv_sc *sc);
    // Poll for interrupts/device service
    void (*poll)(struct eth_drv_sc *sc);
    // Get interrupt information from hardware driver
    int (*int_vector)(struct eth_drv_sc *sc);
    // Logical driver interface
    struct eth_drv_funs *eth_drv, *eth_drv_old;
};

struct eth_drv_sc {
    struct eth_hwr_funs *funs;
    void                *driver_private;
    const char          *dev_name;
    int                  state;
    struct arpcom        sc_arpcom; /* ethernet common */
};
```

Note

If you have two instances of the same hardware, you only need one struct eth_hwr_funs shared between them.

There is another structure which is used to communicate with the rest of the stack:

```
struct eth_drv_funs {
    // Logical driver - initialization
    void (*init)(struct eth_drv_sc *sc,
                 unsigned char *enaddr);
    // Logical driver - incoming packet notifier
    void (*recv)(struct eth_drv_sc *sc,
                 int total_len);
    // Logical driver - outgoing packet notifier
    void (*tx_done)(struct eth_drv_sc *sc,
                    CYG_ADDRESS key,
                    int status);
};
```

Your driver does *not* create an instance of this structure. It is provided for driver code to use in the eth_drv member of the function record. Its usage is described below in the section called “Upper Layer Functions”

One more function completes the API with which your driver communicates with the rest of the stack:

```
extern void eth_drv_dsr(cyg_vector_t vector,
                        cyg_ucount32 count,
                        cyg_addrword_t data);
```

This function is designed so that it can be registered as the DSR for your interrupt handler. It will awaken the “Network Delivery Thread” to call your deliver routine. See the section called “Deliver function”.

You create an instance of struct eth_drv_sc using the `ETH_DRV_SC()` macro which sets up the structure, including the prototypes for the functions, etc. By doing things this way, if the internal design of the ethernet drivers changes (e.g. we need to add a new low-level implementation function), existing drivers will no longer compile until updated. This is much better than to have all of the definitions in the low-level drivers themselves and have them be (quietly) broken if the interfaces change.

The “magic” which gets the drivers started (and indeed, linked) is similar to what is used for the I/O subsystem. This is done using the `NETDEVTAB_ENTRY()` macro, which defines an initialization function and the basic data structures for the low-level driver.

```
  typedef struct cyg_netdevtab_entry {
      const char        *name;
      bool             (*init)(struct cyg_netdevtab_entry *tab);
      void              *device_instance;
      unsigned long     status;
  } cyg_netdevtab_entry_t;
```

The `device_instance` entry here would point to the struct eth_drv_sc entry previously defined. This allows the network driver setup to work with any class of driver, not just ethernet drivers. In the future, there will surely be serial PPP drivers, etc. These will use the `NETDEVTAB_ENTRY()` setup to create the basic driver, but they will most likely be built on top of other high-level device driver layers.

To instantiate itself, and connect it to the system, a hardware driver will have a template (boilerplate) which looks something like this:

```
#include <cyg/infra/cyg_type.h>
#include <cyg/hal/hal_arch.h>
#include <cyg/infra/diag.h>
#include <cyg/hal/drv_api.h>
#include <cyg/io/eth/netdev.h>
#include <cyg/io/eth/eth_drv.h>

```

```
ETH_DRV_SC(DRV_sc,
           0,             // No driver specific data needed
           "eth0",        // Name for this interface
           HRDWR_start,
           HRDWR_stop,
           HRDWR_control,
           HRDWR_can_send
           HRDWR_send,
           HRDWR_recv,
           HRDWR_deliver,
           HRDWR_poll,
           HRDWR_int_vector
);

NETDEVTAB_ENTRY(DRV_netdev,
                "DRV",
                DRV_HRDWR_init,
                &DRV_sc);
```

This, along with the referenced functions, completely define the driver.

Note

If one needed the same low-level driver to handle multiple similar hardware interfaces, you would need multiple invocations of the `ETH_DRV_SC()`/`NETDEVTAB_ENTRY()` macros. You would add a pointer to some instance specific data, e.g. containing base addresses, interrupt numbers, etc, where the

```
        0, // No driver specific data
```

is currently.

Review of the functions

Now a brief review of the functions. This discussion will use generic names for the functions — your driver should use hardware-specific names to maintain uniqueness against any other drivers.

Init function

```
static bool DRV_HDWR_init(struct cyg_netdevtab_entry *tab)
```

This function is called as part of system initialization. Its primary function is to decide if the hardware (as indicated via tab->device_instance) is working and if the interface needs to be made available in the system. If this is the case, this function needs to finish with a call to the ethernet driver function:

```
    struct eth_drv_sc *sc = (struct eth_drv_sc *)tab->device_instance;
    ….initialization code….
    // Initialize upper level driver
    (sc->funs->eth_drv->init)( sc, unsigned char *enaddr );
```

where *`enaddr`* is a pointer to the ethernet station address for this unit, to inform the stack of this device's readiness and availability.

Note

The ethernet station address (ESA) is supposed to be a world-unique, 48 bit address for this particular ethernet interface. Typically it is provided by the board/hardware manufacturer in ROM.

In many packages it is possible for the ESA to be set from RedBoot, (perhaps from 'fconfig' data), hard-coded from CDL, or from an EPROM. A driver should choose a run-time specified ESA (e.g. from RedBoot) preferentially, otherwise (in order) it should use a CDL specified ESA if one has been set, otherwise an EPROM set ESA, or otherwise fail. See the `cl/cs8900a` ethernet driver for an example.

Start function

```
static void
HRDWR_start(struct eth_drv_sc *sc, unsigned char *enaddr, int flags)
```

This function is called, perhaps much later than system initialization time, when the system (an application) is ready for the interface to become active. The purpose of this function is to set up the hardware interface to start accepting packets from the network and be able to send packets out. The receiver hardware should not be enabled prior to this call.

Notes:

- This function will be called whenever the up/down state of the logical interface changes, e.g. when the IP address changes, or when promiscuous mode is selected by means of an `ioctl()` call in the application. This may occur more than once, so this function needs to be prepared for that case.
- In future, the *`flags`* field (currently unused) may be used to tell the function how to start up, e.g. whether interrupts will be used, alternate means of selecting promiscuous mode etc.

Stop function

```
static void HRDWR_stop(struct eth_drv_sc *sc)
```

This function is the inverse of “start.” It should shut down the hardware, disable the receiver, and keep it from interacting with the physical network.

Control function

```
static int
HRDWR_control(
        struct eth_drv_sc *sc, unsigned long key,
        void *data, int len)
```

This function is used to perform low-level “control” operations on the interface. These operations would typically be initiated via `ioctl()` calls in the BSD stack, and would be anything that might require the hardware setup to change (i.e. cannot be performed totally by the platform-independent layers).

The *`key`* parameter selects the operation, and the *`data`* and *`len`* params point describe, as required, some data for the operation in question.

Warning

Debugging of applications or execution of tests that use low-level filtering is strongly discouraged when connecting over an ethernet connection to RedBoot.

In such instances the ethernet device is shared between eCos and RedBoot. Low-level “control” operations instructing the device to filter ethernet packets by IP address, port or VLAN can filter ethernet packets destined to or from RedBoot.

Where these is no alternative, the developer must ensure that their application does not filter away ethernet packets to or from RedBoot by adjusting the filters accordingly. e.g. Ensure that the RedBoot TCP port (default 9000) and address are never filtered out.

Certain network tests (e.g. `control`) will detect when such a connection is made and either report that the test is NOTAPPLICABLE or skip over the filtering portion of the test.

Available Operations:

ETH_DRV_SET_MAC_ADDRESS

This operation sets the ethernet station address (ESA or MAC) for the device. Normally this address is kept in non-volatile memory and is unique in the world. This function must at least set the interface to use the new address. It may also update the NVM as appropriate.

ETH_DRV_GET_IF_STATS_UD
ETH_DRV_GET_IF_STATS

These acquire a set of statistical counters from the interface, and write the information into the memory pointed to by *data*. The "UD" variant explicitly instructs the driver to acquire up-to-date values. This is a separate option because doing so may take some time, depending on the hardware.

The definition of the data structure is in `cyg/io/eth/eth_drv_stats.h`.

This call is typically made by SNMP.

ETH_DRV_SET_MC_LIST

This entry instructs the device to set up multicast packet filtering to receive only packets addressed to the multicast ESAs in the list pointed to by *data*.

The format of the data is a 32-bit count of the ESAs in the list, followed by packed bytes which are the ESAs themselves, thus:

```
struct eth_drv_mc_list {
    int len;
    unsigned char addrs[CYGNUM_IO_ETH_DRIVERS_FILTER_LIST_SIZE][ETHER_ADDR_LEN];
};
```

Pass an empty list (*len*=0) to clear any existing multicast filters.

Some driver/hardware combinations can support a large number of ESAs, which can lead to a very large `struct eth_drv_mc_list` object if all the available address slots are supported. The `CYGNUM_IO_ETH_DRIVERS_FILTER_LIST_SIZE` CDL option can be tuned to reflect the upper limit required by an application configuration to minimise the overhead of passing unnecessarily large `struct eth_drv_mc_list` objects around.

ETH_DRV_SET_MC_ALL

This entry instructs the device to receive all multicast packets, and delete any explicit filtering which had been set up.

ETH_DRV_SET_DA_LIST

This entry allows a list of unicast-DA (Destination Address) values to be supplied, and any perfect filtering supported by the underlying driver to be configured appropriately.

The `eth_drv_filter_list_t` structure is used to provide the unicast-DA addresses to replace any existing DA filtering in place.

Pass an empty list (*len*=0) to clear any existing unicast-DA filters.

ETH_DRV_SET_SA_LIST

This entry allows a `eth_drv_filter_list_t` supplied list of SA (Source Address) filters to be specified.

Pass an empty list (*len*=0) to clear any existing SA filters.

ETH_DRV_FILTER_OPTIONS

This entry is provided as a single API for get/set of multiple filtering options (minimising the number of calls and the code required). It uses a standard AND/EOR approach to provide a single get/set interface.

For example, assuming the variable declaration:

```
struct eth_drv_options fo;
```

then the following will perform a GET without changing any flag state:

```
fo.u.mand = 0xFFFFFFFF;
fo.eor = 0x00000000;
```

To set an explicit value then the corresponding flag bit can be 0 for the AND. e.g.

```
fo.u.mand = 0x00000000;
fo.eor = 0x12345678;
```

To set an explicit value then the corresponding flag bit can be 0 for the AND. e.g. to set flag bit-0 to regardless of the current state:

```
fo.u.mand = 0xFFFFFFFE;
fo.eor = 0x00000001;
```

Toggling bits can also be supported. e.g. to toggle bit-2 and bit-4:

```
fo.u.mand = 0xFFFFFFFF;
fo.eor = 0x00000014;
```

After a successful request the `eth_drv_options` field `u.val` is updated to reflect the current driver option flag state after any changes that may have been requested.

Currently the following flags are defined, but not all drivers will necessarily support all the features:

The `ETH_DRV_FILTER_OPT_PROMISC` flag is provided as an alternative to the existing `ETH_DRV_SET_PROMISC` *`key`* option, just so that the control of the feature can be managed along with the other flags. It controls promiscuous mode.

The `ETH_DRV_FILTER_OPT_BLOCK_BCAST` flag controls whether all broadcast frames are dropped.

The `ETH_DRV_FILTER_OPT_INVERSE_DA` controls whether any enabled unicast DA (Destination Address) or multicast filtering (as set via `ETH_DRV_SET_DA_LIST` or `ETH_DRV_SET_MC_LIST`) operates in inverse filtering mode where matches are dropped, and non-matching frames are allowed through.

The `ETH_DRV_FILTER_OPT_INVERSE_SA` controls whether any enabled SA (Source Address) filtering (set by `ETH_DRV_SET_SA_LIST`) operates in inverse filtering mode where SA matches are dropped and non-SA matches allowed.

The `ETH_DRV_FILTER_OPT_L4_TCPUDP_ONLY` flag controls whether any enabled L4 filtering will drop all non-TCP and non-UDP packets. e.g. ICMP.

ETH_DRV_SET_FILTER_L3L4

This entry allows a L3 and/or L4 filter to be added. The `struct eth_drv_filter_l3l4` descriptor provides the filter configuration settings. The port numbers, IPv4 and IPv6 addresses must all be provided in network byte order.

The `flags` field is a combination of binary (boolean) flags describing the filter to be applied:

`ETH_DRV_L3L4_L3SRC` is set when the supplied L3 source address (SA) should be used for the match.

`ETH_DRV_L3L4_L3SRC_IPV6` is used to distinguish the type of SA supplied: unset (0) for IPv4, and set (1) for IPv6.

`ETH_DRV_L3L4_L3SRC_INV` is set when an inverted SA match should be configured.

`ETH_DRV_L3L4_L3SRC_MASK` is set when the `l3src_mb` SA bitmask should be applied.

`ETH_DRV_L3L4_L3DST` is set when the supplied L3 destination address (DA) should be used for the match.

`ETH_DRV_L3L4_L3DST_IPV6` is used to distinguish the type of DA supplied: unset (0) for IPv4, and set (1) for IPv6.

`ETH_DRV_L3L4_L3DST_INV` is set when an inverted DA match should be configured.

`ETH_DRV_L3L4_L3DST_MASK` is set when the `l3dst_mb` DA bitmask should be applied.

`ETH_DRV_L3L4_L4SRC` is set when a L4 source port filter should be applied as supplied in `l4_src`.

`ETH_DRV_L3L4_L4SRC_UDP` is set for L4 source UDP match, and unset for TCP.

`ETH_DRV_L3L4_L4SRC_INV` is set when an inverted L4 source match should be applied.

`ETH_DRV_L3L4_L4DST` is set when a L4 destination port filter should be applied as supplied in `l4_dst`.

`ETH_DRV_L3L4_L4DST_UDP` is set for L4 destination UDP match, and unset for TCP.

`ETH_DRV_L3L4_L4DST_INV` is set when an inverted L4 destination match should be applied.

Note

Not all drivers may support all of the L3/L4 filtering options available in this API. The developer should be aware of the features and limitations of the underlying Ethernet hardware MAC interface (and driver) in use.

ETH_DRV_CLR_FILTER_L3L4

This entry allows a L3/L4 filter to be removed. The `eth_drv_filter_l3l4` structure should be populated as per the original `ETH_DRV_SET_FILTER_L3L4` call.

ETH_DRV_SET_VLANTAG

This operation instructs the device to configure a single, perfect, VLAN Tag filter.

The passed `eth_drv_vlantag` structure defines the VLAN Tag to be set for the filter, along with control flags that can affect the operation. The following values can be ORed into the `flags` field to control the filter:

`ETH_DRV_VLANTAG_FLG_INVERSE` if set configures the filter as an inverted match; where only packets matching the VLAN Tag are dropped.

`ETH_DRV_VLANTAG_FLG_12BIT` configures the driver to only match against the least-significant 12-bits of the supplied `vt` field.

`ETH_DRV_VLANTAG_FLG_SVLAN` configures the driver to also accept the S-VLAN Tag (`0x88A8`) as a valid match.

The special flag `ETH_DRV_VLANTAG_FLG_DISABLE` is used to disable the VLAN Tag driver feature. The other `flags` settings are ignored, as-is the `vt` value.

ETH_DRV_GET_VLANTAG

This call will return the current VLAN Tag filter setting in the supplied `eth_drv_vlantag` structure. The extra flag `ETH_DRV_VLANTAG_FLG_VALID` in the returned `flags` field indicates whether a valid VLAN Tag filter has been set, and whether the contents of the structure can be interpreted.

ETH_DRV_OPTIONS

This entry allows control of the operation of the underlying device driver. It is provided as a single API for get/set of multiple options using a standard AND/EOR approach, though currently only the RX interrupt-vs-polled option is provided.

See `ETH_DRV_FILTER_OPTIONS` for more detail regarding using AND/EOR for get and set operations.

The RX operation mode is controlled by multiple bits covered by the `ETH_DRV_OPTION_RX_MODE_MASK`.

The `ETH_DRV_OPTION_RX_INT` mode selects interrupt driven RX mode and is the default driver mode.

The `ETH_DRV_OPTION_RX_POLL` mode, where supported by the underlying driver, selects a RX polled mode of operation. Normally this would not be desirable, but for some applications the (undefined) interrupt overhead of a high rate of RX activity may adversely affect the performance of other subsystems; such that limiting RX reception (at the cost of increased missed packets) is desired.

Note

The polled operation is less efficient with CPU bandwidth than the normal interrupt driven driver mode so throughput will be lower when polled mode is selected.

Care should be taken with the driver specific poll-period selected since high-frequency polling when a high-priority networking stack control thread is in use can be just as "bad" as an interrupt storm in denying other threads CPU time.

The use of the `ETH_DRV_OPTION_RX_POLL` mode should be viewed as an option in extremis. Suitable selection of the network thread priority levels, in conjunction with the driver and network stack buffering options, should allow for correct application operation in a well constructed application when present on a RX saturated network. If supported by the driver then H/W filtering options can further reduce the S/W load of the system hopefully avoiding the need to switch to polled RX.

The `ETH_DRV_OPTION_RX_AUTO` mode, where supported by the underlying driver, selects a mode of operation where (under driver specific configuration) the driver will switch between interrupt and polled modes depending on the RX activity. This can be used to ensure that if the driver and network stack are receiving high volumes of data that the RX interrupt load of the system can be reduced by throttling RX reception using the polled mode.

This function should return zero if the specified operation was completed successfully. It should return non-zero if the operation could not be performed, for any reason.

Can-send function

```
static int HRDWR_can_send(struct eth_drv_sc *sc)
```

This function is called to determine if it is possible to start the transmission of a packet on the interface. Some interfaces will allow multiple packets to be "queued" and this function allows for the highest possible utilization of that mode.

Return the number of packets which could be accepted at this time, zero implies that the interface is saturated/busy.

Send function

```
struct eth_drv_sg {
    CYG_ADDRESS  buf;
    CYG_ADDRWORD len;
};

static void
HRDWR_send(
        struct eth_drv_sc *sc,
        struct eth_drv_sg *sg_list, int sg_len,
        int total_len, unsigned long key)
```

This function is used to send a packet of data to the network. It is the responsibility of this function to somehow hand the data over to the hardware interface. This will most likely require copying, but just the address/length values could be used by smart hardware.

Note

All data in/out of the driver is specified via a “scatter-gather” list. This is just an array of address/length pairs which describe sections of data to move (in the order given by the array), as in the struct eth_drv_sg defined above and pointed to by *`sg_list`*.

Once the data has been successfully sent by the interface (or if an error occurs), the driver should call `(sc->funs->eth_drv->tx_done)()` (see the section called “Callback Tx-Done function”) using the specified *`key`*. Only then will the upper layers release the resources for that packet and start another transmission.

Note

In future, this function may be extended so that the data need not be copied by having the function return a “disposition” code (done, send pending, etc). At this point, you should move the data to some “safe” location before returning.

Deliver function

```
static void
HRDWR_deliver(struct eth_drv_sc *sc)
```

This function is called from the “Network Delivery Thread” in order to let the device driver do the time-consuming work associated with receiving a packet — usually copying the entire packet from the hardware or a special memory location into the network stack's memory.

After handling any outstanding incoming packets or pending transmission status, it can unmask the device's interrupts, and free any relevant resources so it can process further packets.

It will be called when the interrupt handler for the network device has called

```
    eth_drv_dsr( vector, count, (cyg_addrword_t)sc );
```

to alert the system that “something requires attention.” This `eth_drv_dsr()` call must occur from within the interrupt handler's DSR (not the ISR) or actually *be* the DSR, whenever it is determined that the device needs attention from the foreground. The third parameter (*`data`* in the prototype of `eth_drv_dsr()` *must* be a valid struct eth_drv_sc pointer `sc`.

The reason for this slightly convoluted train of events is to keep the DSR (and ISR) execution time as short as possible, so that other activities of higher priority than network servicing are not denied the CPU by network traffic.

To deliver a newly-received packet into the network stack, the deliver routine must call the following which will in turn call the receive function, which we talk about next.

```
(sc->funs->eth_drv->recv)(sc, len);
```

See also the section called “Callback Receive function” below.

Receive function

```
static void
HRDWR_recv(
        struct eth_drv_sc *sc,
        struct eth_drv_sg *sg_list, int sg_len)
```

This function is a call back, only invoked after the upper-level function

```
(sc->funs->eth_drv->recv)(struct eth_drv_sc *sc, int total_len)
```

has been called itself from your deliver function when it knows that a packet of data is available on the interface. The `(sc->funs->eth_drv->recv)()` function then arranges network buffers and structures for the data and then calls `HRDWR_recv()` to actually move the data from the interface.

A scatter-gather list (struct eth_drv_sg) is used once more, just like in the send case.

Poll function

```
static void
HRDWR_poll(struct eth_drv_sc *sc)
```

This function is used when in a non-interrupt driven system, e.g. when interrupts are completely disabled. This allows the driver time to check whether anything needs doing either for transmission, or to check if anything has been received, or if any other processing needs doing.

It is perfectly correct and acceptable for the poll function to look like this:

```
static void
HRDWR_poll(struct eth_drv_sc *sc)
{
   my_interrupt_ISR(sc);
   HRDWR_deliver(struct eth_drv_sc *sc);
}
```

provided that both the ISR and the deliver functions are idempotent and harmless if called when there is no attention needed by the hardware. Some devices might not need a call to the ISR here if the deliver function contains all the “intelligence.”

Interrupt-vector function

```
static int
HRDWR_int_vector(struct eth_drv_sc *sc)
```

This function returns the interrupt vector number used for receive interrupts. This is so that the common GDB stubs can detect when to check for incoming “CTRL-C” packets (used to asynchronously halt the application) when debugging over ethernet. The GDB stubs need to know which interrupt the ethernet device uses so that they can mask or unmask that interrupt as required.

Upper Layer Functions

Upper layer functions are called by drivers to deliver received packets or transmission completion status back up into the network stack.

These functions are defined by the hardware independent upper layers of the networking driver support. They are present to hide the interfaces to the actual networking stack so that the hardware drivers may be used by different network stack implementations without change.

These functions require a pointer to a struct eth_drv_sc which describes the interface at a logical level. It is assumed that the low level hardware driver will keep track of this pointer so it may be passed “up” as appropriate.

Callback Init function

```
void (sc->funs->eth_drv->init)(
                struct eth_drv_sc *sc, unsigned char *enaddr)
```

This function establishes the device at initialization time. It should be called once per device instance only, from the initialization function, if all is well (see the section called “Init function”). The hardware should be totally initialized (*not* “started”) when this function is called.

Callback Tx-Done function

```
void (sc->funs->eth_drv->tx_done)(
                struct eth_drv_sc *sc,
                unsigned long key, int status)
```

This function is called when a packet completes transmission on the interface. The *key* value must be one of the keys provided to *HRDWR*_send() above. The value *status* should be non-zero (details currently undefined) to indicate that an error occurred during the transmission, and zero if all was well.

It should be called from the deliver function (see the section called “Deliver function”) or poll function (see the section called “Poll function”).

Callback Receive function

```
void (sc->funs->eth_drv->recv)(struct eth_drv_sc *sc, int len)
```

This function is called to indicate that a packet of length *len* has arrived at the interface. The callback *HRDWR*_recv() function described above will be used to actually unload the data from the interface into buffers used by the device independent layers.

It should be called from the deliver function (see the section called “Deliver function”) or poll function (see the section called “Poll function”).

Calling graph for Transmission and Reception

It may be worth clarifying further the flow of control in the transmit and receive cases, where the hardware driver does use interrupts and so DSRs to tell the “foreground” when something asynchronous has occurred.

Transmission

1. Some foreground task such as the application, SNMP “daemon”, DHCP management thread or whatever, calls into network stack to send a packet, or the stack decides to send a packet in response to incoming traffic such as a “ping” or ARP request.

2. The driver calls the *HRDWR*_can_send() function in the hardware driver.

3. *HRDWR*_can_send() returns the number of available "slots" in which it can store a pending transmit packet. If it cannot send at this time, the packet is queued outside the hardware driver for later; in this case, the hardware is already busy transmitting, so expect an interrupt as described below for completion of the packet currently outgoing.

4. If it can send right now, *HRDWR*_send() is called. *HRDWR*_send() copies the data into special hardware buffers, or instructs the hardware to “send that.” It also remembers the key that is associated with this tx request.

5. These calls return … time passes …

6. Asynchronously, the hardware makes an interrupt to say “transmit is done.” The ISR quietens the interrupt source in the hardware and requests that the associated DSR be run.

7. The DSR calls (or *is*) the eth_drv_dsr() function in the generic driver.

8. eth_drv_dsr() in the generic driver awakens the “Network Delivery Thread” which calls the deliver function *HRDWR*_deliver() in the driver.

9. The deliver function realizes that a transmit request has completed, and calls the callback tx-done function `(sc->funs->eth_drv->tx_done)()` with the same key that it remembered for this tx.

10. The callback tx-done function uses the key to find the resources associated with this transmit request; thus the stack knows that the transmit has completed and its resources can be freed.

11. The callback tx-done function also enquires whether *`HRDWR`*_can_send() now says “yes, we can send” and if so, dequeues a further transmit request which may have been queued as described above. If so, then *`HRDWR`*_send() copies the data into the hardware buffers, or instructs the hardware to "send that" and remembers the new key, as above. These calls then all return to the “Network Delivery Thread” which then sleeps, awaiting the next asynchronous event.

12. All done …

Receive

1. Asynchronously, the hardware makes an interrupt to say “there is ready data in a receive buffer.” The ISR quietens the interrupt source in the hardware and requests that the associated DSR be run.

2. The DSR calls (or *is*) the `eth_drv_dsr()` function in the generic driver.

3. `eth_drv_dsr()` in the generic driver awakens the “Network Delivery Thread” which calls the deliver function *`HRDWR`*_deliver() in the driver.

4. The deliver function realizes that there is data ready and calls the callback receive function `(sc->funs->eth_drv->recv)()` to tell it how many bytes to prepare for.

5. The callback receive function allocates memory within the stack (eg. MBUFs in BSD/Unix style stacks) and prepares a set of scatter-gather buffers that can accommodate the packet.

6. It then calls back into the hardware driver routine *`HRDWR`*_recv(). *`HRDWR`*_recv() must copy the data from the hardware's buffers into the scatter-gather buffers provided, and return.

7. The network stack now has the data in-hand, and does with it what it will. This might include recursive calls to transmit a response packet. When this all is done, these calls return, and the “Network Delivery Thread” sleeps once more, awaiting the next asynchronous event.

Chapter 168. lwIP Direct Ethernet Device Driver

Introduction

This chapter provides a simple description of the basic requirements for a low-level, hardware specific, lwIP-direct ethernet driver.

Using a lwIP-direct driver provides benefits in performance and smaller code- and memory-footprints. It also allows for the potential for zero-copy UDP support and reduced (single) copy TCP support depending on the hardware available. The main disadvantage over the standard ethernet driver world is the lack of RedBoot network debugging support.

The high-level driver implemented by this package (which is only code, without state of its own) is used to provide a common interface for lwIP to either a lwIP-specific direct driver (as described in this chapter), or via a wrapper interface to a standard generic ethernet driver (covered by the section called “Generic Ethernet API”).

Unlike the generic ethernet (standard) device driver support the lwIP device driver interface uses a fixed namespace between the lwIP and driver layers. Normally only a single driver instance exists for a lwIP configured world, so the use of a fixed namespace is, in reality, not an issue since lwIP is designed for lightweight, low resource, deeply-embedded systems. If a target platform really does provide more than one distinct ethernet hardware implementation, requiring completely different hardware drivers, then a wrapper layer conforming to the “direct” driver interface is provided when the option `CYGFUN_IO_ETH_DRIVERS_LWIP_DRIVER_DIRECT_MULTI` is configured. This implements a per-driver descriptor interface between the individual low-level hardware interfaces for the platform and this common Ethernet I/O package.

Normally a direct driver implementation will also provide a driver specific header file which is referenced from the lwIP CDL option `CYGBLD_LWIP_HW_DRIVER_OVERRIDE_HEADER`. The CDL covering the direct driver package should explicitly set the value to the required header file name. Similarly when support is configured for multiple direct drivers, the CDL option `CYGBLD_LWIP_VARIANT_OVERRIDE_HEADER` can be used to reference a header providing any needed platform/variant/driver specific features.

These header files can be used to provide access to prototypes and manifests needed to support specific lwIP features as required. For example, if the hardware driver uses DMA, and requires timely support for re-using PBUFs once lwIP has finished processing them, then the `ECOS_LWIP_PBUF_POOL_FREE_HOOK` manifest can be defined to reference a callback function (See *`DRV_HDWR`*_pbuf_pool_free_hook()).

The following sections give an overview of the small set of functions that the driver needs to provide to be usable by this package. When the multiple direct driver support is being used then these named functions are provided by this common `CYGPKG_IO_ETH_DRIVERS` I/O Ethernet package, with a per-driver descriptor structure used to reference the specific driver implementations (See the section called “Multiple direct drivers”).

API reference

The following function definitions document the namespace used by the eCos lwIP TCP/IP stack to interact with hardware drivers.

Name

cyg_lwip_eth_ecos_init() — Initialize the hardware driver

Synopsis

#include <cyg/io/eth/eth_drv.h>

```
void cyg_lwip_eth_ecos_init();
```

Description

This function should perform the necessary hardware initialization, along with attaching any required eCos ISR and DSR support. As part of the initialization the upper-layer (generic) ethernet driver routine `cyg_lwip_eth_drv_init_netif()` should be called.

The direct driver DSR should call the lwIP routine `cyg_lwip_eth_dsr()` on completion of its DSR handling to ensure the lwIP delivery mechanism is notified.

Name

cyg_lwip_eth_low_level_output() — Transmit a packet

Synopsis

```
#include <cyg/io/eth/eth_drv.h>
```

```
err_t cyg_lwip_eth_low_level_output(netif, p);
```

Description

This function is called by higher layers to perform the actual transmission of the data packet referenced by *p*. The passed pointer may be a chain of linked struct pbuf descriptors containing the data of the single packet, and is not a chain of packets.

Return value

This function returns a standard error code, as defined in `<lwip/err.h>`, with ERR_OK being returned on success.

Name

cyg_lwip_eth_run_deliveries() — Packet buffer house-keeping

Synopsis

#include <cyg/io/eth/eth_drv.h>

```
void cyg_lwip_eth_run_deliveries();
```

Description

This function is called from the lwIP thread context if the DSR has indicated that an ethernet delivery event needs to happen. It can be used by the device driver to re-fill transmission buffers, or to pass pending receptions to the higher layers as required by the hardware state. For example, if a received packet is available it should pass it into the stack via the common driver routine `cyg_lwip_eth_drv_ecosif_input()`.

Name

cyg_lwip_eth_ioctl() — Control interface

Synopsis

#include <cyg/io/eth/eth_drv.h>

```
int cyg_lwip_eth_ioctl(netif, key, data, data_length);
```

Description

This function is used to perform low-level “control” operations on the specified lwIP network interface. It provides an interface to the hardware where the function cannot be performed totally by the platform-independent layers.

The *`key`* parameter selects the operation, and the *`data`* and *`data_length`* parameters describe, as required, some data for the specified operation.

Available Operations:

ETH_DRV_SET_MAC_ADDRESS

This operation sets the ethernet station address (ESA or MAC) for the specified network interface. Normally this address would be kept in non-volatile memory and is unique in the world. This function must at minimum set the hardware interface to use the supplied address, but (if required) it may also update the non-volatile memory as appropriate.

ETH_DRV_SET_MC_LIST

Configure the driver with the given list of multicast filters so that only received packets with a matching filter are accepted and passed onto the lwIP stack.

The common ethernet support currently defines a fixed size vector for holding the “list” of multicast filter addresses:

```
struct eth_drv_mc_list {
    int len;
    unsigned char addrs[CYGNUM_IO_ETH_DRIVERS_FILTER_LIST_SIZE][ETHER_ADDR_LEN];
};
```

For the lwIP ethernet driver support the passed list may have unused entries (marked by the first byte having the multicast flag bit 0 clear). This is an optimisation, and still allows for users to pass a front-filled *`len`* count of used entries, or for the driver to avoid having to copy-down data when list entries are removed by marking individual passed list entries as unused.

For simple, lightweight, drivers it is common for the list support to simply perform the equivalent of the `ETH_DRV_SET_MC_ALL` option, where the lwIP stack filters unwanted multicast packets instead of the driver having pre-filtered based on the specified list.

ETH_DRV_SET_MC_ALL

Configure the driver to accept all multicast packets.

ETH_DRV_GET_IF_STATS, ETH_DRV_GET_IF_STATS_UD

These options acquire a set of statistical counters from the interface, and write the information into the memory referenced by *`data`*. The calls to these options are typically made by SNMP agents. The “UD” variant explicitly instructs the driver to acquire up-to-date values. This is a separate option because doing so may take some time, depending on the hardware.

The definition of the data structure can be found in the header file `cyg/io/eth/eth_drv_stats.h`.

ETH_DRV_SET_DA_LIST
ETH_DRV_SET_SA_LIST
ETH_DRV_SET_FILTER_OPTIONS
ETH_DRV_SET_FILTER_L3L4
ETH_DRV_CLR_FILTER_L3L4
ETH_DRV_SET_VLANTAG
ETH_DRV_GET_VLANTAG
ETH_DRV_SET_OPMODE_RX

Refer to the section called “Control function” for the documentation for these filtering control options.

Return value

Successful completion of the operation is indicated by a result of 0 being returned. If a specific *key* operation is not supported by the driver, or there is an error processing the requested operation then a result of 1 is returned to indicate failure.

Name

*DRV_HDWR*_pbuf_pool_free_hook() — PBUF free hook callback

Synopsis

#include <cyg/io/eth/eth_drv.h>

u8_t ***DRV_HDWR*_pbuf_pool_free_hook**(*p*);

Description

If the driver specific header file defines ECOS_LWIP_PBUF_POOL_FREE_HOOK then the driver should implement a hardware-specific function matching this defined prototype.

The function is called when lwIP is releasing a packet buffer, allowing the low-level device driver access to the (now unused) packet buffer. This avoids the overhead of lwIP having to complete the free operation, and for the driver having to make a subsequent allocation call.

If the driver does want to make use of the packet buffer descriptor (for example, to replace a DMA buffer slot) then it must call the lwIP routine pbuf_pool_reinit() to ensure a valid descriptor state prior to reuse.

Return value

If the driver does not make use of the referenced struct pbuf then it returns a value of 1 to indicate that the packet buffer has not been reused.

If the driver does claim the packet buffer then it should return 0 to indicate that the packet buffer descriptor has been reused.

Multiple direct drivers

When support for multiple direct drivers is configured then a driver instance is contained within a cyg_lwip_eth_t structure:

```
typedef struct cyg_lwip_eth {
  const char *name; // NUL terminated ASCII human-readable name
  void (*init)(struct cyg_lwip_eth *drvdesc);
  void (*run_deliveries)(void *instance);
  err_t (*ll_output)(struct netif *netif,struct pbuf *p);
  int (*pbuf_free_hook)(void *instance,struct pbuf *p);
  void (*phy_event)(struct netif *netif);
  int (*ioctl)(struct netif *netif,unsigned long key,void *data,int data_length);
  void *instance;
  cyg_uint32 flags;
} CYG_HAL_TABLE_TYPE cyg_lwip_eth_t;
```

This CYGPKG_IO_ETH_DRIVERS package will implement the wrapper namespace to support lwIP, calling the relevant individual device driver registered functions as required.

You create an instance of cyg_lwip_eth_t using the CYG_LWIP_DRIVER macro, which sets up the structure. Using this macro ensures that if the internal design changes then existing source will fail to compile until updated to reflect the changed functionality. This is better than having definitions within the low-level drivers themselves, with the possibility of them building successfully but then failing at run-time.

The individual hardware drivers are initialised automatically via the wrapper provided cyg_lwip_eth_ecos_init() function, which iterates over the __LWIPDEVTAB__ vector containing the driver instance descriptors as required.

Note

When lwIP direct drivers are written to support `CYGFUN_IO_ETH_DRIVERS_LWIP_DRIVER_DIRECT_MULTI` configurations they *MUST* reference their cyg_lwip_eth_t descriptor via the `state` field of the struct netif describing the lwIP network interface. The `instance` field of the cyg_lwip_eth_t can be used to hold driver specific instance data.

The function pointers referenced from the cyg_lwip_eth_t descriptor closely match the raw namespace, with the exception that initialisation is passed the cyg_lwip_eth_t driver descriptor pointer, and the `run_deliveries` and `pbuf_free_hook` implementations are passed the private `instance` pointer. This ensures that the individual driver implementation can access the necessary state as would be the case for a single driver configuration.

Note

For the `pbuf_free_hook` support we should ideally pass the `pbuf` back to the original driver instance that allocated that specific `pbuf`. However, for the moment, the code just offers the `pbuf` to each configured driver in turn (the alternative would introduce complexity into the driver model for minimal gains).

This “do you want this `pbuf`” approach does not affect the behaviour, only the performance, of the driver when used in a multi-driver configuration. If the developer needs to ensure that a particular driver instance is “higher priority” than other lwIP Ethernet drivers for `pbuf` re-use then they should enforce a mechanism for ensuring the ordering of the `__LWIPDEVTAB__`device table.

lwIP MANUAL initialisation

Normally lwIP will default to `DHCP` for network interface address acquisition, but alternative methods can be configured (`AUTOIP`, `STATIC` or `MANUAL`). The relevant configuration specific interface initialisation code is actually performed in this common IO Ethernet package by the `cyg_lwip_eth_drv_init_netif()` function. When configured to use fixed `STATIC` addresses those are held in the eCos configuration file for the build. The `MANUAL` option, however, allows for the application code to manually supply address information and perform the interface initialisation.

When `MANUAL` address configuration is selected for an lwIP interface then an explicitly named function **must** be supplied by the application run-time, with the prototype:

```
char cyg_lwip_eth_init_manual(struct netif *netif, char inum, unsigned char *enaddr);
```

The *`netif`* parameter references the underlying lwIP network interface descriptor, with the parameter *`inum`* being the logical (indexed from 0) interface number. The *`enaddr`* references the IEEE MAC address for the interface.

It is expected that the application supplied routine will set the address configuration et al., before adding the interface, based on some per-device stored/calculated values.

It is expected that if manual application interface initialisation is being used that the developer **has** a reasonable understanding of lwIP and its internal requirements, and is au fait with the eCos network source base.

The following is a simple example implementation of the basic operations that need to be performed by the application to provide `MANUAL` interface support:

```
char cyg_lwip_eth_init_manual(struct netif *netif, char inum, unsigned char *enaddr)
{
    ip4_addr_t ipaddr;
    ip4_addr_t netmask;
    ip4_addr_t gw;

    application_code_to_fill_addresses_for_interface_number(inum, &ipaddr, &netmask, &gw);

    char ok = (NULL != netif_add((netif),
                                 &ipaddr,
                                 &netmask,
                                 &gw,
                                 (netif)->state,
                                 cyg_lwip_eth_netif_init,
                                 ethernet_input));

    if (ok) {
#if LWIP_CHECKSUM_CTRL_PER_NETIF // per-interface checksum offload control
        // Set following as desired for the application configuration, or the
        // target H/W driver feature support:
        (netif)->chksum_flags = NETIF_CHECKSUM_DISABLE_ALL;
#endif // LWIP_CHECKSUM_CTRL_PER_NETIF
        netif_set_up(netif);
    }

    return ok;
}
```

Chapter 169. CDC-EEM Target USB driver

Introduction

eCosPro-CDCEEM is eCosCentric's commercial name for the USB peripheral device CYGPKG_DEVS_ETH_USB_CDCEEM package. The package is not included as standard in eCosPro Developer's Kit releases, but is available as a separate add-on package.

The CYGPKG_DEVS_ETH_USB_CDCEEM package implements a USB peripheral device CDC-EEM transport driver. The current implementation makes use of the generic Ethernet driver package CYGPKG_DEVS_ETH_GENERIC_DIRECT to integrate with the lwIP TCP/IP stack.

The CDC-EEM peripheral driver is currently limited to use with the lwIP network stack, and is not available for the BSD network stacks. This is a limitation of the parent CYGPKG_DEVS_ETH_GENERIC_DIRECT package, and not explicitly a limitation of this CDC-EEM peripheral driver.

Normally the eCos lwIP network interface should be configured to use AutoIP, so that a link-local network address is assigned. This ensures that when connected to hosts that do not provide a DHCP daemon, or support for routing to manual or application set network addresses, an automatic connection is still configured.

API

There is no “user” API as such, since the cyg_eth_drv_generic_transport_cdceem structure is exported via the __ETH_TRANSPORT_TAB__ table constructed at build-time, and referenced from the generic Ethernet device driver. The CDC-EEM driver just provides a transport driver for the generic Ethernet world.

The exported CDC-EEM device features are controlled by the CDL for the package.

Configuration

This section shows how to include the CDC-EEM support into an eCos configuration, and how to configure it once installed.

Configuration Overview

The CDC-EEM driver is contained in a single eCos package CYGPKG_DEVS_ETH_USB_CDCEEM. However, it depends on the services of a collection of other packages for complete functionality. Currently the CDC-EEM implementation is tightly bound with the generic Ethernet driver package CYGPKG_DEVS_ETH_GENERIC_DIRECT.

Incorporating the CDC-EEM driver into your application is straightforward. The essential starting point is to incorporate the CDC-EEM eCos package (CYGPKG_DEVS_ETH_USB_CDCEEM) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Configuring the CDC-EEM driver

Once added to the eCos configuration, the CDC-EEM package has a number of configuration options.

CYGPKG_DEVS_ETH_USB_CDCEEM_VID

The device VendorID. The VendorID number space is managed by the USB organisation, www.usb.org, and a unique ID must be formally obtained.

In conjunction with the `CYGPKG_DEVS_ETH_USB_CDCEEM_PID` value this is used to uniquely identify a specific peripheral product to the host O/S environment.

Note

The VID is normally expressed as a 16-bit hexadecimal number, but the eCos graphical configurarion tool will normally display the value as a decimal.

`CYGPKG_DEVS_ETH_USB_CDCEEM_PID`

The device ProductID. The ProductID number space is managed by the vendor. This ID is sometimes used to uniquely identify specific devices as regards the host device driver needed to communicate with the target device. It is the responsibility of the developer to manage this internal (company) number space.

Note

The PID is normally expressed as a 16-bit hexadecimal number, but the eCos graphical configurarion tool will normally display the value as a decimal.

`CYGPKG_DEVS_ETH_USB_CDCEEM_MANUFACTURER`

A human-readable device manufacturer identification string, that is returned as part of the device USB description. The string may be used by the host O/S in its description of the product presented to end-users.

`CYGPKG_DEVS_ETH_USB_CDCEEM_PRODUCT`

A human-readable product identification string, that is returned as part of the device USB description. Like the manufacturer string this may be used on the host when presenting a device to the user.

`CYGPKG_DEVS_ETH_USB_CDCEEM_SERIAL_FIXED`

Depending on the product requirements the serial number returned as part of the USB descriptor can either be supplied at run-time by the application HAL or defined by the CDL and fixed for a binary build.

The former approach relies on the HAL having a method of obtaining a unique identifier from the hardware from which to construct a unique serial number string. This is normally the preferred approach to providing per-device unique identification, and is used when this option is *disabled*. When this option is *enabled* the build uses the string defined by this option as the value returned in the device USB description. This latter approach is less flexible if different physical devices need a unique ID since the CDL will need to be modified and a unique binary constructed for each specific device. If the devices do not need to present a unique identity then the same serial number can be configured into the binary build with the same value being used across *all* target devices.

`CYGPKG_DEVS_ETH_USB_CDCEEM_POWERED`

This option defines how the device declares its power state to the host, and should be configured to match the hardware implementation supporting the CDC-EEM target driver. When configured as `Bus` powered then a further configuration option is made available:

`CYGPKG_DEVS_ETH_USB_CDCEEM_MAXPOWER`

When bus-powered this option specifies the maximum power consumption of the device.

`CYGIMP_CDCEEM_CRC_RX`

When enabled verify EEM packet CRC on reception. If disabled then the CRC is ignored and all received packets are passed to the parent Ethernet driver.

CYGIMP_CDCEEM_CRC_TX

If enabled then a CRC is calculated for every EEM packet transmitted. When disabled the special 0xDEADBEEF CRC sentinel is used. NOTE: It is recommended to leave this option disabled currently, since problems have been seen where Linux host drivers will incorrectly calculate the CRC and drop packets."

CYGDBG_CDCEEM_DIAGNOSTICS

When enabled this option allows diagnostic output to be generated for different subsystems within the CDC-EEM driver, and a set of further options are made available for configuration. This information is primarily for internal driver development, and is not normally needed when debugging applications using the USB CDC-EEM network driver. The debug output is sent to the diagnostic console channel as configured for the application.

Debug and Test

Debugging

Asserts

If the target platform resources allow the first step in debugging should be to enable ASSERTs. The inclusion of assert checking will increase the code footprint and lower the performance, but do allow the code to catch internal errors from unexpected data values. e.g. when the application/client is not able to guarantee the validity of data passed into the CDC-EEM layer.

The CDC-EEM transport driver asserts are controlled via the standard eCos Infrastructure CYGPKG_INFRA package CYGDBG_USE_ASSERTS option. If enabled then run-time assertion checks are performed by the CDC-EEM driver.

If assertions are enabled, and a debugger is being used it is normally worth-while setting a breakpoint on the cyg_assert_fail symbol so that the debugger will stop prior to entering the default busy-loop processing.

Diagnostic Output

In conjuction with the CYGDBG_CDCEEM_DIAGNOSTICS CDL configuration setting, the source-file src/cdceem.c implements the CDC-EEM specific diagnostics control.

When CYGDBG_CDCEEM_DIAGNOSTICS is enabled a set of individually selectable sub-systems are available to control the diagnostic output generated.

However, when developing or debugging the CDC-EEM driver implementation it may be simpler (with less build side-effects) to control the debugging output via uncommenting the necessary manifests at the head of the src/cdceem.c source file than re-configuring the complete eCos configuration via the CDL. That way only the CDC-EEM package will be re-built.

Note

Some diagnostic output if enabled may adversely affect the operation of the CDC-EEM driver as seen by 3rd-party code. For example, “slow” serial diagnostic output of the packet parsing and response generation could mean that a significant amount of time passes, such that the CDC-EEM driver no longer adheres to the timings required by the USB host driver.

Chapter 170. RNDIS Target USB driver

Introduction

eCosPro-RNDIS is eCosCentric's commercial name for the USB peripheral device CYGPKG_DEVS_ETH_USB_RNDIS package. The package is not included as standard in eCosPro Developer's Kit releases, but is available as a separate add-on package.

The CYGPKG_DEVS_ETH_USB_RNDIS package implements a USB peripheral device Remote NDIS transport driver. The current implementation makes use of the generic Ethernet driver package CYGPKG_DEVS_ETH_GENERIC_DIRECT to integrate with the lwIP TCP/IP stack.

This driver has been tested against a range of host operating systems, including:

- Linux

  Most modern Linux distributions will, by default, have support for RNDIS USB devices. For example, Ubuntu 12, CentOS 6, etc. The target driver has been explicitly tested against 2.6 and 3.8 kernel based hosts.

- Mac OS X

  The 3rd-party, open-source, HoRNDIS driver needs to be installed on the host. The eCos RNDIS driver has been explicitly tested against Mac OS X versions 10.8.5 and 10.9, though earlier versions of Mac OS X should present no problems assuming available HoRNDIS support.

- Windows

  Windows XP (SP2), 7 (SP1), 8 and 8.1 have been testing using the standard Windows RNDIS host driver support.

The RNDIS peripheral driver is currently limited to use with the lwIP network stack, and is not available for the BSD network stacks. This is a limitation of the parent CYGPKG_DEVS_ETH_GENERIC_DIRECT package, and not explicitly a limitation of this RNDIS peripheral driver.

Normally the eCos lwIP network interface should be configured to use AutoIP, so that a link-local network address is assigned. This ensures that when connected to hosts that do not provide a DHCP daemon, or support for routing to manual or application set network addresses, an automatic connection is still configured.

One side-effect of the RNDIS networking model (as opposed to CDC-EEM for example) is that two network interfaces exist; the host-end network interface created by the host O/S, and the peripheral lwIP interface providing the target application networking. This means that each device configured to use the RNDIS USB target driver needs to provide two IEEE MAC addresses. The platform HAL support supplying the MAC address to this driver, in conjunction with the developer/manufacturer build world, must be aware of the requirements for managing the “unique identity” 24-bit MAC space in conjunction with the 24-bit IEEE OUI space specific to the device manufacturer.

API

There is no “user” API as such, since the cyg_eth_drv_generic_transport_rndis structure is exported via the __ETH_TRANSPORT_TAB__ table constructed at build-time, and referenced from the generic Ethernet device driver. The RNDIS driver just provides a transport driver for the generic Ethernet world.

The exported RNDIS device features are controlled by the CDL for the package.

Configuration

This section shows how to include the RNDIS support into an eCos configuration, and how to configure it once installed.

Configuration Overview

The RNDIS driver is contained in a single eCos package `CYGPKG_DEVS_ETH_USB_RNDIS`. However, it depends on the services of a collection of other packages for complete functionality. Currently the RNDIS implementation is tightly bound with the generic Ethernet driver package `CYGPKG_DEVS_ETH_GENERIC_DIRECT`.

Incorporating the RNDIS driver into your application is straightforward. The essential starting point is to incorporate the RNDIS eCos package (`CYGPKG_DEVS_ETH_USB_RNDIS`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Configuring the RNDIS driver

Once added to the eCos configuration, the RNDIS package has a number of configuration options.

`CYGPKG_DEVS_ETH_USB_RNDIS_VID`

The device VendorID. The VendorID number space is managed by the USB organisation, www.usb.org, and a unique ID must be formally obtained.

In conjunction with the `CYGPKG_DEVS_ETH_USB_RNDIS_PID` value this is used to uniquely identify a specific peripheral product to the host O/S environment.

Note

The VID is normally expressed as a 16-bit hexadecimal number, but the eCos graphical configurarion tool will normally display the value as a decimal.

`CYGPKG_DEVS_ETH_USB_RNDIS_PID`

The device ProductID. The ProductID number space is managed by the vendor. This ID is sometimes used to uniquely identify specific devices as regards the host device driver needed to communicate with the target device. It is the responsibility of the developer to manage this internal (company) number space.

Note

The PID is normally expressed as a 16-bit hexadecimal number, but the eCos graphical configurarion tool will normally display the value as a decimal.

`CYGPKG_DEVS_ETH_USB_RNDIS_MANUFACTURER`

A human-readable device manufacturer identification string, that is returned as part of the device USB description. The string may be used by the host O/S in its description of the product presented to end-users.

`CYGPKG_DEVS_ETH_USB_RNDIS_PRODUCT`

A human-readable product identification string, that is returned as part of the device USB description. Like the manufacturer string this may be used on the host when presenting a device to the user.

`CYGPKG_DEVS_ETH_USB_RNDIS_SERIAL_FIXED`

Depending on the product requirements the serial number returned as part of the USB descriptor can either be supplied at run-time by the application HAL or defined by the CDL and fixed for a binary build.

The former approach relies on the HAL having a method of obtaining a unique identifier from the hardware from which to construct a unique serial number string. This is normally the preferred approach to providing per-device unique identification, and is used when this option is *disabled*. When this option is *enabled* the build uses the string defined by this option as the value returned in the device USB description. This latter approach is less flexible if different physical devices need a unique ID since the CDL will need to be modified and a unique binary constructed for each specific device. If the devices do not need to present a unique identity then the same serial number can be configured into the binary build with the same value being used across *all* target devices.

CYGPKG_DEVS_ETH_USB_RNDIS_POWERED

This option defines how the device declares its power state to the host, and should be configured to match the hardware implementation supporting the RNDIS target driver. When configured as Bus powered then a further configuration option is made available:

CYGPKG_DEVS_ETH_USB_RNDIS_MAXPOWER

When bus-powered this option specifies the maximum power consumption of the device.

CYGDBG_RNDIS_DIAGNOSTICS

When enabled this option allows diagnostic output to be generated for different subsystems within the RNDIS driver, and a set of further options are made available for configuration. This information is primarily for internal driver development, and is not normally needed when debugging applications using the USB RNDIS network driver. The debug output is sent to the diagnostic console channel as configured for the application.

Debug and Test

Debugging

Asserts

If the target platform resources allow the first step in debugging should be to enable ASSERTs. The inclusion of assert checking will increase the code footprint and lower the performance, but do allow the code to catch internal errors from unexpected data values. e.g. when the application/client is not able to guarantee the validity of data passed into the RNDIS layer.

The RNDIS transport driver asserts are controlled via the standard eCos Infrastructure CYGPKG_INFRA package CYGDBG_USE_ASSERTS option. If enabled then run-time assertion checks are performed by the RNDIS driver.

If assertions are enabled, and a debugger is being used it is normally worth-while setting a breakpoint on the cyg_assert_fail symbol so that the debugger will stop prior to entering the default busy-loop processing.

Diagnostic Output

In conjuction with the CYGDBG_RNDIS_DIAGNOSTICS CDL configuration setting, the source-file src/rndis.c implements the RNDIS specific diagnostics control.

When CYGDBG_RNDIS_DIAGNOSTICS is enabled a set of individually selectable sub-systems are available to control the diagnostic output generated.

However, when developing or debugging the RNDIS driver implementation it may be simpler (with less build side-effects) to control the debugging output via uncommenting the necessary manifests at the head of the src/rndis.c source file than re-configuring the complete eCos configuration via the CDL. That way only the RNDIS package will be re-built.

Note

Some diagnostic output if enabled may adversely affect the operation of the RNDIS driver as seen by 3rd-party code. For example, “slow” serial diagnostic output of the packet parsing and response generation could mean that a significant amount of time passes, such that the RNDIS driver no longer adheres to the timings required by the USB host driver.

Chapter 171. Ethernet PHY Device Support

Ethernet PHY Device API

Modern ethernet subsystems are often separated into two pieces, the media access controller (sometimes known as a MAC) and the physical device or line interface (often referred to as a PHY). In this case, the MAC handles generating and parsing physical frames and the PHY handles how this data is actually moved to/from the wire. The MAC and PHY communicate via a special protocol, known as MII. This MII protocol can handle control over the PHY which allows for selection of such transmission criteria as line speed, duplex mode, etc.

In most cases, ethernet drivers only need to bother with the PHY during system initialization. Since the details of the PHY are separate from the MAC, there are different drivers for each. The drivers for the PHY are described by a set of exported functions which are commonly used by the MAC. The primary use of these functions currently is to initialize the PHY and determine the status of the line connection.

The connection between the MAC and the PHY differs from MAC to MAC, so the actual routines to manipulate this data channel are a property of the MAC instance. Furthermore, there are many PHY devices each with their own internal operations. A complete MAC/PHY driver setup will be comprised of the MAC MII access functions and the PHY internal driver.

A driver instance is contained within a eth_phy_access_t:

```
#define PHY_BIT_LEVEL_ACCESS_TYPE 0
#define PHY_REG_LEVEL_ACCESS_TYPE 1

typedef struct {
    int ops_type;  // 0 => bit level, 1 => register level
    bool init_done;
    void (*init)(void);
    void (*reset)(void);
    union {
        struct {
            void (*set_data)(int);
            int  (*get_data)(void);
            void (*set_clock)(int);
            void (*set_dir)(int);
        } bit_level_ops;
        struct {
            void (*put_reg)(int reg, int unit, unsigned short data);
            bool (*get_reg)(int reg, int unit, unsigned short *data);
        } reg_level_ops;
    } ops;
    int phy_addr;
    struct _eth_phy_dev_entry *dev;  // Chip access functions
} eth_phy_access_t;

struct _eth_phy_dev_entry {
    char          *name;
    cyg_uint32    id;
    bool         (*stat)(eth_phy_access_t *f, int *stat);
    unsigned int (*event)(eth_phy_access_t *f, unsigned int bitmask); // Configuration option
    cyg_uint32    idmask; // Masked with id to determine if there's a match
};
```

The `dev` element points to the PHY specific support functions. Currently, the only function which must be defined is `stat()`.

The MAC-MII-PHY interface is a narrow connection, with commands and status moving between the MAC and PHY using a bit-serial protocol. Some MAC devices contain the intelligence to run this protocol, exposing a mechanism to access PHY registers one at a time. Other MAC devices may only provide access to the MII data lines (or even still, this may be considered completely separate from the MAC). In these cases, the PHY support layer must handle the serial protocol. The choice between the access methods is in the `ops_type` field. If it has the value `PHY_BIT_LEVEL_ACCESS_TYPE`, then the PHY device layer will run the protocol, using the access functions `set_data()`, `get_data()`, `set_clock()`, `set_dir()` are used to control the MII signals and run the protocol. If `ops_type` has the value `PHY_REG_LEVEL_ACCESS_TYPE`, then the routines `put_reg()`, and `get_reg()` are used to access the PHY registers.

Two additional functions may be defined. These are `init()`, and `reset()`. The purpose of these functions is for gross-level management of the MII interface. The `init()` function will be called once, at system initialization time. It should do whatever operations are necessary to prepare the MII channel. In the case of `PHY_BIT_LEVEL_ACCESS_TYPE` devices, `init()` should prepare the signals for use, i.e. set up the appropriate parallel port registers, etc. The `reset()` function may be called by a driver to cause the PHY device to be reset to a known state. Not all drivers will require this and this function may not even be possible, so it's use and behavior is somewhat target specific.

Currently, the only function required of device specific drivers is `stat()`. This routine should query appropriate registers in the PHY and return a status bitmap indicating the state of the physical connection. In the case where the PHY can auto-negotiate a line speed and condition, this information may be useful to the MAC to indicate what speed it should provide data, etc. The status bitmask contains these bits:

```
#define ETH_PHY_STAT_LINK  0x0001   // Link up/down
#define ETH_PHY_STAT_100MB 0x0002   // Connection is 100Mb/10Mb
#define ETH_PHY_STAT_FDX   0x0004   // Connection is full/half duplex
```

Note: the usage here is that if the bit is set, then the condition exists. For example, if the `ETH_PHY_STAT_LINK` is set, then a physical link has been established.

For platforms capable of supporting asynchronous PHY event notification the `event()` function can be implemented. The CDL for the specific PHY and Ethernet driver combination defines whether the `CYGINT_DEVS_ETH_PHY_PLF_IF_EVENTS` controlled feature is actually included. The `event()` function, for simplicity, provides both the event control and status support depending on the *`bitmask`* setting passed to the function. This function provides the following functionality:

- configure the PHY for the events we are interested in receiving asynchronous notification for
- ascertain which events have occurred when an event is triggered
- clear any pending event (interrupt) status on the PHY
- ascertain the current status of the PHY

All of the above functionality is rolled into the single function to avoid the need for a separate `stat()` call to be made to the PHY when processing a PHY interrupt at the Ethernet driver layer. Also the `event()` function should never block, unlike the `stat()` implementation which may block depending on the PHY driver requirements.

In addition to the status bitmask bits defined for `stat()` (as listed above) extra status and control bits are defined. The status bit:

```
#define ETH_PHY_STAT_ANC  0x0008   // Auto-Negotiation Completed
```

is used to reflect whether Auto-Negotiation has completed. When requesting enable/disable control, or detecting a change in state indicated in the function result, the extra bits:

```
#define ETH_PHY_EVENT_LINK    (1 << 16) // Link up/down change
#define ETH_PHY_EVENT_SPEED   (1 << 17) // Speed (e.g. 10-/100-Mb/s) change
#define ETH_PHY_EVENT_DUPLEX  (1 << 18) // Duplex (half/full) change
#define ETH_PHY_EVENT_AUTONEG (1 << 19) // Auto-Negotiation completed
```

are available. When passing the *`bitmask`* to the function the bit:

```
#define ETH_PHY_EVENT_UPDATE  (1 << 31) // Update enabled events
```

is used to control both the enabling and disabling of specific PHY events. If `ETH_PHY_EVENT_UPDATE` if set then the `ETH_PHY_EVENT_` bit setting is used to control the enable (bit is set) or disable (bit is clear) state of the corresponding PHY event. If this `ETH_PHY_EVENT_UPDATE` bit is not set then the PHY event configuration is not changed, allowing the function call to be used purely for the clearing of pending events and ascertaing the event status and current PHY state. The returned result bitmask will have the bit:

```
#define ETH_PHY_EVENT_STATUS  (1 << 30) // Valid EVENT status flags
```

set if the event status information returned is valid. This is used to distinguish from the error value 0, used when the underlying PHY operations are either not available (PHY event support not actually included) or an error has occurred.

Note

The default starting state for PHY drivers is that all PHY events should be disabled. The Ethernet driver then requires an explicit call to enable PHY event support. For example to enable the LINK up/down event, and check that the PHY actually supports the functionality, a driver could make the call:

```
    if (_eth_phy_event(eth->phy, (ETH_PHY_EVENT_LINK | ETH_PHY_EVENT_UPDATE)) & ETH_PHY_EVENT_STATUS) {
      // create, attach and enable platform specific PHY interrupt handler
    }
```

Chapter 172. Synopsys DesignWare Ethernet GMAC Driver

Name

CYGPKG_DEVS_ETH_DWC_GMAC — eCos Support for Synopsys DesignWare Ethernet GMAC Devices

Description

The CYGPKG_DEVS_ETH_DWC_GMAC package only implements the standard eCos driver interface. When used with the lwIP TCP/IP network stack it provides implementations of the io/eth extended filtering options, and also provides support for automatically throttling RX frame processing to limit the system overhead when used on a saturated network. See the section called “Control function”.

Configuration Options

This Ethernet package should be loaded automatically when selecting a target containing a DWC GMAC controller, and it should never be necessary to load it explicitly. If the application does not actually require Ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic Ethernet I/O package CYGPKG_IO_ETH_DRIVERS. Typically the choice of eCos template causes the right thing to happen. For example the default template does not include any TCP/IP stack so CYGPKG_IO_ETH_DRIVERS is not included, but the net, redboot and lwip_eth templates do include a TCP/IP stack so will specify that package and hence enable the Ethernet driver.

All eCos network devices need a unique name. By default the first Ethernet device is assigned the name eth0. The platform specific package providing the DWC GMAC network device descriptor also normally provides the interface name in its struct eth_drv_sc structure instance.

The hardware requires that incoming Ethernet frames are received into one of a small number of buffers, arranged in a ring. Once a frame has been received and its size is known the driver will pass it up to higher-level code for further processing. The number of these buffers is provided in the platform specific package providing the dwc_gmac_priv structure instance.

In the standard Ethernet driver, each receive buffer requires 1528 bytes of memory. The package header file if_dwc_gmac.h defines the manifest DWC_GMAC_RX_BUFF_SIZE which is used as the size of the receive descriptor ring buffers. A smaller number of buffers increases the probability that incoming Ethernet frames have to be discarded. TCP/IP stacks are designed to cope with the occasional lost packet, but if too many frames are discarded then this will greatly affect performance. A key issue here is that passing the incoming frames up to higher-level code happens at thread level and hence the system behaviour is defined in large part by the priority of various threads running in the TCP/IP stack. If application code has high-priority threads that take up much of the available CPU time and the TCP/IP stack gets little chance to run then there will be little opportunity to pass received frames up the stack. Similarly the priority of the TCP/IP network stack threads may affect the CPU bandwidth available for other lower-priority application threads in a saturated network. Balancing out the various thread priorities and the number of receive buffers is the responsibility of the application developer.

By default the Ethernet driver will raise interrupts using a low priority level. The exact value will depend on the processor being used, and is held in the vector_pri field supplied by the platform specific package dwc_gmac_common structure definition. The driver does very little at interrupt level, instead the real work is done via threads inside the TCP/IP stack. Hence the interrupt priority has little or no effect on the system's behaviour. The RX interrupts are disabled whilst RX processing by the thread level TCP/IP stack is pending; and only re-enabled once the thread level code has processed the RX ring buffer.

RX throttling

CYGIMP_DEVS_ETH_DWC_GMAC_NET_RX_AUTO

By default the driver uses interrupt driven RX frame handling, but allows for manual control of whether interrupt or polled RX operation is used (via the ETH_DRV_OPTIONS interface). If CYGIMP_DEVS_ETH_DWC_GMAC_NET_RX_AUTO is enabled then the driver will also support automatic switching between modes. Enabling this feature does not affect the run-time operation of the driver by itself. It is the responsibility of the application to manually select ETH_DRV_OPTION_RX_AUTO mode via the ETH_DRV_OPTIONS control API if required.

```
// Simplistic example of setting driver AUTO-throttle option

struct netif *p_nif = netif_default;
struct eth_drv_sc *p_sc = (struct eth_drv_sc *)(netif->state);

if (p_sc->funs->control) {
    cyg_uint32 mode = ETH_DRV_OPTION_RX_AUTO;
    struct eth_drv_options drvopt;

    drvopt.u.mand = ~ETH_DRV_OPTION_RX_MODE_MASK;
    drvopt.eor = mode;

    int res = (p_sc->funs->control)(p_sc,ETH_DRV_OPTIONS,&drvopt,sizeof(drvopt));
    // Check mode is configured as requested:
    if (0 == res) {
        if (mode == (drvopt.u.val & ETH_DRV_OPTION_RX_MODE_MASK)) {
            success = true;
        } else {
            res = -1;
        }
    }
}
```

When AUTO-throttling is enabled other configuration options are made available to control the behaviour of the AUTO-throttle support.

CYGNUM_DEVS_ETH_DWC_GMAC_RUNAVG_SAMPLES

This option configures the number of samples used for the running averages. A smaller value will be coarser, but result in quicker transitions on large deltas. A greater number of samples value will result in a smoother transition over a longer period of time.

CYGSEM_DEVS_ETH_DWC_GMAC_NET_RX_AUTO_INTAVG

This option enables the AUTO support tracking of the RX load when in INT (interrupt) state. Since this has an impact on the performance of the RX path the feature can be disabled by deselecting this option. When this option is disabled the INT-to-POLL transition will only occur on network buffer exhaustion. When enabled the code will also track the active RX load when in AUTO-INT mode and switch to polled mode when the CYGNUM_DEVS_ETH_DWC_GMAC_WM_INT2POLL_PPMS configured watermark is exceeded.

CYGNUM_DEVS_ETH_DWC_GMAC_WM_INT2POLL_PPMS

When the AUTO-throttle feature is enabled this option specifies the load threshold (packets-per-millisecond) over which we will switch from INT mode into POLL mode. This watermark is only used when AUTO mode is enabled, and AUTO-INT state is active, and triggers a switch to POLL mode When the load average rises above this threshold. It should be tuned appropriately.

CYGNUM_DEVS_ETH_DWC_GMAC_WM_POLL2INT_PPMS

When the AUTO-throttle feature is enabled this option specifies the load threshold (packets-per-millisecond) under which we switch from POLL mode back to INT mode when the load average drops below this threshold. It should be tuned appropriately.

CYGNUM_DEVS_ETH_DWC_GMAC_NET_RX_POLL_PERIOD

When the driver is configured for RX polled operation, this value is the number of milliseconds used between polled receiver calls.

Note

Care should be taken when setting a short poll period; since on networks where the driver will accepts large numbers of RX packets, and a large amount of packet buffer space is allocated allowing the system to hold a large number of pending RX packets, then depending on the relative priority of the network stack control thread other application threads can be denied bandwidth.

MAC Address

All Ethernet devices should have a unique address which has to be provided from somewhere. There are a number of possibilities:

1. The platform supplied driver instance `dwc_gmac_priv` structure provides the `enaddr` field which can be pre-initialised by the platform specific world. The MAC address supplied in the referenced structure is used if neither of the run-time options detailed below are provided. For example, the `cyclone5_sx` platform provides the CDL variable `CYGDAT_DEVS_ETH_CYCLONE5_SX_MACADDR_ETH0` which is used to initialise the descriptor `enaddr` field for the eth0 instance.

2. The platform HAL can provide the address. For example the target board may have a small serial EPROM or similar which is initialized during board manufacture. The platform HAL can read the serial EPROM during system startup and provide the information to the Ethernet driver. If this is the case then the platform HAL should provide a macro `CYGHWR_DEVS_ETH_DWC_GMAC_GET_ESA` in the exported header `cyg/hal/plf_arch.h`.

3. If the target hardware boots via RedBoot and uses a block of flash to hold configuration variables then one of these variables will be the MAC address. This is normally indicated by `CYGSEM_HAL_VIRTUAL_VECTOR_SUPPORT` being defined, in which case the driver will attempt to access the MAC address via the `CYGNUM_CALL_IF_FLASH_CFG_GET` interface to read the `CYGNUM_FLASH_CFG_TYPE_CONFIG_ESA` option. The MAC address to use can be manipulated at the RedBoot prompt using the **fconfig** command, thus giving each board a unique address. An eCos application containing the Ethernet driver will automatically pick up this address.

When designing a new target board it is recommended that the board comes with a unique network address supported by the platform HAL, rather than relying on users to change the address. The latter approach can be error-prone and will lead to failures that are difficult to track down.

Platform-specific PHY

The Ethernet GMAC hardware relies on an external media independent interface (MII), also known as a PHY chip. This separate chip handles the low-level details of Ethernet communication, for example negotiating a link speed with the hub. In most scenarios the PHY chip simply does the right thing and needs no support from the Ethernet driver. If there are special requirements, for example if the board has to be hardwired to communicate at 10Mbps rather than autonegotiate the link speed, then usually this is handled by fixed logic levels on some of the PHY pins or by using jumpers.

The driver supports asynchronous reporting of PHY events when the CDL option `CYGSEM_DEVS_ETH_DWC_GMAC_PHY_EVENT` is configured. Currently this event support is only available when using the lwIP TCP/IP networking stack.

Chapter 173. Freescale ColdFire Ethernet Driver

Name

CYGPKG_DEVS_ETH_MCFxxxx — eCos Support for Freescale ColdFire On-chip Ethernet Devices

Description

Some members of the Freescale ColdFire family of processors come with an on-chip ethernet device. This package provides an eCos driver for that device. The driver supports both polled mode for use by RedBoot and interrupt-driven mode for use by a full TCP/IP stack.

The original version of the driver was written specifically for the MCF5272 processor. It has since been made to work on other members of the ColdFire family.

There are in fact two driver implementations within this driver package, one standard driver suitable for use with various TCP/IP stacks including at least RedBoot, BSD and lwIP; and one specific to lwIP. The lwIP-specific driver is a streamlined efficient version designed for very low RAM overhead. As a result it is implemented intentionally at the expense of features such as multiple network device support, and network debugging under RedBoot, but has improvements such as zero-copy reception as well as zero-copy transmission if certain constraints are met by the data packet to be transmitted.

Configuration Options

This ethernet package should be loaded automatically when selecting a target containing a ColdFire processor with on-chip ethernet, and it should never be necessary to load it explicitly. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package CYGPKG_IO_ETH_DRIVERS. Typically the choice of eCos template causes the right thing to happen. For example the default template does not include any TCP/IP stack so CYGPKG_IO_ETH_DRIVERS is not included, but the net, redboot and lwip_eth templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver.

The choice between using the standard driver, or the lwIP-specific driver is not made within this package, but is instead made in the generic ethernet I/O package CYGPKG_IO_ETH_DRIVERS using the options within the lwIP driver model component (CYGIMP_IO_ETH_DRIVERS_LWIP_DRIVER_MODEL). The standard driver is the default.

All eCos network devices need a unique name. By default the on-chip ethernet device is assigned the name eth0 but can be changed through the configuration option CYGDAT_DEVS_ETH_MCFxxxx_NAME. This is useful if for example the target hardware includes a number of additional off-chip ethernet devices. This setting is unused for the lwIP-specific driver.

The hardware requires that incoming ethernet frames are received into one of a small number of buffers, arranged in a ring. Once a frame has been received and its size is known the driver will pass it up to higher-level code for further processing. The number of these buffers is configurable via the option CYGNUM_DEVS_ETH_MCFxxxx_RXBUFFERS. In the standard ethernet driver, each receive buffer requires 1528 bytes of memory; with the lwIP-specific driver, the size of each buffer is set with the lwIP option CYGNUM_LWIP_PBUF_POOL_BUFSIZE, and multiple buffers are chained if needed to fulfil the requirements of incoming frames. A smaller number of buffers increases the probability that incoming ethernet frames have to be discarded. TCP/IP stacks are designed to cope with the occasional lost packet, but if too many frames are discarded then this will greatly affect performance. A key issue here is that passing the incoming frames up to higher-level code typically happens at thread level and hence the system behaviour is defined in large part by the priority of various threads running in the TCP/IP stack. If application code has high-priority threads that take up much of the available cpu time and the TCP/IP stack gets little chance to run then there will be little opportunity to pass received frames up the stack. Balancing out the various thread priorities and the number of receive buffers is the responsibility of the application developer.

By default the ethernet driver will raise interrupts using a low priority level. The exact value will depend on the processor being used, for example the MCF5282 interrupt controllers impose specific constraints on interrupt priorities. The driver does very little at interrupt level, instead the real work is done via threads inside the TCP/IP stack. Hence the interrupt priority has little or no effect on the system's behaviour. If the default priorities are inappropriate for some reason then they can be changed through the configuration options CYGNUM_DEVS_ETH_MCFxxxx_ISR_RX_PRIORITY and CYGNUM_DEVS_ETH_MCFxxxx_ISR_TX_PRIORITY.

There is an option related to the default network MAC address, CYGDAT_DEVS_ETH_MCFxxxx_PLATFORM_MAC. This is discussed in more detail below.

Optionally the ethernet driver can maintain statistics about the number of incoming and transmitted ethernet frames, receive overruns, collisions, and other conditions. Maintaining and providing these statistics involves some overhead, and is controlled by the configuration option CYGFUN_DEVS_ETH_MCFxxxx_STATISTICS. Typically these statistics are only accessed through SNMP, so by default statistics gathering is enabled if the configuration includes CYGPKG_SNMPAGENT and disabled otherwise.

MAC Address

The ColdFire processors do not have a built-in unique network MAC address since that would require slightly different manufacturing for each chip. All ethernet devices should have a unique address so this has to come from elsewhere. There are a number of possibilities:

1. The platform HAL can provide the address. For example the target board may have a small serial EPROM or similar which is initialized during board manufacture. The platform HAL can read the serial EPROM during system startup and provide the information to the ethernet driver. If this is the case then the platform HAL should implement the CDL interface CYGINT_DEVS_ETH_MCFxxxx_PLATFORM_MAC and provide a macro HAL_MCFxxxx_ETH_GET_MAC_ADDRESS in the exported header cyg/hal/plf_arch.h.

2. There is a configuration option CYGDAT_DEVS_ETH_MCFxxxx_PLATFORM_MAC which specifies the default MAC address. Manipulating this option is fine if the configuration will only be used on a single board. However if multiple boards run applications with the same configuration then they would all have the same MAC address, and the resulting behaviour is undefined.

3. If the target hardware boots via RedBoot and uses a block of flash to hold configuration variables then one of these variables will be the MAC address. It can be manipulated at the RedBoot prompt using the **fconfig** command, thus giving each board a unique address. An eCos application containing the ethernet driver will automatically pick up this address.

When designing a new target board it is recommended that the board comes with a unique network address supported by the platform HAL, rather than relying on users to change the address. The latter approach can be error-prone and will lead to failures that are difficult to track down.

Platform-specific PHY

The on-chip ethernet hardware relies on an external media independent interface (MII), also known as a PHY chip. This separate chip handles the low-level details of ethernet communication, for example negotiating a link speed with the hub. In most scenarios the PHY chip simply does the right thing and needs no support from the ethernet driver. If there are special requirements, for example if the board has to be hardwired to communicate at 10Mbps rather than autonegotiate the link speed, then usually this is handled by fixed logic levels on some of the PHY pins or by using jumpers.

The eCos ethernet driver assumes that the PHY is already fully operational and does not interact with it in any way. If the target hardware does require software initialization of the PHY chip then usually this will be done in the platform HAL, because the choice of PHY chip is a characteristic of the platform.

Chapter 174. Nios II Triple Speed Ethernet Driver

Name

`CYGPKG_DEVS_ETH_NIOS2_TSE` — eCos Support for Nios II Triple-Speed Ethernet Devices

Description

A Nios II hardware design can include one or more triple speed ethernet devices or TSEs. The package `CYGPKG_DEVS_ETH_NIOS2_TSE` provides an eCos driver for a single TSE device. It supports both polled mode for use by RedBoot and interrupt-driven mode for use by a full TCP/IP stack.

Configuration Options

The Nios II TSE driver package should be loaded automatically when creating an eCos configuration for a hardware design which includes the required devices, and it should never be necessary to load the package explicitly. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package `CYGPKG_IO_ETH_DRIVERS`. Typically the choice of eCos template causes the right thing to happen. For example the default template does not include any TCP/IP stack so `CYGPKG_IO_ETH_DRIVERS` is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver.

The driver package will only instantiate the support for a single TSE device. If the hardware design involves multiple TSE devices then support for the additional ones can be instantiated by application code. This can be achieved largely by cloning file `src/tse0.c` in this package.

There are two configuration options related to the device instantiation. `CYGDAT_DEVS_ETH_NIOS2_TSE0_NAME` sets the device name, defaulting to “eth0”. Typically this only needs to be changed if the hardware design includes other types of ethernet device and their drivers also attempt to create a device “eth0”. `CYGDAT_DEVS_ETH_NIOS2_TSE_ETH0_MAC` specifies the fallback ethernet station address or MAC address. In typical eCos systems the MAC address is provided via a RedBoot fconfig option, allowing each board to have its own address. However if the fconfig functionality is unavailable, for example when debugging via jtag, then the fallback address will be used instead. Note that each board on a network must have a unique MAC address, so if there are several boards on the network using the fallback address and the same eCos configuration then network communication can be expected to fail. Applications can also change the MAC address at run-time using a `SIOCSIFHWADDR` `ioctl`. However this `ioctl` should not be used when debugging over ethernet because it will break the debug channel.

Porting

Each triple speed ethernet device requires three units in the hardware design: the tse_mac unit itself, and sgdma_rx and sgdma_tx scatter-gather DMA controllers. Typically the hardware design will also include a bank of on-chip RAM to hold the DMA descriptors. The settings for these units are best cloned from a reference hardware design such as the TSE_SGDMA examples in the Nios II Embedded Design Suite, or the eCosPro_TSEplus design. The h/w design HAL package should provide address and interrupt vector definitions for the various units.

Chapter 175. SMSC LAN9118 Ethernet Driver

Name

CYGPKG_DEVS_ETH_SMSC_LAN9118 — eCos Support for SMSC LAN9118 Ethernet Devices

Description

The SMSC LAN9118 chip is a high performance single chip ethernet controller which can be interfaced to a variety of embedded processors. This package provides an eCos driver for that device. The driver supports both polled mode for use by RedBoot and interrupt-driven mode for use by a full TCP/IP stack.

The exact interface between the LAN9118 chip and the main processor is determined by the platform HAL. On some platforms there may even be multiple LAN9118 chips. This package only provides the platform-independent code. It is up to the platform HAL to instantiate one or more device instances and to provide information such as the base address and interrupt vector. There is also no explicit support for features like auto-negotiation or advanced flow control. These are left to the platform HAL or to the application, although usually the default settings will be acceptable for most applications.

Configuration Options

This package should be loaded automatically when selecting a target equipped with a LAN9118 ethernet chip. and it should never be necessary to load it explicitly. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package CYGPKG_IO_ETH_DRIVERS. Typically the choice of eCos template causes the right thing to happen. For example the default template does not include any TCP/IP stack so CYGPKG_IO_ETH_DRIVERS is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver.

Optionally the ethernet driver can maintain statistics about the number of incoming and transmitted ethernet frames, receive overruns, collisions, and other conditions. Maintaining and providing these statistics involves some overhead, and is controlled by the configuration option CYGFUN_DEVS_ETH_SMSC_LAN9118_STATISTICS. Typically these statistics are only accessed through SNMP, so by default statistics gathering is enabled if the configuration includes CYGPKG_SNMPAGENT and disabled otherwise.

Porting the Driver to New Hardware

It is the responsibility of the platform HAL to instantiate one or more devices, depending on the number of LAN9118 chips present. Typically this involves a separate file in the platform HAL sources:

```
#include <cyg/io/lan9118.h>

LAN9118_INSTANCE(alaia, 0, "eth0", alaia_eth_init);

static bool
alaia_eth_init(struct cyg_netdevtab_entry* tab)
{
    …

    return cyg_lan9118_eth_init(tab);
}
```

The first two arguments to the LAN9118_INSTANCE macro identify the platform and the device instance, and are used to construct unique variable names. The third argument gives the device name, and the final argument is a platform-specific initialization function. The platform HAL should also contain suitable CDL to build this file:

```
cdl_component CYGHWR_HAL_ALAIA_ETH {
    display   "External ethernet support"
    parent    CYGPKG_IO_ETH_DRIVERS
    flavor    none
    active_if CYGPKG_IO_ETH_DRIVERS
    implements  CYGNUM_DEVS_ETH_SMSC_LAN9118_COUNT
    compile   -library=libextras.a alaia_eth.c
    description "
              The Alaia board comes with a single LAN9118 ethernet device."

    cdl_option CYGNUM_HAL_ALAIA_ETH_ISR_PRIORITY {
        …
    }
    …
}
```

If the configuration does not include the generic ethernet support then this component will be inactive. Otherwise the file alaia_eth.c will get built into libextras.a, ensuring the device instance does not get eliminated by linker garbage collection. The interface CYGNUM_DEVS_ETH_SMSC_LAN9118_COUNT should be implemented once per LAN9118 chip. If additional configuration options are needed, for example to control the MAC address or the interrupt priority, then these can go inside the component.

The driver needs to know where to access the device. If there is a single LAN9118 chip then the required information can be supplied via #define's in the plf_io.h header:

```
#define HAL_LAN9118_BASE            0xBA000000
#define HAL_LAN9118_ISRVEC          CYGNUM_HAL_ISR_LAN9118
#define HAL_LAN9118_ISRPRI          CYGNUM_HAL_ALAIA_ETH_ISR_PRIORITY
```

Otherwise the platform-specific initialization function should put this information in fields in the LAN9118 instance structure:

```
static bool
alaia_eth_init(struct cyg_netdevtab_entry* tab)
{
    LAN9118_INSTANCE_NAME(alaia, 0).lan9118_base   = 0xBA000000;
    LAN9118_INSTANCE_NAME(alaia, 0).lan9118_isrvec = CYGNUM_HAL_ISR_PIO4;
    LAN9118_INSTANCE_NAME(alaia, 0).lan9118_isrpri = 1;
    LAN9118_INSTANCE_NAME(alaia, 1).lan9118_base   = 0xBB000000;
    LAN9118_INSTANCE_NAME(alaia, 1).lan9118_isrvec = CYGNUM_HAL_ISR_PIO5;
    LAN9118_INSTANCE_NAME(alaia, 1).lan9118_isrpri = 1;
    …
    return cyg_lan9118_eth_init(tab);
}
```

The initialization function should ensure that the processor's bus interface is set up correctly for talking to the ethernet chip, and that the interrupt vector has been configured correctly for level vs. edge interrupts. This must happen before calling the driver init function. Also the *lan9118_hw_flags* should be set correctly as per the flags in lan9118.h, for example:

```
static bool
alaia_eth_init(struct cyg_netdevtab_entry* tab)
{
    …
    LAN9118_INSTANCE_NAME(alaia, 0).lan9118_hw_flags  =
        (LAN9118_HW_FLAGS_IRQ_POL_ACTIVE_HIGH    |
         LAN9118_HW_FLAGS_IRQ_PUSH_PULL          |
         LAN9118_HW_FLAGS_HAS_LED1               |
         LAN9118_HW_FLAGS_HAS_LED2);
    …
    return cyg_lan9118_eth_init(tab);
}
```

The LAN9118 can be accessed via either a 16-bit or 32-bit bus, and from big-endian or little-endian processors. This gives a number of combinations. The chip is inherently little-endian, so on a little-endian processor there should be no problems. On a big-endian processor there are two possibilities. If the LAN9118 is interfaced in the obvious way then it will be necessary to swap the data of all incoming and outgoing packets, which imposes a significant performance penalty. On a 16-bit bus the LAN9118_HW_FLAGS_16BIT_BE flag should be set. Alternatively the bytes on the bus can be swapped, either by the hardware or by programming the processor's bus interface. This means no swapping is needed for data, but all accesses to the LAN9118's command and status registers need swapping instead. However most of that swapping can be done at compile-time so has no overhead. Defining `HAL_LAN9118_SWAP_COMMANDS` in `plf_io.h` sets up this mode. If there are multiple ethernet chips then the driver assumes they are all wired the same way. For further details consult the driver's source code.

All ethernet devices require a unique MAC address. Ideally this will be provided by a serial EEPROM or similar, and if such a device is present and attached to the LAN9118 then it will be used automatically by the ethernet chip to set the MAC address. If the platform does not have a suitable EEPROM then the MAC address must come from elsewhere, for example a RedBoot fconfig option, and the platform-specific initialization function should fill in the instance's *`lan9118_mac`* field.

Chapter 176. Synthetic Target Ethernet Driver

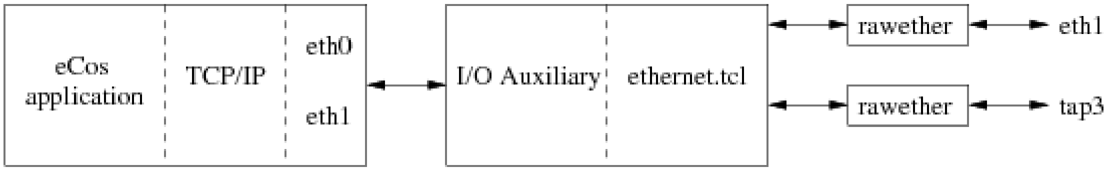
Name

Synthetic Target Ethernet Support — Allow synthetic target applications to perform ethernet I/O

Overview

The synthetic target ethernet package can provide up to four network devices, `eth0` to `eth3`. These can be used directly by the eCos application or, more commonly, by a TCP/IP stack that is linked with the eCos application. Each eCos device can be mapped on to a real Linux network device. For example, if the Linux PC has two ethernet cards and `eth1` is not currently being used by Linux itself, then one of the eCos devices can be mapped on to this Linux device. Alternatively, it is possible to map some or all of the eCos devices on to the ethertap support provided by the Linux kernel.

The ethernet package depends on the I/O auxiliary provided by the synthetic target architectural HAL package. During initialization the eCos application will attempt to instantiate the desired devices, by sending a request to the auxiliary. This will load a Tcl script `ethernet.tcl` that is responsible for handling the instantiation request and subsequent I/O operations, for example transmitting an ethernet packet. However, some of the low-level I/O operations cannot conveniently be done by a Tcl script so `ethernet.tcl` will actually run a separate program **rawether** to interact with the Linux network device.



On the target-side there are configuration options to control which network devices should be present. For many applications a single device will be sufficient, but if the final eCos application is something like a network bridge then the package can support multiple devices. On the host-side each eCos network device needs to be mapped on to a Linux one, either a real ethernet device or an ethertap device. This is handled by an entry in the target definition file:

```
synth_device ethernet {
    eth0 real eth1
    eth1 ethertap tap3 00:01:02:03:FE:05
    …
}
```

The ethernet package also comes with support for packet logging, and provides various facilities for use by user Tcl scripts.

Installation

Before a synthetic target eCos application can access ethernet devices it is necessary to build and install host-side support. The relevant code resides in the `host` subdirectory of the synthetic target ethernet package, and building it involves the standard **configure**, **make** and **make install** steps. The build involves a new executable **rawether** which must be able to access a raw Linux network device. This is achieved by installing it suid root, so the **make install** step has to be run with superuser privileges.

Caution

Installing **rawether** suid root introduces a potential security problem. Although normally **rawether** is executed only by the I/O auxiliary, theoretically it can be run by any program. Effectively it gives any user the ability to monitor all ethernet traffic and to inject arbitrary packets into the network. Also, as with any suid root programs there may be as yet undiscovered exploits. Users and system administrators should consider the risks before running **make install**.

There are two main ways of building the host-side software. It is possible to build both the generic host-side software and all package-specific host-side software, including the ethernet support, in a single build tree. This involves using the **configure** script at the toplevel of the eCos repository. For more information on this, see the `README.host` file at the top of the repository. Note that if you have an existing build tree which does not include the synthetic target ethernet support then it will be necessary to rerun the toplevel configure script: the search for appropriate packages happens at configure time.

The alternative is to build just the host-side for this package. This requires a separate build directory, building directly in the source tree is disallowed. The **configure** options are much the same as for a build from the toplevel, and the `README.host` file can be consulted for more details. It is essential that the ethernet support be configured with the same `--prefix` option as other eCos host-side software, especially the I/O auxiliary provided by the architectural synthetic target HAL package, otherwise the I/O auxiliary will be unable to locate the ethernet support.

Target-side Configuration Options

The target-side code can be configured to support up to four ethernet devices, `eth0` to `eth3`. By default `eth0` is enabled if the configuration includes a TCP/IP stack, otherwise it is disabled. The other three devices are always disabled by default. If any of the devices are enabled then there will also be the usual configuration options related to building this package. Other options related to network devices, for example whether or not to use DHCP, are provided by the generic network device package.

Real Ethernet

One obvious way of providing a synthetic target eCos application with ethernet I/O is to use a real ethernet device in the PC: transmitted packets go out on a real network, and packets on the network addressed to the right MAC address are passed on to eCos. This way synthetic target networking behaves just like networking on a real target with ethernet hardware. For example, if there is a DHCP server anywhere on the network then eCos will be able to contact it during networking startup and get hold of IP address information.

Configuring the ethernet support to use a real ethernet device requires a simple entry in the target definition file:

```
synth_device ethernet {
    <eCos device> real <linux device>
    …
}
```

For example, to map the eCos network device `eth0` to the Linux device `eth1`:

```
synth_device ethernet {
    eth0 real eth1
    …
}
```

It is not possible for an ethernet device to be shared by both the eCos TCP/IP stack and the Linux one: there would be no simple way to work out which stack incoming packets are intended for. In theory it might be possible to do some demultiplexing using distinct IP addresses, but it would be impossible to support some functionality such as DHCP. Therefore the **rawether** program will refuse to access any ethernet device already in use. On a typical Linux system `eth0` will be used for Linux networking, and the PC will have to be equipped with additional ethernet devices for use by eCos.

The **rawether** program will access the hardware via the appropriate Linux device driver, so it is important that the system is set up such that the relevant module will be automatically loaded or is already loaded. The details of this will depend on the installed distribution and version, but typically it will involve an entry in `/etc/modules.conf`.

Ethertap

The Linux kernel's ethertap facility provides a virtual network interface. A Linux application, for example the **rawether** program, can open a special character device `/dev/net/tun`, perform various `ioctl` calls, and then `write` and `read` ethernet packets. When the device is opened the Linux kernel automatically creates a new network interface, for example `tap0`. The Linux TCP/IP stack can be made to use this network interface like any other interface, receiving and transmitting ethernet packets. The net effect is a virtual network connecting just the Linux and eCos TCP/IP stacks, with no other nodes attached. By default all traffic remains inside this virtual network and is never forwarded to a real network.

Support for the ethertap facility may or may not be provided automatically, depending on your Linux distribution and version. If your system does not have a device `/dev/net/tun` or a module `tun.o` then the appropriate kernel documentation should be consulted, for example /usr/src/linux-2.4/Documentation/networking/tuntap.txt. If you are using an old Linux kernel then the ethertap functionality may be missing completely. When the **rawether** program is configured and built, the **configure** script will check for a file /usr/include/linux/if_tun.h. If that file is missing then **rawether** will be built without ethertap functionality, and only real ethernet interfaces will be supported.

The target definition file is used to map eCos network devices on to ethertap devices. The simplest usage is:

```
synth_device ethernet {
    eth0 ethertap
    …
}
```

The Linux kernel will automatically allocate the next available tap network interface. Usually this will be tap0 but if other software is using the ethertap facility, for example to implement a VPN, then a different number may be allocated. Usually it will be better to specify the particular tap device that should be used for each eCos device, for example:

```
synth_device ethernet {
    eth0 ethertap tap3
    eth1 ethertap tap4
    …
}
```

The user now knows exactly which eCos device is mapped onto which Linux device, avoiding much potential confusion. Because the virtual devices are emulated ethernet devices, they require MAC addresses. There is no physical hardware to provide these addresses, so normally MAC addresses will be invented. That means that each time the eCos application is run it will have different MAC addresses, which makes it more difficult to compare the results of different runs. To get more deterministic behaviour it is possible to specify the MAC addresses in the target definition file:

```
synth_device ethernet {
    eth0 ethertap tap3 00:01:02:03:FE:05
    eth1 ethertap tap4 00:01:02:03:FE:06
    …
}
```

During the initialization phase the eCos application will instantiate the various network devices. This will cause the I/O auxiliary to load the ethernet.tcl script and spawn **rawether** processes, which in turn will open /dev/net/tun and perform the appropriate ioctl calls. On the Linux side there will now be new network interfaces such as tap3, and these can be configured like any other network interface using commands such as **ifconfig**. In addition, if the Linux system is set up with hotplug support then it may be possible to arrange for the network interface to become active automatically. On a Red Hat Linux system this would require files such as /etc/sysconfig/network-scripts/ifcfg-tap3, containing data like:

```
DEVICE="tap3"
BOOTPROTO="none"
BROADCAST=10.2.2.255
IPADDR="10.2.2.1"
NETMASK="255.255.255.0"
NETWORK=10.2.2.0
ONBOOT="no"
```

This gives the Linux interface the address 10.2.2.1 on the network 10.2.2.0. The eCos network device should be configured with a compatible address. One way of doing this would be to enable CYGHWR_NET_DRIVER_ETH0_ADDRS, set CYGHWR_NET_DRIVER_ETH0_ADDRS_IP to 10.2.2.2, and similarly update the NETMASK, BROADCAST, GATEWAY and SERVER configuration options.

It should be noted that the ethertap facility provides a virtual network, and any packets transmitted by the eCos application will not appear on a real network. Therefore usually there will no accessible DHCP server, and eCos cannot use DHCP or BOOTP to obtain IP address information. Instead the eCos configuration should use manual or static addresses.

When **rawether** exits, the tap interface is removed by the kernel. By adding the parameter persistent **rawether** will set the persistent flag on the tap device.

```
synth_device ethernet {
    eth0 ethertap tap3 00:01:02:03:FE:05
    eth1 ethertap tap4 00:01:02:03:FE:06 persistent
    …
}
```

With this flag set the kernel will not remove the interface when **rawether** exits. This means applications such as **dhcpd**, **radvd**, and **tcpdump** will continue to run on the interface between invocations of synthetic targets. As a result the target can dynamically obtain its IP addresses from these daemons. Note it is a good idea to specify a MAC address otherwise a different random MAC address will be used each time and the dhcpd daemon will not be able to reissue the same IP address.

Host daemons like dhcpd, ntpd, radvd etc are started at boot time. Since the tap device does not exists at this point in time it is not possible for these daemons to bind to the tap device. A simple solution is to use the program **install/bin/mktap**. This takes one parameter, the name of the tap device it should create. eg, `tap3`.

An alternative approach would be to set up the Linux box as a network bridge, using commands like **brctl** to connect the virtual network interface `tap3` to a physical network interface such as `eth0`. Any packets sent by the eCos application will get forwarded automatically to the real network, and some packets on the real network will get forwarded over the virtual network to the eCos application. Note that the eCos application might also get some packets that were not intended for it, but usually those will just be discarded by the eCos TCP/IP stack. The exact details of setting up a network bridge are left as an exercise to the reader.

Packet Logging

The ethernet support comes with support for logging the various packets that are transferred, including a simple protocol analyser. This generates simple text output using the filter mechanisms provided by the I/O auxiliary, so it is possible to control the appearance and visibility of different types of output. For example the user might want to see IPv4 headers and all ICMPv4 and ARP operations, but not TCP headers or any of the packet data.

The protocol analyser is not intended to be a fully functional analyser with knowledge of many different TCP/IP protocols, advanced search facilities, graphical traffic displays, and so on. Functionality like that is already provided by other tools such as ethereal and tcpdump. Achieving similar levels of functionality would require a lot of work, for very little gain. It is still useful to have some protocol analysis functionality available because the output will be interleaved with other output, for example `printf` calls from the application. That may make it easier to understand the sequence of events.

One problem with logging ethernet traffic is that it can involve very large amounts of data. If the application is expected to run for a long time or is very I/O intensive then it is easy to end up with many megabytes. When running in graphical mode all the logging data will be held in memory, even data that is not currently visible. At some point the system will begin to run low on memory and performance will suffer. To avoid problems, the ethernet script maintains a flag that controls whether or not packet logging is active. The default is to run with logging disabled, but this can be changed in the target definition file:

```
synth_device ethernet {
    …
    logging 1
}
```

The ethernet script will add a toolbar button that allows this flag to be changed at run-time, allowing the user to capture traffic for certain periods of time while the application continues running.

The target definition file can contain the following entries for the various packet logging filters:

```
synth_device ethernet {
    …
    filter ether  -hide 0 -background LightBlue -foreground "#000080"
    filter arp    -hide 0 -background LightBlue -foreground "#000050"
    filter ipv4   -hide 0 -background LightBlue -foreground "#000040"
    filter ipv6   -hide 1 -background LightBlue -foreground "#000040"
    filter icmpv4 -hide 0 -background LightBlue -foreground "#000070"
    filter icmpv6 -hide 1 -background LightBlue -foreground "#000070"
    filter udp    -hide 0 -background LightBlue -foreground "#000030"
    filter tcp    -hide 0 -background LightBlue -foreground "#000020"
    filter hexdata   -hide 1 -background LightBlue -foreground "#000080"
    filter asciidata -hide 1 -background LightBlue -foreground "#000080"
}
```

All output will show the eCos network device, for example `eth0`, and the direction relative to the eCos application. Some of the filters will show packet headers, for example `ether` gives details of the ethernet packet header and `tcp` gives information about TCP headers such as whether or not the SYN flag is set. The TCP and UDP filters will also show source and destination addresses, using numerical addresses and if possible host names. However, host names will only be shown if the host appears in `/etc/hosts`: doing full DNS lookups while the data is being captured would add significantly to complexity and overhead. The `hexdata` and `asciidata` filters show the remainder of the packets after the ethernet, IP and TCP or UDP headers have been stripped.

Some of the filters will provide raw dumps of some of the packet data. Showing up to 1500 bytes of data for each packet would be expensive, and often the most interesting information is near the start of the packet. Therefore it is possible to set a limit on the number of bytes that will be shown using the target definition file. The default limit is 64 bytes.

```
synth_device ethernet {
    …
    max_show 128
}
```

User Interface Additions

When running in graphical mode the ethernet script extends the user interface in two ways: a button is added to the toolbar so that users can enable or disable packet logging; and an entry is added to the Help menu for the ethernet-specific documentation.

Command Line Arguments

The synthetic target ethernet support does not use any command line arguments. All configuration is handled through the target definition file.

Hooks

The ethernet support defines two hooks that can be used by other scripts, especially user scripts: `ethernet_tx` and `ethernet_rx`. The tx hook is called whenever eCos tries to transmit a packet. The rx hook is called whenever an incoming packet is passed to the eCos application. Note that this may be a little bit after the packet was actually received by the I/O auxiliary since it can buffer some packets. Both hooks are called with two arguments, the name of the network device and the packet being transferred. Typical usage might look like:

```
  proc my_tx_hook { arg_list } {
    set dev [lindex $arg_list 0]
    incr ::my_ethernet_tx_packets($dev)
    incr ::my_ethernet_tx_bytes($dev) [string length [lindex $arg_list 1]]
  }
  proc my_rx_hook { arg_list } {
    set dev [lindex $arg_list 0]
    incr ::my_ethernet_rx_packets($dev)
    incr ::my_ethernet_rx_bytes($dev) [string length [lindex $arg_list 1]]
  }
  synth::hook_add "ethernet_tx" my_tx_hook
  synth::hook_add "ethernet_rx" my_rx_hook
```

The global arrays `my_ethernet_tx_packets` etc. will now be updated whenever there is ethernet traffic. Other code, probably running at regular intervals by use of the Tcl **after** procedure, can then use this information to update a graphical monitor of some sort.

Additional Tcl Procedures

The ethernet support provides one additional Tcl procedure that can be used by other scripts;

```
ethernet::devices_get_list
```

This procedure returns a list of the ethernet devices that have been instantiated, for example `{eth0 eth1}`.

Part XLVI. DNS for eCos and RedBoot

eCos and RedBoot can both use the DNS package to perform network name lookups.

Table of Contents

Chapter 177. DNS

DNS API

The DNS client uses the normal BSD API for performing lookups: `gethostbyname()`, `gethostbyaddr()`, `getaddrinfo()`, `getnameinfo()`.

There are a few restrictions:

- If the DNS server returns multiple authoritive records for a host name to `gethostbyname`, the hostent will only contain a record for the first entry. If multiple records are desired, use `getaddrinfo`, which will return multiple results.
- The code has been made thread safe. ie multiple threads may call `gethostbyname()` without causing problems to the hostent structure returned. What is not safe is one thread using both `gethostbyname()` and `gethostbyaddr()`. A call to one will destroy the results from the previous call to the other function. `getaddrinfo()` and `getnameinfo()` are thread safe and so these are the preferred interfaces. They are also address family independent so making it easier to port code to IPv6.
- The DNS client will only return IPv4 addresses to RedBoot. At the moment this is not really a limitation, since RedBoot only supports IPv4 and not IPv6.

To initialise the DNS client the following function must be called:

```
#include <network.h>
int cyg_dns_res_start(char * dns_server)
```

Where dns_server is the address of the DNS server. The address must be in numeric form and can be either an IPv4 or an IPv6 address.

There also exists a deprecated function to start the DNS client:

```
int cyg_dns_res_init(struct in_addr *dns_server)
```

where dns_server is the address of the DNS server the client should query. The address should be in network order and can only be an IPv4 address.

On error both this function returns -1, otherwise 0 for success. If lookups are attemped before this function has been called, they will fail and return NULL, unless numeric host addresses are passed. In this cause, the address will be converted and returned without the need for a lookup.

A default, hard coded, server may be specified in the CDL option `CYGDAT_NS_DNS_DEFAULT_SERVER`. The use of this is controlled by `CYGPKG_NS_DNS_DEFAULT`. If this is enabled, `init_all_network_interfaces()` will initialize the resolver with the hard coded address. The DHCP client or user code my override this address by calling `cyg_dns_res_init` again.

The DNS client understands the concepts of the target being in a domain. By default no domain will be used. Host name lookups should be for fully qualified names. The domain name can be set and retrieved using the functions:

`int` **`getdomainname`**`(`*`name`*`, `*`len`*`);`

`int` **`setdomainname`**`(`*`name`*`, `*`len`*`);`

Alternatively, a hard coded domain name can be set using CDL. The boolean `CYGPKG_NS_DNS_DOMAINNAME` enables this and the domain name is taken from `CYGPKG_NS_DNS_DOMAINNAME_NAME`.

Once set, the DNS client will use some simple heuristics when deciding how to use the domainname. If the name given to the client ends with a "." it is assumed to be a FQDN and the domain name will not be used. If the name contains a "." somewhere within it, first a lookup will be performed without the domainname. If that fails the domainname will be appended and looked up. If the name does not contain a ".", the domainname is appended and used for the first query. If that fails, the unadorned name is lookup.

The `getaddrinfo` will return both IPv4 and IPv6 addresses for a given host name, when IPv6 is enabled in the eCos configuration. The CDL option `CYGOPT_NS_DNS_FIRST_FAMILY` controls the order IPv6 and IPv4 addresses are returned in the linked list of `addrinfo` structures. If the value `AF_INET` is used, the IPv4 addresses will be first. If the value `AF_INET6`, which is the default, is used, IPv6 address will be first. This ordering will control how clients attempt to connect to servers, ie using IPv6 or IPv4 first.

DNS Client Testing

The DNS client has a test program, dns1.c, which tests many of the features of the DNS client and the functions `gethostbyname()`, `gethostbyaddr()`, `getaddrinfo()`, `getnameinfo()`.

In order for this test to work, a DNS server must be configured with a number of names and addresses. The following is an example forward address resolution database for bind v9, which explains the requirements.

```
@         1D IN SOA       @ hostmaster.ecoscentric.com. (
                        2017022501      ; serial
                        3H              ; refresh
                        2H              ; retry
                        2W              ; expiry
                        1D )            ; minimum

          1D IN NS        ns0
          1D IN NS        ns1
          1D IN NS        dns1.zoneedit.com.
          1D IN NS        dns2.zoneedit.com.

albus     1D IN A         212.13.207.200
barn      1D IN A         87.127.120.188
farm      1D IN A         88.97.17.238
fawkes    1D IN A         212.13.207.202
www       1D IN CNAME     albus
www2      1D IN CNAME     fawkes
```

The actual names and addresses do not matter, since they are configurable in the test. What is important is the relationship between the names and the addresses and there family. ie hostnamev4 should map to one IPv4 address. hostnamev46 should map to both an IPv4 and an IPv6 address. cnamev4 should be a CNAME record for hostname4. Reverse lookup information is also needed by the test.

The information placed into the DNS server is also need in the test case. A structure is defined to hold this information:

```
struct test_info_s {
    char * dns_server_v4;
    char * dns_server_v6;
    char * domain_name;
    char * hostname_v4;
    char * cname_v4;
    char * ip_addr_v4;
    char * hostname_v6;
    char * cname_v6;
    char * ip_addr_v6;
    char * hostname_v46;
    char * cname_v46;
    char * ip_addr_v46_v4;
    char * ip_addr_v46_v6;
};
```

The test program may hold a number of such structures for different DNS server. The test will use each structure in turn to perform the tests. If IPv6 is not enabled in the eCos configuration, the entries which use IPv6 may be assigned to NULL.

Part XLVII. eCosPro-SecureSockets

Important

eCosPro-SecureSockets is an optional add-on package and may not be included in your release of eCosPro. If this package is not listed in either the graphical or command line eCos Configuration tool, please contact eCosCentric for availability and pricing.

Table of Contents

Chapter 178. OpenSSL eCos Support

Introduction

The eCosPro-SecureSockets package is a port of OpenSSL to eCos. It currently comprises a port of version 1.0.1u, but eCosCentric will issue updates from time to time after new releases become avaliable.

Licensing, Copyrights and Patents

OpenSSL is distributed under a BSD-style Open Source license. The user is referred to the file `LICENSE` in the OpenSSL release for details, and is responsible for complying with the conditions therein.

The following text on the subject of patents is adapted from text in the `README` file in the OpenSSL release:

> Various companies hold various patents for various algorithms in various locations around the world. *YOU* are responsible for ensuring that your use of any algorithms is legal by checking if there are any patents in your country. The following are some of the patents that we know about or are rumoured to exist. This is not a definitive list.
>
> - RSA Security holds software patents on the RC5 algorithm. If you intend to use this cipher, you must contact RSA Security for licensing conditions. Their web page is http://www.rsasecurity.com/.
> - RC4 is a trademark of RSA Security, so use of this label should perhaps only be used with RSA Security's permission.
> - The IDEA algorithm used to be patented by Ascom, but as of 2012, there are no longer any valid patents remaining so it may now be used patent-free.
> - NTT and Mitsubishi have patents and pending patents on the Camellia algorithm, but allow use at no charge without requiring an explicit licensing agreement: http://info.isl.ntt.co.jp/crypt/eng/info/chiteki.html.

To ensure that these patents are not accidentally violated, these algorithms are disabled by default and must be enabled explicitly by the user to be included.

Part of the conditions of using OpenSSL is that the following acknowledgment be displayed and applies not only to us, here, now, but to *you* as well:

> This product includes cryptographic software written by Eric Young (eay@cryptsoft.com).

Configuration

OpenSSL is designed to work in large, fully featured operating systems. It expects to find a filesystem, a networking stack and a full C library. All of these things are available in eCos. However, a full configuration of this sort can be very large, both in terms of the link library generated and the size of executables. This may not be appropriate for an embedded system with limited memory availability. To mitigate these effects, the eCos port for OpenSSL has been adapted to work in three basic configurations. Users can then adapt these further to their own needs.

Full Configuration

Accessing the complete functionality of OpenSSL requires a fully configured version of eCos. This should be based on the `net` template together with a number of additional packages and configurations. These additions are contained in the `openssl_full.ecm` file in the package `misc` directory. This configuration may be built using the following sequence of shell commands.

```
$ mkdir openssl_full
$ cd openssl_full
$ ecosconfig new TARGET net
$ ecosconfig import $ECOS_REPOSITORY/services/openssl/VERSION/misc/openssl_full.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The same effect can be achieved from the graphical **configtool** by selecting the net template and then importing the ECM file.

Default Configuration

If no networking is available, openssl may still be built, but only the cryptographic and filesystem based functions may be used. This configuration is based on the `default` template which included file I/O functions and the C library, but no networking, plus the addition of an ECM file. This configuration may be built with the following sequence of commands, or the equivalent in the **configtool**:

```
$ mkdir openssl_default
$ cd openssl_default
$ ecosconfig new TARGET default
$ ecosconfig import $ECOS_REPOSITORY/services/openssl/VERSION/misc/openssl_default.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

Kernel Configuration

OpenSSL will also build in a minimal kernel only configuration. This will be based on the `kernel` template plus an ECM file. This may be built with the following commands, or the equivalent in the **configtool**:

```
$ mkdir openssl_kernel
$ cd openssl_kernel
$ ecosconfig new TARGET kernel
$ ecosconfig import $ECOS_REPOSITORY/services/openssl/VERSION/misc/openssl_kernel.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

This configuration is very basic, with no networking or file I/O, only the basic cryptographic functions will be available. The ECM file adds only STDLIB and Internationalization, mainly so that `qsort()` can be include; without this ASN1 support, and therefore most cryptographic components, cannot be built.

Serial Line Support

Some parts of the OpenSSL library read data from standard input; in particular some functions read passwords with echoing disabled. They achieve this by using TERMIOS functions on the device. For this to work correctly it is necessary to configure the standard I/O to use a serial driver, and to enable TERMIOS support on it. If you intend to use serial line 0 for this, then the following ECM fragment will set up the serial device correctly:

```
cdl_configuration eCos {
    package CYGPKG_IO_SERIAL current ;
};

# Enable serial device support
cdl_component CYGPKG_IO_SERIAL_DEVICES {
    user_value 1 ;
};

# Enable general TERMIOS support
cdl_component CYGPKG_IO_SERIAL_TERMIOS {
    user_value 1;
};
```

```
# Enable TERMIOS on serial 0
cdl_component CYGPKG_IO_SERIAL_TERMIOS_TERMIOS0 {
    user_value 1;
};

# Switch standard I/O to TERMIOS device 0
cdl_option CYGDAT_LIBC_STDIO_DEFAULT_CONSOLE {
    user_value "\"/dev/termios0\"";
};
```

Substitute a different serial device number for 0 in the above where necessary.

File System Dependencies

Much of OpenSSL can function without access to a filesystem. However, there are parts that expect to load or store data to or from files. If your application already uses a filesystem for other purposes (for example JFFS2 or YAFFS), then is should be easy to store OpenSSL's files there.

Where no external file store is available, the RAM filesystem can be used for temporary storage. The RAM filesystem can be mounted on system startup, and can be populated with files from data stored in memory. The following code shows how this might be done:

```
#define SERVER_CERT "/ram/server.pem"
static const char server_pem[] {
    ….
};

void init_ramfs( void )
{
    int fd;
    int err;
    size_t done;

    // Mount the RAM filesystem
    err = mount( "", "/ram", "ramfs" );
    if( err != 0 )
        diag_printf("RAMFS mount failed\n");

    // Write server.pem to RAM filesystem
    fd = open( SERVER_CERT, O_WRONLY|O_CREAT );
    done = write( fd, server_pem, sizeof(server_pem) );
    if( done != sizeof(server_pem) )
        diag_printf("server_pem write failed\n");
    close(fd);
}
```

Constant files can also be stored in the ROM filesystem, using **mkromfs** to create a file tree that can then be mounted and read.

Configuring OpenSSL

In addition to configuring eCos for OpenSSL, OpenSSL also contains a number of configuration points. The OpenSSL sources have been separated into a number of components, mainly corresponding to specific cryptographic algorithms and other components. Each of these is controlled by its own CDL option. By default only a subset of components are enabled. Other components may be enabled individually and alternatively all components may be enabled by setting `CYGPKG_OPENSSL_ALL`.

Various components of OpenSSL depend on different sets of operating system functionality, such as networking or file I/O. OpenSSL has internal configuration options to control the inclusion of different functional elements. In general we try to use those to control the build process. We have also encoded some dependencies in the CDL, both internal and external, to control the inclusion of entire components. However, the OpenSSL code is not normally compiled in systems with missing functionality, so even if the CDL and OpenSSL dependencies are correct, it is still possible for builds to fail with compile or link errors.

openssl Command Tool

The OpenSSL package contains a command line tool, **openssl**, that can be used to test the openssl package and to generate keys and certificates. This command can either execute a single command at a time, or run in interactive mode where successive commands are issued to a prompt. Under eCos it only runs in interactive mode, taking commands and issuing responses to the serial console.

The **openssl** tool will only build and run in the full configuration and additionally needs the RAM filesystem. If passwords are to be supplied, the serial line support described earlier should be enabled.

The command executable is created and saved in the `INSTALL_DIR/bin` directory. Both the original ELF file and an SREC file, `openssl.srec` are saved here. To run the command transfer the SREC file to your TFTP server and download and run it under RedBoot. You should see something similar to the following:

```
RedBoot> load openssl.srec
Using default protocol (TFTP)
Entry point: 0x20040040, address range: 0x20040000-0x201e76ec

[eth_drv_ioctl] Warning: Driver can't set multi-cast mode
Start OpenSSL
OpenSSL> version
OpenSSL 1.0.0c 2 Dec 2010
OpenSSL>
```

The RAM filesystem is mounted and `/ram` is set as the current directory. It is therefore possible to test the generation of keys and certificates into files:

```
OpenSSL> req -x509 -nodes -days 36500 \
            -subj "/C=GB/ST=England/L=Cambridge/O=eCosCentric/CN=ecoscentric.com" \
            -newkey rsa:1024 -keyout mycert.pem -out mycert.pem
Generating a 1024 bit RSA private key
```

```
…………........++++++

writing new private key to 'mycert.pem'
-----
OpenSSL>
```

If you want to enter passwords without reflection, you need to enable the TERMIOS support described above.

The eCos hosted **openssl** command serves as a test for OpenSSL functionality, and is a good check that the library is complete. However, it is of little practical use and has some limitations. While is possible to generate key files and certificates, it is not then easy to get then off the board for future use, unless they are stored to an external medium such as an SD card. It is recommended, instead, that a host based version of **openssl** be used to do this. Files may then be imported via removable media, or written to the RAM filesystem as described above. Another limitation is that if you run the **s_server** command, you cannot terminate it. Under Unix/Linux this command relies on catching the signal generated by a Ctrl-C to terminate; there is no support for this under eCos and the only way to terminate this command is to reboot and reload **openssl**.

Thread Safety

The OpenSSL library does not directly contain support for thread safe code. Instead it relies on application code to register some callbacks to perform the locking required. Under eCos there are two ways of doing this: through the POSIX compatibility package and directly using eCos APIs.

POSIX locking support is already available in OpenSSL. Example code is available in `src/crypto/threads/th-lock.c`, and similar code is tested in the `mttest` test program. However, this code will only work in threads that have been created using `pthread_create()`, or in the `main()` application thread.

eCos locking support uses lower level primitives and can be used from any kind of thread. In order to provide locking, an application must register two callbacks with the library, and set up an array of locks that the library will request it to lock and unlock. The following code does this:

```
// Forward definitions for callback functions.
void ecos_locking_callback(int mode, int type, char *file, int line);
unsigned long ecos_thread_id_callback(void);

// Pointer to array of locks.
static cyg_mutex_t *lock_cs;

// This function allocates and initializes the lock array
// and registers the callbacks. This should be called
// after the OpenSSL library has been initialized and
// before any new threads are created.
void thread_setup(void)
{
    int i;

    // Allocate lock array according to OpenSSL's requirements
    lock_cs=OPENSSL_malloc(CRYPTO_num_locks() * sizeof(cyg_mutex_t));

    // Initialize the locks
    for (i=0; i<CRYPTO_num_locks(); i++)
    {
        cyg_mutex_init(&(lock_cs[i]));
    }

    // Register callbacks
    CRYPTO_set_id_callback((unsigned long (*)())ecos_thread_id_callback);
    CRYPTO_set_locking_callback((void (*)())ecos_locking_callback);
}

// This function deallocates the lock array and deregisters the
// callbacks. It should be called after all threads have
// terminated.
```

```
void thread_cleanup(void)
{
    int i;

    // Deregister locking callback. No real need to
    // deregister id callback.
    CRYPTO_set_locking_callback(NULL);

    // Destroy the locks
    for (i=0; i<CRYPTO_num_locks(); i++)
    {
        cyg_mutex_destroy(&(lock_cs[i]));
    }

    // Release the lock array.
    OPENSSL_free(lock_cs);
}

// Locking callback. The type, file and line arguments are
// ignored. The file and line may be used to identify the site of the
// call in the OpenSSL library for diagnostic purposes if required.
void ecos_locking_callback(int mode, int type, char *file, int line)
{
    if (mode & CRYPTO_LOCK)
    {
        cyg_mutex_lock(&(lock_cs[type]));
    }
    else
    {
        cyg_mutex_unlock(&(lock_cs[type]));
    }
}

// Thread id callback.
unsigned long ecos_thread_id_callback(void)
{
    return (unsigned long)cyg_thread_get_id(cyg_thread_self());
}
```

Example code similar to this can be found in the `mttest_ecos` test program.

eCos Customization

The eCos port of OpenSSL contains a number of customizations to adapt OpenSSL to the eCos environment.

Random Number Support

To function correctly, OpenSSL requires a source of cryptographically strong random numbers. These are usually sourced either from operating system level entropy gathering or from a hardware random number generator. At present eCos does not have any entropy gathering mechanism so the only viable source is a hardware RNG. Without entropy gathering or hardware RNG use, some forms of encrypted data may be more vulnerable to attack. Contact eCosCentric if a solution is required for this.

OpenSSL gathers random numbers by calling `RAND_poll()` when necessary. This function is responsible for calling `RAND_add()` to mix new random data into OpenSSL's PRNG state. Application code can also call `RAND_add()` directly to add entropy from any source.

The source file `src/ecos/rand_ecos.c` contains an implementation of `RAND_poll()` that adds data from a static table whenever called. This is clearly not cryptographically strong, since the same random data will be added each time an application starts. This implementation is adequate for testing the library only and should not be used for real applications. The eCos port of OpenSSL does not automatically use a hardware RNG if present, and so application code is responsible for calling `RAND_add()` to incorporate random entropy from a hardware RNG into OpenSSL's PRNG.

BIO_diag

OpenSSL implements a general purpose data source/sink/filter object called a BIO. These may be attached to various sources and sinks such as C library FILEs, file descriptors and sockets. Many functions that need to output messages take a pointer to a BIO as an argument, which is typically attached to stdout or stderr. In certain eCos configurations these streams are not present, but we still want to use these functions and supply a BIO for output.

eCos implements a new BIO type, BIO_diag which outputs any data on the eCos diagnostic channel. It can be created using the new function BIO *BIO_new_diag(void), and can subsequently be used in place of any other output-only BIO. It may be freed in the usual way with BIO_free().

Tests

OpenSSL contains a number of test programs that validate the correctness of various cryptographic algorithms and test the functioning of the OpenSSL library. Most of these tests have been ported directly to eCos with only minor changes to allow them to function in the eCos test environment. Since all these tests expect to use C library standard I/O (STDIO) for output, they will only be built if that package is configured in.

A small number of encryption algorithm tests have been further adapted to function without needing STDIO. This has mainly involved replacing (f)printf with diag_printf, but also includes spawning a thread to run the test with sufficient stack. These tests are all named the same as the base OpenSSL test from which they were derived with the addition of _ecos to the file name.

The test program ssltest1 is the only purpose written SSL test program. It is a simple client that attempts to contact an SSL server and send it some data. The server it contacts is defined by the configuration options CYGDAT_OPENSSL_TESTS_SERVER_IP and CYGDAT_OPENSSL_TESTS_SERVER_PORT which are used to set IP address and port number of the server to contact. A suitable server can be run using the **s_server** command of the **openssl** tool on the host with the configured IP address. The shell script in misc/runtest within the eCos OpenSSL package in the package repository should do this correctly for any Linux host.

The test program openssl1 is a version of the **openssl** command line tool that runs a sequence of predefined commands to test the library as a whole. One of the commands that this test runs is a timing test against the same server that ssltest1 uses.

Limitations

OpenSSL includes files crypto/asn1/a_utctm.c and src/crypto/asn1/a_time.c which have hard-coded year limits of 2050. Use beyond that year is at present unsupported, although it is expected that upstream OpenSSL will resolve this at some point.

Chapter 179. OpenSSL Manual

openssl Command Line Tool

Name

openssl — OpenSSL command line tool

Synopsis

```
opensslcommand [ command_opts ] [ command_args ]
```

```
openssl [ list-standard-commands | list-message-digest-commands |
    list-cipher-commands | list-cipher-algorithms | list-message-digest-algorithms |
    list-public-key-algorithms]
```

```
opensslno-XXX [ arbitrary options ]
```

DESCRIPTION

OpenSSL is a cryptography toolkit implementing the Secure Sockets Layer (SSL v2/v3) and Transport Layer Security (TLS v1) network protocols and related cryptography standards required by them.

The **openssl** program is a command line tool for using the various cryptography functions of OpenSSL's **crypto** library from the shell. It can be used for

```
o  Creation and management of private keys, public keys and parameters
o  Public key cryptographic operations
o  Creation of X.509 certificates, CSRs and CRLs
o  Calculation of Message Digests
o  Encryption and Decryption with Ciphers
o  SSL/TLS Client and Server Tests
o  Handling of S/MIME signed or encrypted mail
o  Time Stamp requests, generation and verification
```

COMMAND SUMMARY

The **openssl** program provides a rich variety of commands (*command* in the SYNOPSIS above), each of which often has a wealth of options and arguments (*command_opts* and *command_args* in the SYNOPSIS).

The pseudo-commands **list-standard-commands**, **list-message-digest-commands**, and **list-cipher-commands** output a list (one entry per line) of the names of all standard commands, message digest commands, or cipher commands, respectively, that are available in the present **openssl** utility.

The pseudo-commands **list-cipher-algorithms** and **list-message-digest-algorithms** list all cipher and message digest names, one entry per line. Aliases are listed as:

```
from => to
```

The pseudo-command **list-public-key-algorithms** lists all supported public key algorithms.

The pseudo-command **no-***XXX* tests whether a command of the specified name is available. If no command named *XXX* exists, it returns 0 (success) and prints **no-***XXX*; otherwise it returns 1 and prints *XXX*. In both cases, the output goes to **stdout** and nothing is printed to **stderr**. Additional command line arguments are always ignored. Since for each cipher there is a command of the same name, this provides an easy way for shell scripts to test for the availability of ciphers in the **openssl** program. (**no-***XXX* is not able to detect pseudo-commands such as **quit**, **list-**…**-commands** or **no-***XXX* itself.)

STANDARD COMMANDS

asn1parse

Parse an ASN.1 sequence.

ca

Certificate Authority (CA) Management.

ciphers

Cipher Suite Description Determination.

cms

CMS (Cryptographic Message Syntax) utility

crl

Certificate Revocation List (CRL) Management.

crl2pkcs7

CRL to PKCS#7 Conversion.

dgst

Message Digest Calculation.

dh

Diffie-Hellman Parameter Management. Obsoleted by **dhparam**.

dhparam

Generation and Management of Diffie-Hellman Parameters. Superseded by **genpkey** and **pkeyparam**

dsa

DSA Data Management.

dsaparam

DSA Parameter Generation and Management. Superseded by **genpkey** and **pkeyparam**

ec

EC (Elliptic curve) key processing

ecparam

EC parameter manipulation and generation

enc

Encoding with Ciphers.

engine

Engine (loadble module) information and manipulation.

errstr

Error Number to Error String Conversion.

gendh

Generation of Diffie-Hellman Parameters. Obsoleted by **dhparam**.

gendsa

Generation of DSA Private Key from Parameters. Superseded by **genpkey** and **pkey**

genpkey

Generation of Private Key or Parameters.

genrsa

Generation of RSA Private Key. Superceded by **genpkey**.

nseq

Create or examine a netscape certificate sequence

ocsp

Online Certificate Status Protocol utility.

passwd

Generation of hashed passwords.

pkcs12

PKCS#12 Data Management.

pkcs7

PKCS#7 Data Management.

pkey

Public and private key management.

pkeyparam

Public key algorithm parameter management.

pkeyutl

Public key algorithm cryptographic operation utility.

rand

Generate pseudo-random bytes.

req

PKCS#10 X.509 Certificate Signing Request (CSR) Management.

rsa

RSA key management.

rsautl

RSA utility for signing, verification, encryption, and decryption. Superseded by **pkeyutl**

s_client

This implements a generic SSL/TLS client which can establish a transparent connection to a remote server speaking SSL/TLS. It's intended for testing purposes only and provides only rudimentary interface functionality but internally uses mostly all functionality of the OpenSSL **ssl** library.

s_server

This implements a generic SSL/TLS server which accepts connections from remote clients speaking SSL/TLS. It's intended for testing purposes only and provides only rudimentary interface functionality but internally uses mostly all functionality of the OpenSSL **ssl** library. It provides both an own command line oriented protocol for testing SSL functions and a simple HTTP response facility to emulate an SSL/TLS-aware webserver.

s_time

SSL Connection Timer.

sess_id

SSL Session Data Management.

smime

S/MIME mail processing.

speed

Algorithm Speed Measurement.

spkac

SPKAC printing and generating utility

ts

Time Stamping Authority tool (client/server)

verify

X.509 Certificate Verification.

version

OpenSSL Version Information.

x509

X.509 Certificate Data Management.

MESSAGE DIGEST COMMANDS

md2

MD2 Digest

md5

MD5 Digest

mdc2

MDC2 Digest

PASS PHRASE ARGUMENTS

Several commands accept password arguments, typically using **-passin** and **-passout** for input and output passwords respectively. These allow the password to be obtained from a variety of sources. Both of these options take a single argument whose format is described below. If no password argument is given and a password is required then the user is prompted to enter one: this will typically be read from the current terminal with echoing turned off.

pass:password

the actual password is **password**. Since the password is visible to utilities (like 'ps' under Unix) this form should only be used where security is not important.

env:var

obtain the password from the environment variable **var**. Since the environment of other processes is visible on certain platforms (e.g. ps under certain Unix OSes) this option should be used with caution.

file:pathname

the first line of **pathname** is the password. If the same **pathname** argument is supplied to **-passin** and **-passout** arguments then the first line will be used for the input password and the next line for the output password. **pathname** need not refer to a regular file: it could for example refer to a device or named pipe.

fd:number

read the password from the file descriptor **number**. This can be used to send the data via a pipe for example.

stdin

read the password from standard input.

HISTORY

The openssl(1) document appeared in OpenSSL 0.9.2. The **list-*XXX*-commands** pseudo-commands were added in OpenSSL 0.9.3; The **list-*XXX*-algorithms** pseudo-commands were added in OpenSSL 1.0.0; the **no-*XXX*** pseudo-commands were added in OpenSSL 0.9.5a. For notes on the availability of other commands, see their individual manual pages.

Name

asn1parse — ASN.1 parsing tool

Synopsis

```
opensslasn1parse
[-inform PEM|DER]
[-in filename]
[-out filename]
[-noout]
[-offset number]
[-length number]
[-i]
[-oid filename]
[-dump]
[-dlimit num]
[-strparse offset]
[-genstr string]
[-genconf file]
```

DESCRIPTION

The **asn1parse** command is a diagnostic utility that can parse ASN.1 structures. It can also be used to extract data from ASN.1 formatted data.

OPTIONS

-inform DER|PEM

the input format. **DER** is binary format and **PEM** (the default) is base64 encoded.

-in filename

the input file, default is standard input

-out filename

output file to place the DER encoded data into. If this option is not present then no data will be output. This is most useful when combined with the **-strparse** option.

-noout

don't output the parsed version of the input file.

-offset number

starting offset to begin parsing, default is start of file.

-length number

number of bytes to parse, default is until end of file.

-i

indents the output according to the "depth" of the structures.

-oid filename

a file containing additional OBJECT IDENTIFIERs (OIDs). The format of this file is described in the NOTES section below.

-dump

dump unknown data in hex format.

-dlimit num

like **-dump**, but only the first **num** bytes are output.

-strparse offset

parse the contents octets of the ASN.1 object starting at **offset**. This option can be used multiple times to "drill down" into a nested structure.

-genstr string, **-genconf file**

generate encoded data based on **string**, **file** or both using ASN1_generate_nconf(3) format. If **file** only is present then the string is obtained from the default section using the name **asn1**. The encoded data is passed through the ASN1 parser and printed out as though it came from a file, the contents can thus be examined and written to a file using the **out** option.

OUTPUT

The output will typically contain lines like this:

```
0:d=0  hl=4 l= 681 cons: SEQUENCE
```

…

```
229:d=3  hl=3 l= 141 prim: BIT STRING
373:d=2  hl=3 l= 162 cons: cont [ 3 ]
376:d=3  hl=3 l= 159 cons: SEQUENCE
379:d=4  hl=2 l=  29 cons: SEQUENCE
381:d=5  hl=2 l=   3 prim: OBJECT            :X509v3 Subject Key Identifier
386:d=5  hl=2 l=  22 prim: OCTET STRING
410:d=4  hl=2 l= 112 cons: SEQUENCE
412:d=5  hl=2 l=   3 prim: OBJECT            :X509v3 Authority Key Identifier
417:d=5  hl=2 l= 105 prim: OCTET STRING
524:d=4  hl=2 l=  12 cons: SEQUENCE
```

…..

This example is part of a self signed certificate. Each line starts with the offset in decimal. **d=XX** specifies the current depth. The depth is increased within the scope of any SET or SEQUENCE. **hl=XX** gives the header length (tag and length octets) of the current type. **l=XX** gives the length of the contents octets.

The **-i** option can be used to make the output more readable.

Some knowledge of the ASN.1 structure is needed to interpret the output.

In this example the BIT STRING at offset 229 is the certificate public key. The contents octets of this will contain the public key information. This can be examined using the option **-strparse 229** to yield:

```
  0:d=0  hl=3 l= 137 cons: SEQUENCE
  3:d=1  hl=3 l= 129 prim: INTEGER         :E5D21E1F5C8D208EA7A2166C7FAF9F6BDF2059669C60876DDB70840F1A5AAFA59699FE471F379F1D \
                                            D6A487E7D5409AB6A88D4A9746E24B91D8CF55DB3521015460C8EDE44EE8A4189F7A7BE77D6CD3A9 \
                                            AF2696F486855CF58BF0EDF2B4068058C7A947F52548DDF7E15E96B385F86422BEA9064A3EE9E115 \
                                            8A56E4A6F47E5897
135:d=1  hl=2 l=   3 prim: INTEGER         :010001
```

NOTES

If an OID is not part of OpenSSL's internal table it will be represented in numerical form (for example 1.2.3.4). The file passed to the **-oid** option allows additional OIDs to be included. Each line consists of three columns, the first column is the OID in numerical format and should be followed by white space. The second column is the "short name" which is a single word followed by white space. The final column is the rest of the line and is the "long name". **asn1parse** displays the long name. Example:

```
1.2.3.4 shortName A long name
```

EXAMPLES

Parse a file:

```
openssl asn1parse -in file.pem
```

Parse a DER file:

```
openssl asn1parse -inform DER -in file.der
```

Generate a simple UTF8String:

```
openssl asn1parse -genstr 'UTF8:Hello World'
```

Generate and write out a UTF8String, don't print parsed output:

```
openssl asn1parse -genstr 'UTF8:Hello World' -noout -out utf8.der
```

Generate using a config file:

```
openssl asn1parse -genconf asn1.cnf -noout -out asn1.der
```

Example config file:

```
asn1=SEQUENCE:seq_sect

[seq_sect]

field1=BOOL:TRUE
field2=EXP:0, UTF8:some random string
```

BUGS

There should be options to change the format of output lines. The output of some ASN.1 types is not well handled (if at all).

DESCRIPTION

The **ca** command is a minimal CA application. It can be used to sign certificate requests in a variety of forms and generate CRLs it also maintains a text database of issued certificates and their status.

The options descriptions will be divided into each purpose.

CA OPTIONS

-config filename

specifies the configuration file to use.

-name section

specifies the configuration file section to use (overrides **default_ca** in the **ca** section).

-in filename

an input filename containing a single certificate request to be signed by the CA.

-ss_cert filename

a single self signed certificate to be signed by the CA.

-spkac filename

a file containing a single Netscape signed public key and challenge and additional field values to be signed by the CA. See the **SPKAC FORMAT** section for information on the required input and output format.

-infiles

if present this should be the last option, all subsequent arguments are assumed to the the names of files containing certificate requests.

-out filename

the output file to output certificates to. The default is standard output. The certificate details will also be printed out to this file in PEM format (except that **-spkac** outputs DER format).

-outdir directory

the directory to output certificates to. The certificate will be written to a filename consisting of the serial number in hex with ".pem" appended.

-cert

the CA certificate file.

-keyfile filename

the private key to sign requests with.

-keyform PEM|DER

the format of the data in the private key file. The default is PEM.

-key password

the password used to encrypt the private key. Since on some systems the command line arguments are visible (e.g. Unix with the 'ps' utility) this option should be used with caution.

-selfsign

indicates the issued certificates are to be signed with the key the certificate requests were signed with (given with **-keyfile**). Cerificate requests signed with a different key are ignored. If **-spkac**, **-ss_cert** or **-gencrl** are given, **-selfsign** is ignored.

A consequence of using **-selfsign** is that the self-signed certificate appears among the entries in the certificate database (see the configuration option **database**), and uses the same serial number counter as all other certificates sign with the self-signed certificate.

-passin arg

the key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-verbose

this prints extra details about the operations being performed.

-notext

don't output the text form of a certificate to the output file.

-startdate date

this allows the start date to be explicitly set. The format of the date is YYMMDDHHMMSSZ (the same as an ASN1 UTCTime structure).

-enddate date

this allows the expiry date to be explicitly set. The format of the date is YYMMDDHHMMSSZ (the same as an ASN1 UTCTime structure).

-days arg

the number of days to certify the certificate for.

-md alg

the message digest to use. Possible values include md5, sha1 and mdc2. This option also applies to CRLs.

-policy arg

this option defines the CA "policy" to use. This is a section in the configuration file which decides which fields should be mandatory or match the CA certificate. Check out the **POLICY FORMAT** section for more information.

-msie_hack

this is a legacy option to make **ca** work with very old versions of the IE certificate enrollment control "certenr3". It used UniversalStrings for almost everything. Since the old control has various security bugs its use is strongly discouraged. The newer control "Xenroll" does not need this option.

-preserveDN

Normally the DN order of a certificate is the same as the order of the fields in the relevant policy section. When this option is set the order is the same as the request. This is largely for compatibility with the older IE enrollment control which would only accept certificates if their DNs match the order of the request. This is not needed for Xenroll.

-noemailDN

The DN of a certificate can contain the EMAIL field if present in the request DN, however it is good policy just having the e-mail set into the altName extension of the certificate. When this option is set the EMAIL field is removed from the certificate' subject and set only in the, eventually present, extensions. The **email_in_dn** keyword can be used in the configuration file to enable this behaviour.

-batch

this sets the batch mode. In this mode no questions will be asked and all certificates will be certified automatically.

-extensions section

the section of the configuration file containing certificate extensions to be added when a certificate is issued (defaults to **x509_extensions** unless the **-extfile** option is used). If no extension section is present then, a V1 certificate is created. If the extension section is present (even if it is empty), then a V3 certificate is created. See the:w x509v3_config(5) manual page for details of the extension section format.

-extfile file

an additional configuration file to read certificate extensions from (using the default section unless the **-extensions** option is also used).

-engine id

specifying an engine (by its unique **id** string) will cause **ca** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

-subj arg

supersedes subject name given in the request. The arg must be formatted as */type0=value0/type1=value1/type2=...*, characters may be escaped by \ (backslash), no spaces are skipped.

-utf8

this option causes field values to be interpreted as UTF8 strings, by default they are interpreted as ASCII. This means that the field values, whether prompted from a terminal or obtained from a configuration file, must be valid UTF8 strings.

-multivalue-rdn

this option causes the -subj argument to be interpretedt with full support for multivalued RDNs. Example:

/DC=org/DC=OpenSSL/DC=users/UID=123456+CN=John Doe

If -multi-rdn is not used then the UID value is *123456+CN=John Doe*.

CRL OPTIONS

-gencrl

this option generates a CRL based on information in the index file.

-crldays num

the number of days before the next CRL is due. That is the days from now to place in the CRL nextUpdate field.

-crlhours num

the number of hours before the next CRL is due.

-revoke filename

a filename containing a certificate to revoke.

-status serial

displays the revocation status of the certificate with the specified serial number and exits.

-updatedb

Updates the database index to purge expired certificates.

-crl_reason reason

revocation reason, where **reason** is one of: **unspecified**, **keyCompromise**, **CACompromise**, **affiliationChanged**, **superseded**, **cessationOfOperation**, **certificateHold** or **removeFromCRL**. The matching of **reason** is case insensitive. Setting any revocation reason will make the CRL v2.

In practive **removeFromCRL** is not particularly useful because it is only used in delta CRLs which are not currently implemented.

-crl_hold instruction

This sets the CRL revocation reason code to **certificateHold** and the hold instruction to **instruction** which must be an OID. Although any OID can be used only **holdInstructionNone** (the use of which is discouraged by RFC2459) **holdInstructionCallIssuer** or **holdInstructionReject** will normally be used.

-crl_compromise time

This sets the revocation reason to **keyCompromise** and the compromise time to **time**. **time** should be in GeneralizedTime format that is **YYYYMMDDHHMMSSZ**.

-crl_CA_compromise time

This is the same as **crl_compromise** except the revocation reason is set to **CACompromise**.

-crlexts section

the section of the configuration file containing CRL extensions to include. If no CRL extension section is present then a V1 CRL is created, if the CRL extension section is present (even if it is empty) then a V2 CRL is created. The CRL extensions specified are CRL extensions and **not** CRL entry extensions. It should be noted that some software (for example Netscape) can't handle V2 CRLs. See x509v3_config(5) manual page for details of the extension section format.

CONFIGURATION FILE OPTIONS

The section of the configuration file containing options for **ca** is found as follows: If the **-name** command line option is used, then it names the section to be used. Otherwise the section to be used must be named in the **default_ca** option of the **ca** section of the configuration file (or in the default section of the configuration file). Besides **default_ca**, the following options are read directly from the **ca** section: RANDFILE preserve msie_hack With the exception of **RANDFILE**, this is probably a bug and may change in future releases.

Many of the configuration file options are identical to command line options. Where the option is present in the configuration file and the command line the command line value is used. Where an option is described as mandatory then it must be present in the configuration file or the command line equivalent (if any) used.

oid_file

This specifies a file containing additional **OBJECT IDENTIFIERS**. Each line of the file should consist of the numerical form of the object identifier followed by white space then the short name followed by white space and finally the long name.

oid_section

This specifies a section in the configuration file containing extra object identifiers. Each line should consist of the short name of the object identifier followed by = and the numerical form. The short and long names are the same when this option is used.

new_certs_dir

the same as the **-outdir** command line option. It specifies the directory where new certificates will be placed. Mandatory.

certificate

the same as **-cert**. It gives the file containing the CA certificate. Mandatory.

private_key

same as the **-keyfile** option. The file containing the CA private key. Mandatory.

RANDFILE

a file used to read and write random number seed information, or an EGD socket (see RAND_egd(3)).

default_days

the same as the **-days** option. The number of days to certify a certificate for.

default_startdate

the same as the **-startdate** option. The start date to certify a certificate for. If not set the current time is used.

default_enddate

the same as the **-enddate** option. Either this option or **default_days** (or the command line equivalents) must be present.

default_crl_hours default_crl_days

the same as the **-crlhours** and the **-crldays** options. These will only be used if neither command line option is present. At least one of these must be present to generate a CRL.

default_md

the same as the **-md** option. The message digest to use. Mandatory.

database

the text database file to use. Mandatory. This file must be present though initially it will be empty.

unique_subject

if the value **yes** is given, the valid certificate entries in the database must have unique subjects. if the value **no** is given, several valid certificate entries may have the exact same subject. The default value is **yes**, to be compatible with older (pre 0.9.8) versions of OpenSSL. However, to make CA certificate roll-over easier, it's recommended to use the value **no**, especially if combined with the **-selfsign** command line option.

serial

a text file containing the next serial number to use in hex. Mandatory. This file must be present and contain a valid serial number.

crlnumber

a text file containing the next CRL number to use in hex. The crl number will be inserted in the CRLs only if this file exists. If this file is present, it must contain a valid CRL number.

x509_extensions

the same as **-extensions**.

crl_extensions

the same as **-crlexts**.

preserve

the same as **-preserveDN**

email_in_dn

the same as **-noemailDN**. If you want the EMAIL field to be removed from the DN of the certificate simply set this to 'no'. If not present the default is to allow for the EMAIL filed in the certificate's DN.

msie_hack

the same as **-msie_hack**

policy

the same as **-policy**. Mandatory. See the **POLICY FORMAT** section for more information.

name_opt, **cert_opt**

these options allow the format used to display the certificate details when asking the user to confirm signing. All the options supported by the **x509** utilities **-nameopt** and **-certopt** switches can be used here, except the **no_signame** and **no_sigdump** are permanently set and cannot be disabled (this is because the certificate signature cannot be displayed because the certificate has not been signed at this point).

For convenience the values **ca_default** are accepted by both to produce a reasonable output.

If neither option is present the format used in earlier versions of OpenSSL is used. Use of the old format is **strongly** discouraged because it only displays fields mentioned in the **policy** section, mishandles multicharacter string types and does not display extensions.

copy_extensions

determines how extensions in certificate requests should be handled. If set to **none** or this option is not present then extensions are ignored and not copied to the certificate. If set to **copy** then any extensions present in the request that are not already present are copied to the certificate. If set to **copyall** then all extensions in the request are copied to the certificate: if the extension is already present in the certificate it is deleted first. See the **WARNINGS** section before using this option.

The main use of this option is to allow a certificate request to supply values for certain extensions such as subjectAltName.

POLICY FORMAT

The policy section consists of a set of variables corresponding to certificate DN fields. If the value is "match" then the field value must match the same field in the CA certificate. If the value is "supplied" then it must be present. If the value is "optional" then it may be present. Any fields not mentioned in the policy section are silently deleted, unless the **-preserveDN** option is set but this can be regarded more of a quirk than intended behaviour.

SPKAC FORMAT

The input to the **-spkac** command line option is a Netscape signed public key and challenge. This will usually come from the **KEYGEN** tag in an HTML form to create a new private key. It is however possible to create SPKACs using the **spkac** utility.

The file should contain the variable SPKAC set to the value of the SPKAC and also the required DN components as name value pairs. If you need to include the same component twice then it can be preceded by a number and a '.'.

When processing SPKAC format, the output is DER if the **-out** flag is used, but PEM format if sending to stdout or the **-outdir** flag is used.

EXAMPLES

Note: these examples assume that the **ca** directory structure is already set up and the relevant files already exist. This usually involves creating a CA certificate and private key with **req**, a serial number file and an empty index file and placing them in the relevant directories.

To use the sample configuration file below the directories demoCA, demoCA/private and demoCA/newcerts would be created. The CA certificate would be copied to demoCA/cacert.pem and its private key to demoCA/private/cakey.pem. A file demoCA/serial would be created containing for example "01" and the empty index file demoCA/index.txt.

Sign a certificate request:

```
openssl ca -in req.pem -out newcert.pem
```

Sign a certificate request, using CA extensions:

```
openssl ca -in req.pem -extensions v3_ca -out newcert.pem
```

Generate a CRL

```
openssl ca -gencrl -out crl.pem
```

Sign several requests:

```
openssl ca -infiles req1.pem req2.pem req3.pem
```

Certify a Netscape SPKAC:

```
openssl ca -spkac spkac.txt
```

A sample SPKAC file (the SPKAC line has been truncated for clarity):

```
SPKAC=MIG0MGAwXDANBgkqhkiG9w0BAQEFAANLADBIAkEAn7PDhCeV/xIxUg8V70YRxK2A5
CN=Steve Test
emailAddress=steve@openssl.org
0.OU=OpenSSL Group
1.OU=Another Group
```

A sample configuration file with the relevant sections for **ca**:

```
[ ca ]
default_ca      = CA_default            # The default ca section

[ CA_default ]

dir            = ./demoCA              # top dir
database       = $dir/index.txt        # index file.
new_certs_dir  = $dir/newcerts         # new certs dir

certificate    = $dir/cacert.pem       # The CA cert
serial         = $dir/serial           # serial no file
private_key    = $dir/private/cakey.pem# CA private key
RANDFILE       = $dir/private/.rand    # random number file

default_days   = 365                   # how long to certify for
default_crl_days= 30                   # how long before next CRL
default_md     = md5                   # md to use

policy         = policy_any            # default policy
email_in_dn    = no                    # Don't add the email into cert DN
```

```
name_opt       = ca_default            # Subject name display option
cert_opt       = ca_default            # Certificate display option
copy_extensions = none                 # Don't copy extensions from request

[ policy_any ]
countryName            = supplied
stateOrProvinceName    = optional
organizationName       = optional
organizationalUnitName = optional
commonName             = supplied
emailAddress           = optional
```

FILES

Note: the location of all files can change either by compile time options, configuration file entries, environment variables or command line options. The values below reflect the default values.

```
/usr/local/ssl/lib/openssl.cnf - master configuration file
./demoCA                       - main CA directory
./demoCA/cacert.pem            - CA certificate
./demoCA/private/cakey.pem     - CA private key
./demoCA/serial                - CA serial number file
./demoCA/serial.old            - CA serial number backup file
./demoCA/index.txt             - CA text database file
./demoCA/index.txt.old         - CA text database backup file
./demoCA/certs                 - certificate output file
./demoCA/.rnd                  - CA random seed information
```

ENVIRONMENT VARIABLES

OPENSSL_CONF reflects the location of master configuration file it can be overridden by the **-config** command line option.

RESTRICTIONS

The text database index file is a critical part of the process and if corrupted it can be difficult to fix. It is theoretically possible to rebuild the index file from all the issued certificates and a current CRL: however there is no option to do this.

V2 CRL features like delta CRLs are not currently supported.

Although several requests can be input and handled at once it is only possible to include one SPKAC or self signed certificate.

BUGS

The use of an in memory text database can cause problems when large numbers of certificates are present because, as the name implies the database has to be kept in memory.

The **ca** command really needs rewriting or the required functionality exposed at either a command or interface level so a more friendly utility (perl script or GUI) can handle things properly. The scripts **CA.sh** and **CA.pl** help a little but not very much.

Any fields in a request that are not present in a policy are silently deleted. This does not happen if the **-preserveDN** option is used. To enforce the absence of the EMAIL field within the DN, as suggested by RFCs, regardless the contents of the request' subject the **-noemailDN** option can be used. The behaviour should be more friendly and configurable.

Cancelling some commands by refusing to certify a certificate can create an empty file.

WARNINGS

The **ca** command is quirky and at times downright unfriendly.

The **ca** utility was originally meant as an example of how to do things in a CA. It was not supposed to be used as a full blown CA itself: nevertheless some people are using it for this purpose.

The **ca** command is effectively a single user command: no locking is done on the various files and attempts to run more than one **ca** command on the same database can have unpredictable results.

The **copy_extensions** option should be used with caution. If care is not taken then it can be a security risk. For example if a certificate request contains a basicConstraints extension with CA:TRUE and the **copy_extensions** value is set to **copyall** and the user does not spot this when the certificate is displayed then this will hand the requestor a valid CA certificate.

This situation can be avoided by setting **copy_extensions** to **copy** and including basicConstraints with CA:FALSE in the configuration file. Then if the request contains a basicConstraints extension it will be ignored.

It is advisable to also include values for other extensions such as **keyUsage** to prevent a request supplying its own values.

Additional restrictions can be placed on the CA certificate itself. For example if the CA certificate has:

```
basicConstraints = CA:TRUE, pathlen:0
```

then even if a certificate is issued with CA:TRUE it will not be valid.

Name

ciphers — SSL cipher display and cipher list tool.

Synopsis

```
opensslciphers
[-v]
[-V]
[-ssl2]
[-ssl3]
[-tls1]
[cipherlist]
```

DESCRIPTION

The **ciphers** command converts textual OpenSSL cipher lists into ordered SSL cipher preference lists. It can be used as a test tool to determine the appropriate cipherlist.

COMMAND OPTIONS

-v

Verbose option. List ciphers with a complete description of protocol version (SSLv2 or SSLv3; the latter includes TLS), key exchange, authentication, encryption and mac algorithms used along with any key size restrictions and whether the algorithm is classed as an "export" cipher. Note that without the **-v** option, ciphers may seem to appear twice in a cipher list; this is when similar ciphers are available for SSL v2 and for SSL v3/TLS v1.

-V

Like **-v**, but include cipher suite codes in output (hex format).

-ssl3, **-tls1**

This lists ciphers compatible with any of SSLv3, TLSv1, TLSv1.1 or TLSv1.2.

-ssl2

Only include SSLv2 ciphers.

-h, **-?**

Print a brief usage message.

cipherlist

A cipher list to convert to a cipher preference list. If it is not included then the default cipher list will be used. The format is described below.

CIPHER LIST FORMAT

The cipher list consists of one or more *cipher strings* separated by colons. Commas or spaces are also acceptable separators but colons are normally used.

The actual cipher string can take several different forms.

It can consist of a single cipher suite such as **RC4-SHA**.

It can represent a list of cipher suites containing a certain algorithm, or cipher suites of a certain type. For example **SHA1** represents all ciphers suites using the digest algorithm SHA1 and **SSLv3** represents all SSL v3 algorithms.

Lists of cipher suites can be combined in a single cipher string using the **+** character. This is used as a logical **and** operation. For example **SHA1+DES** represents all cipher suites containing the SHA1 **and** the DES algorithms.

Each cipher string can be optionally preceded by the characters **!**, **-** or **+**.

If **!** is used then the ciphers are permanently deleted from the list. The ciphers deleted can never reappear in the list even if they are explicitly stated.

If **-** is used then the ciphers are deleted from the list, but some or all of the ciphers can be added again by later options.

If **+** is used then the ciphers are moved to the end of the list. This option doesn't add any new ciphers it just moves matching existing ones.

If none of these characters is present then the string is just interpreted as a list of ciphers to be appended to the current preference list. If the list includes any ciphers already present they will be ignored: that is they will not moved to the end of the list.

Additionally the cipher string **@STRENGTH** can be used at any point to sort the current cipher list in order of encryption algorithm key length.

CIPHER STRINGS

The following is a list of all permitted cipher strings and their meanings.

DEFAULT

The default cipher list. This is determined at compile time and is normally **ALL:!EXPORT:!LOW:!aNULL:!eNULL:!SSLv2**. When used, this must be the first cipherstring specified.

COMPLEMENTOFDEFAULT

the ciphers included in **ALL**, but not enabled by default. Currently this is **ADH** and **AECDH**. Note that this rule does not cover **eNULL**, which is not included by **ALL** (use **COMPLEMENTOFALL** if necessary).

ALL

all cipher suites except the **eNULL** ciphers which must be explicitly enabled; as of OpenSSL, the **ALL** cipher suites are reasonably ordered by default

COMPLEMENTOFALL

the cipher suites not enabled by **ALL**, currently being **eNULL**.

HIGH

"high" encryption cipher suites. This currently means those with key lengths larger than 128 bits, and some cipher suites with 128-bit keys.

MEDIUM

"medium" encryption cipher suites, currently some of those using 128 bit encryption.

LOW

Low strength encryption cipher suites, currently those using 64 or 56 bit encryption algorithms but excluding export cipher suites. As of OpenSSL 1.0.1s, these are disabled in default builds.

EXP, **EXPORT**

Export strength encryption algorithms. Including 40 and 56 bits algorithms. As of OpenSSL 1.0.1s, these are disabled in default builds.

EXPORT40

40-bit export encryption algorithms As of OpenSSL 1.0.1s, these are disabled in default builds.

EXPORT56

56-bit export encryption algorithms. In OpenSSL 0.9.8c and later the set of 56 bit export ciphers is empty unless OpenSSL has been explicitly configured with support for experimental ciphers. As of OpenSSL 1.0.1s, these are disabled in default builds.

eNULL, **NULL**

The "NULL" ciphers that is those offering no encryption. Because these offer no encryption at all and are a security risk they are not enabled via either the **DEFAULT** or **ALL** cipher strings. Be careful when building cipherlists out of lower-level primitives such as **kRSA** or **aECDSA** as these do overlap with the **eNULL** ciphers. When in doubt, include **!eNULL** in your cipherlist.

aNULL

The cipher suites offering no authentication. This is currently the anonymous DH algorithms and anonymous ECDH algorithms. These cipher suites are vulnerable to a "man in the middle" attack and so their use is normally discouraged. These are excluded from the **DEFAULT** ciphers, but included in the **ALL** ciphers. Be careful when building cipherlists out of lower-level primitives such as **kDHE** or **AES** as these do overlap with the **aNULL** ciphers. When in doubt, include **!aNULL** in your cipherlist.

kRSA, **RSA**

cipher suites using RSA key exchange.

kDHr, **kDHd**, **kDH**

cipher suites using DH key agreement and DH certificates signed by CAs with RSA and DSS keys or either respectively. Not implemented.

kEDH

cipher suites using ephemeral DH key agreement, including anonymous cipher suites.

EDH

cipher suites using authenticated ephemeral DH key agreement.

ADH

anonymous DH cipher suites, note that this does not include anonymous Elliptic Curve DH (ECDH) cipher suites.

DH

cipher suites using DH, including anonymous DH, ephemeral DH and fixed DH.

kECDHr, **kECDHe**, **kECDH**

cipher suites using fixed ECDH key agreement signed by CAs with RSA and ECDSA keys or either respectively.

kEECDH

cipher suites using ephemeral ECDH key agreement, including anonymous cipher suites.

EECDH

cipher suites using authenticated ephemeral ECDH key agreement.

AECDH

anonymous Elliptic Curve Diffie Hellman cipher suites.

ECDH

cipher suites using ECDH key exchange, including anonymous, ephemeral and fixed ECDH.

aRSA

cipher suites using RSA authentication, i.e. the certificates carry RSA keys.

aDSS, **DSS**

cipher suites using DSS authentication, i.e. the certificates carry DSS keys.

aDH

cipher suites effectively using DH authentication, i.e. the certificates carry DH keys. Not implemented.

aECDH

cipher suites effectively using ECDH authentication, i.e. the certificates carry ECDH keys.

aECDSA, **ECDSA**

cipher suites using ECDSA authentication, i.e. the certificates carry ECDSA keys.

kFZA, **aFZA**, **eFZA**, **FZA**

ciphers suites using FORTEZZA key exchange, authentication, encryption or all FORTEZZA algorithms. Not implemented.

TLSv1.2, **TLSv1**, **SSLv3**, **SSLv2**

TLS v1.2, TLS v1.0, SSL v3.0 or SSL v2.0 cipher suites respectively. Note: there are no ciphersuites specific to TLS v1.1.

AES128, **AES256**, **AES**

cipher suites using 128 bit AES, 256 bit AES or either 128 or 256 bit AES.

AESGCM

AES in Galois Counter Mode (GCM): these ciphersuites are only supported in TLS v1.2.

CAMELLIA128, **CAMELLIA256**, **CAMELLIA**

cipher suites using 128 bit CAMELLIA, 256 bit CAMELLIA or either 128 or 256 bit CAMELLIA.

3DES

cipher suites using triple DES.

DES

cipher suites using DES (not triple DES).

RC4

cipher suites using RC4.

RC2

cipher suites using RC2.

IDEA

cipher suites using IDEA.

SEED

cipher suites using SEED.

MD5

cipher suites using MD5.

SHA1, **SHA**

cipher suites using SHA1.

SHA256, **SHA384**

ciphersuites using SHA256 or SHA384.

aGOST

cipher suites using GOST R 34.10 (either 2001 or 94) for authenticaction (needs an engine supporting GOST algorithms).

aGOST01

cipher suites using GOST R 34.10-2001 authentication.

aGOST94

cipher suites using GOST R 34.10-94 authentication (note that R 34.10-94 standard has been expired so use GOST R 34.10-2001)

kGOST

cipher suites, using VKO 34.10 key exchange, specified in the RFC 4357.

GOST94

cipher suites, using HMAC based on GOST R 34.11-94.

GOST89MAC

cipher suites using GOST 28147-89 MAC **instead of** HMAC.

PSK

cipher suites using pre-shared keys (PSK).

CIPHER SUITE NAMES

The following lists give the SSL or TLS cipher suites names from the relevant specification and their OpenSSL equivalents. It should be noted, that several cipher suite names do not include the authentication used, e.g. DES-CBC3-SHA. In these cases, RSA authentication is used.

SSL v3.0 cipher suites.

```
SSL_RSA_WITH_NULL_MD5                   NULL-MD5
SSL_RSA_WITH_NULL_SHA                   NULL-SHA
SSL_RSA_EXPORT_WITH_RC4_40_MD5          EXP-RC4-MD5
SSL_RSA_WITH_RC4_128_MD5                RC4-MD5
SSL_RSA_WITH_RC4_128_SHA                RC4-SHA
SSL_RSA_EXPORT_WITH_RC2_CBC_40_MD5      EXP-RC2-CBC-MD5
SSL_RSA_WITH_IDEA_CBC_SHA               IDEA-CBC-SHA
SSL_RSA_EXPORT_WITH_DES40_CBC_SHA       EXP-DES-CBC-SHA
SSL_RSA_WITH_DES_CBC_SHA                DES-CBC-SHA

```

NOTES

The non-ephemeral DH modes are currently unimplemented in OpenSSL because there is no support for DH certificates.

Some compiled versions of OpenSSL may not include all the ciphers listed here because some ciphers were excluded at compile time.

EXAMPLES

Verbose listing of all OpenSSL ciphers including NULL ciphers:

```
openssl ciphers -v 'ALL:eNULL'
```

Include all ciphers except NULL and anonymous DH then sort by strength:

```
openssl ciphers -v 'ALL:!ADH:@STRENGTH'
```

Include all ciphers except ones with no encryption (eNULL) or no authentication (aNULL):

```
openssl ciphers -v 'ALL:!aNULL'
```

Include only 3DES ciphers and then place RSA ciphers last:

```
openssl ciphers -v '3DES:+RSA'
```

Include all RC4 ciphers but leave out those without authentication:

```
openssl ciphers -v 'RC4:!COMPLEMENTOFDEFAULT'
```

Include all chiphers with RSA authentication but leave out ciphers without encryption.

```
openssl ciphers -v 'RSA:!COMPLEMENTOFALL'
```

SEE ALSO

s_client(1), s_server(1), ssl(3)

HISTORY

The **COMPLENTOFALL** and **COMPLEMENTOFDEFAULT** selection options for cipherlist strings were added in OpenSSL 0.9.7. The **-V** option for the **ciphers** command was added in OpenSSL 1.0.0.

DESCRIPTION

The **cms** command handles S/MIME v3.1 mail. It can encrypt, decrypt, sign and verify, compress and uncompress S/MIME messages.

COMMAND OPTIONS

There are fourteen operation options that set the type of operation to be performed. The meaning of the other options varies according to the operation type.

-encrypt

encrypt mail for the given recipient certificates. Input file is the message to be encrypted. The output file is the encrypted mail in MIME format. The actual CMS type is <B>EnvelopedData<B>.

Note that no revocation check is done for the recipient cert, so if that key has been compromised, others may be able to decrypt the text.

-decrypt

decrypt mail using the supplied certificate and private key. Expects an encrypted mail message in MIME format for the input file. The decrypted mail is written to the output file.

-debug_decrypt

this option sets the **CMS_DEBUG_DECRYPT** flag. This option should be used with caution: see the notes section below.

-sign

sign mail using the supplied certificate and private key. Input file is the message to be signed. The signed message in MIME format is written to the output file.

-verify

verify signed mail. Expects a signed mail message on input and outputs the signed data. Both clear text and opaque signing is supported.

-cmsout

takes an input message and writes out a PEM encoded CMS structure.

-resign

resign a message: take an existing message and one or more new signers.

-data_create

Create a CMS **Data** type.

-data_out

Data type and output the content.

-digest_create

Create a CMS **DigestedData** type.

-digest_verify

Verify a CMS **DigestedData** type and output the content.

-compress

Create a CMS **CompressedData** type. OpenSSL must be compiled with **zlib** support for this option to work, otherwise it will output an error.

-uncompress

Uncompress a CMS **CompressedData** type and output the content. OpenSSL must be compiled with **zlib** support for this option to work, otherwise it will output an error.

-EncryptedData_encrypt

Encrypt content using supplied symmetric key and algorithm using a CMS **EncrytedData** type and output the content.

-sign_receipt

Generate and output a signed receipt for the supplied message. The input message **must** contain a signed receipt request. Functionality is otherwise similar to the **-sign** operation.

-verify_receipt receipt

Verify a signed receipt in filename **receipt**. The input message **must** contain the original receipt request. Functionality is otherwise similar to the **-verify** operation.

-in filename

the input message to be encrypted or signed or the message to be decrypted or verified.

-inform SMIME|PEM|DER

this specifies the input format for the CMS structure. The default is **SMIME** which reads an S/MIME format message. **PEM** and **DER** format change this to expect PEM and DER format CMS structures instead. This currently only affects the input format of the CMS structure, if no CMS structure is being input (for example with **-encrypt** or **-sign**) this option has no effect.

-rctform SMIME|PEM|DER

specify the format for a signed receipt for use with the **-receipt_verify** operation.

-out filename

the message text that has been decrypted or verified or the output MIME format message that has been signed or verified.

-outform SMIME|PEM|DER

this specifies the output format for the CMS structure. The default is **SMIME** which writes an S/MIME format message. **PEM** and **DER** format change this to write PEM and DER format CMS structures instead. This currently only affects the output format of the CMS structure, if no CMS structure is being output (for example with **-verify** or **-decrypt**) this option has no effect.

-stream -indef -noindef

the **-stream** and **-indef** options are equivalent and enable streaming I/O for encoding operations. This permits single pass processing of data without the need to hold the entire contents in memory, potentially supporting very large files. Streaming is automatically set for S/MIME signing with detached data if the output format is **SMIME** it is currently off by default for all other operations.

-noindef

disable streaming I/O where it would produce and indefinite length constructed encoding. This option currently has no effect. In future streaming will be enabled by default on all relevant operations and this option will disable it.

-content filename

This specifies a file containing the detached content, this is only useful with the **-verify** command. This is only usable if the CMS structure is using the detached signature form where the content is not included. This option will override any content if the input format is S/MIME and it uses the multipart/signed MIME content type.

-text

this option adds plain text (text/plain) MIME headers to the supplied message if encrypting or signing. If decrypting or verifying it strips off text headers: if the decrypted or verified message is not of MIME type text/plain then an error occurs.

-noout

for the **-cmsout** operation do not output the parsed CMS structure. This is useful when combined with the **-print** option or if the syntax of the CMS structure is being checked.

-print

for the **-cmsout** operation print out all fields of the CMS structure. This is mainly useful for testing purposes.

-CAfile file

a file containing trusted CA certificates, only used with **-verify**.

-CApath dir

a directory containing trusted CA certificates, only used with **-verify**. This directory must be a standard certificate directory: that is a hash of each subject name (using **x509 -hash**) should be linked to each certificate.

-md digest

digest algorithm to use when signing or resigning. If not present then the default digest algorithm for the signing key will be used (usually SHA1).

-[cipher]

the encryption algorithm to use. For example triple DES (168 bits) - **-des3** or 256 bit AES - **-aes256**. Any standard algorithm name (as used by the EVP_get_cipherbyname() function) can also be used preceded by a dash, for example **-aes_128_cbc**. See **enc** for a list of ciphers supported by your version of OpenSSL.

If not specified triple DES is used. Only used with **-encrypt** and **-EncryptedData_create** commands.

-nointern

when verifying a message normally certificates (if any) included in the message are searched for the signing certificate. With this option only the certificates specified in the **-certfile** option are used. The supplied certificates can still be used as untrusted CAs however.

-no_signer_cert_verify

do not verify the signers certificate of a signed message.

-nocerts

when signing a message the signer's certificate is normally included with this option it is excluded. This will reduce the size of the signed message but the verifier must have a copy of the signers certificate available locally (passed using the **-certfile** option for example).

-noattr

normally when a message is signed a set of attributes are included which include the signing time and supported symmetric algorithms. With this option they are not included.

-nosmimecap

exclude the list of supported algorithms from signed attributes, other options such as signing time and content type are still included.

-binary

normally the input message is converted to "canonical" format which is effectively using CR and LF as end of line: as required by the S/MIME specification. When this option is present no translation occurs. This is useful when handling binary data which may not be in MIME format.

-nodetach

when signing a message use opaque signing: this form is more resistant to translation by mail relays but it cannot be read by mail agents that do not support S/MIME. Without this option cleartext signing with the MIME type multipart/signed is used.

-certfile file

allows additional certificates to be specified. When signing these will be included with the message. When verifying these will be searched for the signers certificates. The certificates should be in PEM format.

-certsout file

any certificates contained in the message are written to **file**.

-signer file

a signing certificate when signing or resigning a message, this option can be used multiple times if more than one signer is required. If a message is being verified then the signers certificates will be written to this file if the verification was successful.

-recip file

the recipients certificate when decrypting a message. This certificate must match one of the recipients of the message or an error occurs.

-keyid

use subject key identifier to identify certificates instead of issuer name and serial number. The supplied certificate **must** include a subject key identifier extension. Supported by **-sign** and **-encrypt** options.

-receipt_request_all -receipt_request_first

for **-sign** option include a signed receipt request. Indicate requests should be provided by all receipient or first tier recipients (those mailed directly and not from a mailing list). Ignored it **-receipt_request_from** is included.

-receipt_request_from emailaddress

for **-sign** option include a signed receipt request. Add an explicit email address where receipts should be supplied.

-receipt_request_to emailaddress

Add an explicit email address where signed receipts should be sent to. This option **must** but supplied if a signed receipt it requested.

-receipt_request_print

For the **-verify** operation print out the contents of any signed receipt requests.

-secretkey key

specify symmetric key to use. The key must be supplied in hex format and be consistent with the algorithm used. Supported by the **-EncryptedData_encrypt -EncrryptedData_decrypt**, **-encrypt** and **-decrypt** options. When used with **-encrypt** or **-decrypt** the supplied key is used to wrap or unwrap the content encryption key using an AES key in the **KEKRecipientInfo** type.

-secretkeyid id

the key identifier for the supplied symmetric key for **KEKRecipientInfo** type. This option **must** be present if the **-secretkey** option is used with **-encrypt**. With **-decrypt** operations the **id** is used to locate the relevant key if it is not supplied then an attempt is used to decrypt any **KEKRecipientInfo** structures.

-econtent_type type

set the encapsulated content type to **type** if not supplied the **Data** type is used. The **type** argument can be any valid OID name in either text or numerical format.

-inkey file

the private key to use when signing or decrypting. This must match the corresponding certificate. If this option is not specified then the private key must be included in the certificate file specified with the **-recip** or **-signer** file. When signing this option can be used multiple times to specify successive keys.

-passin arg

the private key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

cert.pem…

one or more certificates of message recipients: used when encrypting a message.

-to, -from, -subject

the relevant mail headers. These are included outside the signed portion of a message so they may be included manually. If signing then many S/MIME mail clients check the signers certificate's email address matches that specified in the From: address.

-purpose, -ignore_critical, -issuer_checks, -crl_check, -crl_check_all, -policy_check, -extended_crl, -x509_strict, -policy -check_ss_sig -no_alt_chains

Set various certificate chain valiadition option. See the **verify** manual page for details.

NOTES

The MIME message must be sent without any blank lines between the headers and the output. Some mail programs will automatically add a blank line. Piping the mail directly to sendmail is one way to achieve the correct format.

The supplied message to be signed or encrypted must include the necessary MIME headers or many S/MIME clients wont display it properly (if at all). You can use the **-text** option to automatically add plain text headers.

A "signed and encrypted" message is one where a signed message is then encrypted. This can be produced by encrypting an already signed message: see the examples section.

This version of the program only allows one signer per message but it will verify multiple signers on received messages. Some S/MIME clients choke if a message contains multiple signers. It is possible to sign messages "in parallel" by signing an already signed message.

The options **-encrypt** and **-decrypt** reflect common usage in S/MIME clients. Strictly speaking these process CMS enveloped data: CMS encrypted data is used for other purposes.

The **-resign** option uses an existing message digest when adding a new signer. This means that attributes must be present in at least one existing signer using the same message digest or this operation will fail.

The **-stream** and **-indef** options enable experimental streaming I/O support. As a result the encoding is BER using indefinite length constructed encoding and no longer DER. Streaming is supported for the **-encrypt** operation and the **-sign** operation if the content is not detached.

Streaming is always used for the **-sign** operation with detached data but since the content is no longer part of the CMS structure the encoding remains DER.

If the **-decrypt** option is used without a recipient certificate then an attempt is made to locate the recipient by trying each potential recipient in turn using the supplied private key. To thwart the MMA attack (Bleichenbacher's attack on PKCS #1 v1.5 RSA padding) all recipients are tried whether they succeed or not and if no recipients match the message is "decrypted" using a random key which will typically output garbage. The **-debug_decrypt** option can be used to disable the MMA attack protection and return an error if no recipient can be found: this option should be used with caution. For a fuller description see CMS_decrypt(3)).

EXIT CODES

0 the operation was completely successfully.

1 an error occurred parsing the command options.

2 one of the input files could not be read.

3 an error occurred creating the CMS file or when reading the MIME message.

4 an error occurred decrypting or verifying the message.

5 the message was verified correctly but an error occurred writing out the signers certificates.

COMPATIBILITY WITH PKCS#7 format.

The **smime** utility can only process the older **PKCS#7** format. The **cms** utility supports Cryptographic Message Syntax format. Use of some features will result in messages which cannot be processed by applications which only support the older format. These are detailed below.

The use of the **-keyid** option with **-sign** or **-encrypt**.

The **-outform PEM** option uses different headers.

The **-compress** option.

The **-secretkey** option when used with **-encrypt**.

Additionally the **-EncryptedData_create** and **-data_create** type cannot be processed by the older **smime** command.

EXAMPLES

Create a cleartext signed message:

```
openssl cms -sign -in message.txt -text -out mail.msg \
       -signer mycert.pem
```

Create an opaque signed message

```
openssl cms -sign -in message.txt -text -out mail.msg -nodetach \
       -signer mycert.pem
```

Create a signed message, include some additional certificates and read the private key from another file:

```
openssl cms -sign -in in.txt -text -out mail.msg \
       -signer mycert.pem -inkey mykey.pem -certfile mycerts.pem
```

Create a signed message with two signers, use key identifier:

```
openssl cms -sign -in message.txt -text -out mail.msg \
       -signer mycert.pem -signer othercert.pem -keyid
```

Send a signed message under Unix directly to sendmail, including headers:

```
openssl cms -sign -in in.txt -text -signer mycert.pem \
       -from steve@openssl.org -to someone@somewhere \
       -subject "Signed message" | sendmail someone@somewhere
```

Verify a message and extract the signer's certificate if successful:

```
openssl cms -verify -in mail.msg -signer user.pem -out signedtext.txt
```

Send encrypted mail using triple DES:

```
openssl cms -encrypt -in in.txt -from steve@openssl.org \
       -to someone@somewhere -subject "Encrypted message" \
       -des3 user.pem -out mail.msg
```

Sign and encrypt mail:

```
openssl cms -sign -in ml.txt -signer my.pem -text \
       | openssl cms -encrypt -out mail.msg \
       -from steve@openssl.org -to someone@somewhere \
       -subject "Signed and Encrypted message" -des3 user.pem
```

Note: the encryption command does not include the **-text** option because the message being encrypted already has MIME headers.

Decrypt mail:

```
openssl cms -decrypt -in mail.msg -recip mycert.pem -inkey key.pem
```

The output from Netscape form signing is a PKCS#7 structure with the detached signature format. You can use this program to verify the signature by line wrapping the base64 encoded structure and surrounding it with:

```
-----BEGIN PKCS7-----
-----END PKCS7-----
```

and using the command,

```
openssl cms -verify -inform PEM -in signature.pem -content content.txt
```

alternatively you can base64 decode the signature and use

```
openssl cms -verify -inform DER -in signature.der -content content.txt
```

Create an encrypted message using 128 bit Camellia:

```
openssl cms -encrypt -in plain.txt -camellia128 -out mail.msg cert.pem
```

Add a signer to an existing message:

```
openssl cms -resign -in mail.msg -signer newsign.pem -out mail2.msg
```

BUGS

The MIME parser isn't very clever: it seems to handle most messages that I've thrown at it but it may choke on others.

The code currently will only write out the signer's certificate to a file: if the signer has a separate encryption certificate this must be manually extracted. There should be some heuristic that determines the correct encryption certificate.

Ideally a database should be maintained of a certificates for each email address.

The code doesn't currently take note of the permitted symmetric encryption algorithms as supplied in the SMIMECapabilities signed attribute. this means the user has to manually include the correct encryption algorithm. It should store the list of permitted ciphers in a database and only use those.

No revocation checking is done on the signer's certificate.

HISTORY

The use of multiple **-signer** options and the **-resign** command were first added in OpenSSL 1.0.0

The -no_alt_chains options was first added to OpenSSL 1.0.1n and 1.0.2b.

Name

crl — CRL utility

Synopsis

```
opensslcrl
[-inform PEM|DER]
[-outform PEM|DER]
[-text]
[-in filename]
[-out filename]
[-nameopt option]
[-noout]
[-hash]
[-issuer]
[-lastupdate]
[-nextupdate]
[-CAfile file]
[-CApath dir]
```

DESCRIPTION

The **crl** command processes CRL files in DER or PEM format.

COMMAND OPTIONS

-inform DER|PEM

This specifies the input format. **DER** format is DER encoded CRL structure. **PEM** (the default) is a base64 encoded version of the DER form with header and footer lines.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read from or standard input if this option is not specified.

-out filename

specifies the output filename to write to or standard output by default.

-text

print out the CRL in text form.

-nameopt option

option which determines how the subject or issuer names are displayed. See the description of **-nameopt** in x509(1).

-noout

don't output the encoded version of the CRL.

-hash

output a hash of the issuer name. This can be use to lookup CRLs in a directory by issuer name.

-hash_old

outputs the "hash" of the CRL issuer name using the older algorithm as used by OpenSSL versions before 1.0.0.

-issuer

output the issuer name.

-lastupdate

output the lastUpdate field.

-nextupdate

output the nextUpdate field.

-CAfile file

verify the signature on a CRL by looking up the issuing certificate in **file**

-CApath dir

verify the signature on a CRL by looking up the issuing certificate in **dir**. This directory must be a standard certificate directory: that is a hash of each subject name (using **x509 -hash**) should be linked to each certificate.

NOTES

The PEM CRL format uses the header and footer lines:

```
-----BEGIN X509 CRL-----
-----END X509 CRL-----
```

EXAMPLES

Convert a CRL file from PEM to DER:

```
openssl crl -in crl.pem -outform DER -out crl.der
```

Output the text form of a DER encoded certificate:

```
openssl crl -in crl.der -text -noout
```

BUGS

Ideally it should be possible to create a CRL using appropriate options and files too.

SEE ALSO

crl2pkcs7(1), ca(1), x509(1)

Name

crl2pkcs7 — Create a PKCS#7 structure from a CRL and certificates.

Synopsis

```
opensslcrl2pkcs7
[-inform PEM|DER]
[-outform PEM|DER]
[-in filename]
[-out filename]
[-certfile filename]
[-nocrl]
```

DESCRIPTION

The **crl2pkcs7** command takes an optional CRL and one or more certificates and converts them into a PKCS#7 degenerate "certificates only" structure.

COMMAND OPTIONS

-inform DER|PEM

This specifies the CRL input format. **DER** format is DER encoded CRL structure.**PEM** (the default) is a base64 encoded version of the DER form with header and footer lines.

-outform DER|PEM

This specifies the PKCS#7 structure output format. **DER** format is DER encoded PKCS#7 structure.**PEM** (the default) is a base64 encoded version of the DER form with header and footer lines.

-in filename

This specifies the input filename to read a CRL from or standard input if this option is not specified.

-out filename

specifies the output filename to write the PKCS#7 structure to or standard output by default.

-certfile filename

specifies a filename containing one or more certificates in **PEM** format. All certificates in the file will be added to the PKCS#7 structure. This option can be used more than once to read certificates form multiple files.

-nocrl

normally a CRL is included in the output file. With this option no CRL is included in the output file and a CRL is not read from the input file.

EXAMPLES

Create a PKCS#7 structure from a certificate and CRL:

```
openssl crl2pkcs7 -in crl.pem -certfile cert.pem -out p7.pem
```

Creates a PKCS#7 structure in DER format with no CRL from several different certificates:

```
openssl crl2pkcs7 -nocrl -certfile newcert.pem
```

```
       -certfile demoCA/cacert.pem -outform DER -out p7.der
```

NOTES

The output file is a PKCS#7 signed data structure containing no signers and just certificates and an optional CRL.

This utility can be used to send certificates and CAs to Netscape as part of the certificate enrollment process. This involves sending the DER encoded output as MIME type application/x-x509-user-cert.

The **PEM** encoded form with the header and footer lines removed can be used to install user certificates and CAs in MSIE using the Xenroll control.

[-out filename]
[-sign filename]
[-keyform arg]
[-passin arg]
[-verify filename]
[-prverify filename]
[-signature filename]
[-hmac key]
[-non-fips-allow]
[-fips-fingerprint]
[file…]
```

```
openssl
[digest]
[…]
```

DESCRIPTION

The digest functions output the message digest of a supplied file or files in hexadecimal. The digest functions also generate and verify digital signatures using message digests.

OPTIONS

-c

print out the digest in two digit groups separated by colons, only relevant if **hex** format output is used.

-d

print out BIO debugging information.

-hex

digest is to be output as a hex dump. This is the default case for a "normal" digest as opposed to a digital signature. See NOTES below for digital signatures using **-hex**.

-binary

output the digest or signature in binary form.

-r

output the digest in the "coreutils" format used by programs like **sha1sum**.

-non-fips-allow

Allow use of non FIPS digest when in FIPS mode. This has no effect when not in FIPS mode.

-out filename

filename to output to, or standard output by default.

-sign filename

digitally sign the digest using the private key in "filename".

-keyform arg

Specifies the key format to sign digest with. The DER, PEM, P12, and ENGINE formats are supported.

-engine id

Use engine **id** for operations (including private key storage). This engine is not used as source for digest algorithms, unless it is also specified in the configuration file.

-sigopt nm:v

Pass options to the signature algorithm during sign or verify operations. Names and values of these options are algorithm-specific.

-passin arg

the private key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-verify filename

verify the signature using the the public key in "filename". The output is either "Verification OK" or "Verification Failure".

-prverify filename

verify the signature using the the private key in "filename".

-signature filename

the actual signature to verify.

-hmac key

create a hashed MAC using "key".

-mac alg

create MAC (keyed Message Authentication Code). The most popular MAC algorithm is HMAC (hash-based MAC), but there are other MAC algorithms which are not based on hash, for instance **gost-mac** algorithm, supported by **ccgost** engine. MAC keys and other options should be set via **-macopt** parameter.

-macopt nm:v

Passes options to MAC algorithm, specified by **-mac** key. Following options are supported by both by **HMAC** and **gost-mac**:

key:string

Specifies MAC key as alphnumeric string (use if key contain printable characters only). String length must conform to any restrictions of the MAC algorithm for example exactly 32 chars for gost-mac.

hexkey:string

Specifies MAC key in hexadecimal form (two hex digits per byte). Key length must conform to any restrictions of the MAC algorithm for example exactly 32 chars for gost-mac.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-non-fips-allow

enable use of non-FIPS algorithms such as MD5 even in FIPS mode.

-fips-fingerprint

compute HMAC using a specific key for certain OpenSSL-FIPS operations.

file…

file or files to digest. If no files are specified then standard input is used.

EXAMPLES

To create a hex-encoded message digest of a file: openssl dgst -md5 -hex file.txt

To sign a file using SHA-256 with binary file output: openssl dgst -sha256 -sign privatekey.pem -out signature.sign file.txt

To verify a signature: openssl dgst -sha256 -verify publickey.pem \ -signature signature.sign \ file.txt

NOTES

The digest of choice for all new applications is SHA1. Other digests are however still widely used.

When signing a file, **dgst** will automatically determine the algorithm (RSA, ECC, etc) to use for signing based on the private key's ASN.1 info. When verifying signatures, it only handles the RSA, DSA, or ECDSA signature itself, not the related data to identify the signer and algorithm used in formats such as x.509, CMS, and S/MIME.

A source of random numbers is required for certain signing algorithms, in particular ECDSA and DSA.

The signing and verify options should only be used if a single file is being signed or verified.

Hex signatures cannot be verified using **openssl**. Instead, use "xxd -r" or similar program to transform the hex signature into a binary signature prior to verification.

Name

dhparam — DH parameter manipulation and generation

Synopsis

```
openssl dhparam
[-inform DER|PEM]
[-outform DER|PEM]
[-in filename]
[-out filename]
[-dsaparam]
[-check]
[-noout]
[-text]
[-C]
[-2]
[-5]
[-rand file(s)]
[-engine id]
[numbits]
```

DESCRIPTION

This command is used to manipulate DH parameter files.

OPTIONS

-inform DER|PEM

This specifies the input format. The **DER** option uses an ASN1 DER encoded form compatible with the PKCS#3 DHparameter structure. The PEM form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in *filename*

This specifies the input filename to read parameters from or standard input if this option is not specified.

-out *filename*

This specifies the output filename parameters to. Standard output is used if this option is not present. The output filename should **not** be the same as the input filename.

-dsaparam

If this option is used, DSA rather than DH parameters are read or created; they are converted to DH format. Otherwise, "strong" primes (such that (p-1)/2 is also prime) will be used for DH parameter generation.

DH parameter generation with the **-dsaparam** option is much faster, and the recommended exponent length is shorter, which makes DH key exchange more efficient. Beware that with such DSA-style DH parameters, a fresh DH key should be created for each use to avoid small-subgroup attacks that may be possible otherwise.

-check

check if the parameters are valid primes and generator.

-2, **-5**

The generator to use, either 2 or 5. If present then the input file is ignored and parameters are generated instead. If not present but **numbits** is present, parameters are generated with the default generator 2.

-rand *file(s)*

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

numbits

this option specifies that a parameter set should be generated of size *numbits*. It must be the last option. If this option is present then the input file is ignored and parameters are generated instead. If this option is not present but a generator (**-2** or **-5**) is present, parameters are generated with a default length of 2048 bits.

-noout

this option inhibits the output of the encoded version of the parameters.

-text

this option prints out the DH parameters in human readable form.

-C

this option converts the parameters into C code. The parameters can then be loaded by calling the **get_dh***numbits***()** function.

-engine id

specifying an engine (by its unique **id** string) will cause **dhparam** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

WARNINGS

The program **dhparam** combines the functionality of the programs **dh** and **gendh** in previous versions of OpenSSL and SSLeay. The **dh** and **gendh** programs are retained for now but may have different purposes in future versions of OpenSSL.

NOTES

PEM format DH parameters use the header and footer lines:

```
-----BEGIN DH PARAMETERS-----
-----END DH PARAMETERS-----
```

OpenSSL currently only supports the older PKCS#3 DH, not the newer X9.42 DH.

This program manipulates DH parameters not keys.

BUGS

There should be a way to generate and manipulate DH keys.

SEE ALSO

dsaparam(1)

HISTORY

The **dhparam** command was added in OpenSSL 0.9.5. The **-dsaparam** option was added in OpenSSL 0.9.6.

Name

dsa — DSA key processing

Synopsis

```
openssldsa
[-inform PEM|DER]
[-outform PEM|DER]
[-in filename]
[-passin arg]
[-out filename]
[-passout arg]
[-aes128]
[-aes192]
[-aes256]
[-camellia128]
[-camellia192]
[-camellia256]
[-des]
[-des3]
[-idea]
[-text]
[-noout]
[-modulus]
[-pubin]
[-pubout]
[-engine id]
```

DESCRIPTION

The **dsa** command processes DSA keys. They can be converted between various forms and their components printed out. **Note** This command uses the traditional SSLeay compatible format for private key encryption: newer applications should use the more secure PKCS#8 format using the **pkcs8**

COMMAND OPTIONS

-inform DER|PEM

This specifies the input format. The **DER** option with a private key uses an ASN1 DER encoded form of an ASN.1 SEQUENCE consisting of the values of version (currently zero), p, q, g, the public and private key components respectively as ASN.1 INTEGERs. When used with a public key it uses a SubjectPublicKeyInfo structure: it is an error if the key is not DSA.

The **PEM** form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines. In the case of a private key PKCS#8 format is also accepted.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read a key from or standard input if this option is not specified. If the key is encrypted a pass phrase will be prompted for.

-passin arg

the input file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-out filename

This specifies the output filename to write a key to or standard output by is not specified. If any encryption options are set then a pass phrase will be prompted for. The output filename should **not** be the same as the input filename.

-passout arg

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-aes128|-aes192|-aes256|-camellia128|-camellia192|-camellia256|-des|-des3|-idea

These options encrypt the private key with the specified cipher before outputting it. A pass phrase is prompted for. If none of these options is specified the key is written in plain text. This means that using the **dsa** utility to read in an encrypted key with no encryption option can be used to remove the pass phrase from a key, or by setting the encryption options it can be use to add or change the pass phrase. These options can only be used with PEM format output files.

-text

prints out the public, private key components and parameters.

-noout

this option prevents output of the encoded version of the key.

-modulus

this option prints out the value of the public key component of the key.

-pubin

by default a private key is read from the input file: with this option a public key is read instead.

-pubout

by default a private key is output. With this option a public key will be output instead. This option is automatically set if the input is a public key.

-engine id

specifying an engine (by its unique **id** string) will cause **dsa** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

NOTES

The PEM private key format uses the header and footer lines:

```
-----BEGIN DSA PRIVATE KEY-----
-----END DSA PRIVATE KEY-----
```

The PEM public key format uses the header and footer lines:

```
-----BEGIN PUBLIC KEY-----
-----END PUBLIC KEY-----
```

EXAMPLES

To remove the pass phrase on a DSA private key:

```
openssl dsa -in key.pem -out keyout.pem
```

To encrypt a private key using triple DES:

```
openssl dsa -in key.pem -des3 -out keyout.pem
```

To convert a private key from PEM to DER format:

```
openssl dsa -in key.pem -outform DER -out keyout.der
```

To print out the components of a private key to standard output:

```
openssl dsa -in key.pem -text -noout
```

To just output the public part of a private key:

```
openssl dsa -in key.pem -pubout -out pubkey.pem
```

SEE ALSO

dsaparam(1), gendsa(1), rsa(1), genrsa(1)

Name

dsaparam — DSA parameter manipulation and generation

Synopsis

```
openssl dsaparam
[-inform DER|PEM]
[-outform DER|PEM]
[-in filename]
[-out filename]
[-noout]
[-text]
[-C]
[-rand file(s)]
[-genkey]
[-engine id]
[numbits]
```

DESCRIPTION

This command is used to manipulate or generate DSA parameter files.

OPTIONS

-inform DER|PEM

This specifies the input format. The **DER** option uses an ASN1 DER encoded form compatible with RFC2459 (PKIX) DSS-Parms that is a SEQUENCE consisting of p, q and g respectively. The PEM form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read parameters from or standard input if this option is not specified. If the **numbits** parameter is included then this option will be ignored.

-out filename

This specifies the output filename parameters to. Standard output is used if this option is not present. The output filename should **not** be the same as the input filename.

-noout

this option inhibits the output of the encoded version of the parameters.

-text

this option prints out the DSA parameters in human readable form.

-C

this option converts the parameters into C code. The parameters can then be loaded by calling the **get_dsaXXX()** function.

-genkey

this option will generate a DSA either using the specified or generated parameters.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

numbits

this option specifies that a parameter set should be generated of size **numbits**. It must be the last option. If this option is included then the input file (if any) is ignored.

-engine id

specifying an engine (by its unique **id** string) will cause **dsaparam** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

NOTES

PEM format DSA parameters use the header and footer lines:

```
-----BEGIN DSA PARAMETERS-----
-----END DSA PARAMETERS-----
```

DSA parameter generation is a slow process and as a result the same set of DSA parameters is often used to generate several distinct keys.

Name

ec — EC key processing

Synopsis

```
opensslec
[-inform PEM|DER]
[-outform PEM|DER]
[-in filename]
[-passin arg]
[-out filename]
[-passout arg]
[-des]
[-des3]
[-idea]
[-text]
[-noout]
[-param_out]
[-pubin]
[-pubout]
[-conv_form arg]
[-param_enc arg]
[-engine id]
```

DESCRIPTION

The **ec** command processes EC keys. They can be converted between various forms and their components printed out. **Note** OpenSSL uses the private key format specified in 'SEC 1: Elliptic Curve Cryptography' (http://www.secg.org/). To convert a OpenSSL EC private key into the PKCS#8 private key format use the **pkcs8** command.

COMMAND OPTIONS

-inform DER|PEM

This specifies the input format. The **DER** option with a private key uses an ASN.1 DER encoded SEC1 private key. When used with a public key it uses the SubjectPublicKeyInfo structure as specified in RFC 3280. The **PEM** form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines. In the case of a private key PKCS#8 format is also accepted.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read a key from or standard input if this option is not specified. If the key is encrypted a pass phrase will be prompted for.

-passin arg

the input file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-out filename

This specifies the output filename to write a key to or standard output by is not specified. If any encryption options are set then a pass phrase will be prompted for. The output filename should **not** be the same as the input filename.

-passout arg

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-des|-des3|-idea

These options encrypt the private key with the DES, triple DES, IDEA or any other cipher supported by OpenSSL before outputting it. A pass phrase is prompted for. If none of these options is specified the key is written in plain text. This means that using the **ec** utility to read in an encrypted key with no encryption option can be used to remove the pass phrase from a key, or by setting the encryption options it can be use to add or change the pass phrase. These options can only be used with PEM format output files.

-text

prints out the public, private key components and parameters.

-noout

this option prevents output of the encoded version of the key.

-modulus

this option prints out the value of the public key component of the key.

-pubin

by default a private key is read from the input file: with this option a public key is read instead.

-pubout

by default a private key is output. With this option a public key will be output instead. This option is automatically set if the input is a public key.

-conv_form

This specifies how the points on the elliptic curve are converted into octet strings. Possible values are: **compressed** (the default value), **uncompressed** and **hybrid**. For more information regarding the point conversion forms please read the X9.62 standard. **Note** Due to patent issues the **compressed** option is disabled by default for binary curves and can be enabled by defining the preprocessor macro **OPENSSL_EC_BIN_PT_COMP** at compile time.

-param_enc arg

This specifies how the elliptic curve parameters are encoded. Possible value are: **named_curve**, i.e. the ec parameters are specified by a OID, or **explicit** where the ec parameters are explicitly given (see RFC 3279 for the definition of the EC parameters structures). The default value is **named_curve**. **Note** the **implicitlyCA** alternative ,as specified in RFC 3279, is currently not implemented in OpenSSL.

-engine id

specifying an engine (by its unique **id** string) will cause **ec** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

NOTES

The PEM private key format uses the header and footer lines:

```
-----BEGIN EC PRIVATE KEY-----
```

```
-----END EC PRIVATE KEY-----
```

The PEM public key format uses the header and footer lines:

```
-----BEGIN PUBLIC KEY-----
-----END PUBLIC KEY-----
```

EXAMPLES

To encrypt a private key using triple DES:

```
openssl ec -in key.pem -des3 -out keyout.pem
```

To convert a private key from PEM to DER format:

```
openssl ec -in key.pem -outform DER -out keyout.der
```

To print out the components of a private key to standard output:

```
openssl ec -in key.pem -text -noout
```

To just output the public part of a private key:

```
openssl ec -in key.pem -pubout -out pubkey.pem
```

To change the parameters encoding to **explicit**:

```
openssl ec -in key.pem -param_enc explicit -out keyout.pem
```

To change the point conversion form to **compressed**:

```
openssl ec -in key.pem -conv_form compressed -out keyout.pem
```

SEE ALSO

ecparam(1), dsa(1), rsa(1)

HISTORY

The ec command was first introduced in OpenSSL 0.9.8.

AUTHOR

Nils Larsch for the OpenSSL project (http://www.openssl.org).

Name

ecparam — EC parameter manipulation and generation

Synopsis

```
openssl ecparam
[-inform DER|PEM]
[-outform DER|PEM]
[-in filename]
[-out filename]
[-noout]
[-text]
[-C]
[-check]
[-name arg]
[-list_curves]
[-conv_form arg]
[-param_enc arg]
[-no_seed]
[-rand file(s)]
[-genkey]
[-engine id]
```

DESCRIPTION

This command is used to manipulate or generate EC parameter files.

OPTIONS

-inform DER|PEM

This specifies the input format. The **DER** option uses an ASN.1 DER encoded form compatible with RFC 3279 EcpkParameters. The PEM form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read parameters from or standard input if this option is not specified.

-out filename

This specifies the output filename parameters to. Standard output is used if this option is not present. The output filename should **not** be the same as the input filename.

-noout

This option inhibits the output of the encoded version of the parameters.

-text

This option prints out the EC parameters in human readable form.

-C

This option converts the EC parameters into C code. The parameters can then be loaded by calling the **get_ec_group_XXX()** function.

-check

Validate the elliptic curve parameters.

-name arg

Use the EC parameters with the specified 'short' name. Use **-list_curves** to get a list of all currently implemented EC parameters.

-list_curves

If this options is specified **ecparam** will print out a list of all currently implemented EC parameters names and exit.

-conv_form

This specifies how the points on the elliptic curve are converted into octet strings. Possible values are: **compressed** (the default value), **uncompressed** and **hybrid**. For more information regarding the point conversion forms please read the X9.62 standard. **Note** Due to patent issues the **compressed** option is disabled by default for binary curves and can be enabled by defining the preprocessor macro **OPENSSL_EC_BIN_PT_COMP** at compile time.

-param_enc arg

This specifies how the elliptic curve parameters are encoded. Possible value are: **named_curve**, i.e. the ec parameters are specified by a OID, or **explicit** where the ec parameters are explicitly given (see RFC 3279 for the definition of the EC parameters structures). The default value is **named_curve**. **Note** the **implicitlyCA** alternative ,as specified in RFC 3279, is currently not implemented in OpenSSL.

-no_seed

This option inhibits that the 'seed' for the parameter generation is included in the ECParameters structure (see RFC 3279).

-genkey

This option will generate a EC private key using the specified parameters.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-engine id

specifying an engine (by its unique **id** string) will cause **ecparam** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

NOTES

PEM format EC parameters use the header and footer lines:

```
-----BEGIN EC PARAMETERS-----
-----END EC PARAMETERS-----
```

OpenSSL is currently not able to generate new groups and therefore **ecparam** can only create EC parameters from known (named) curves.

EXAMPLES

To create EC parameters with the group 'prime192v1':

```
openssl ecparam -out ec_param.pem -name prime192v1
```

To create EC parameters with explicit parameters:

```
openssl ecparam -out ec_param.pem -name prime192v1 -param_enc explicit
```

To validate given EC parameters:

```
openssl ecparam -in ec_param.pem -check
```

To create EC parameters and a private key:

```
openssl ecparam -out ec_key.pem -name prime192v1 -genkey
```

To change the point encoding to 'compressed':

```
openssl ecparam -in ec_in.pem -out ec_out.pem -conv_form compressed
```

To print out the EC parameters to standard output:

```
openssl ecparam -in ec_param.pem -noout -text
```

Name

enc — symmetric cipher routines

Synopsis

```
openssl enc -ciphername
[-in filename]
[-out filename]
[-pass arg]
[-e]
[-d]
[-a/-base64]
[-A]
[-k password]
[-kfile filename]
[-K key]
[-iv IV]
[-S salt]
[-salt]
[-nosalt]
[-z]
[-md]
[-p]
[-P]
[-bufsize number]
[-nopad]
[-debug]
[-none]
[-engine id]
```

DESCRIPTION

The symmetric cipher commands allow data to be encrypted or decrypted using various block and stream ciphers using keys based on passwords or explicitly provided. Base64 encoding or decoding can also be performed either by itself or in addition to the encryption or decryption.

OPTIONS

-in filename

the input filename, standard input by default.

-out filename

the output filename, standard output by default.

-pass arg

the password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-salt

use a salt in the key derivation routines. This is the default.

-nosalt

don't use a salt in the key derivation routines. This option **SHOULD NOT** be used except for test purposes or compatibility with ancient versions of OpenSSL and SSLeay.

-e

encrypt the input data: this is the default.

-d

decrypt the input data.

-a

base64 process the data. This means that if encryption is taking place the data is base64 encoded after encryption. If decryption is set then the input data is base64 decoded before being decrypted.

-base64

same as **-a**

-A

if the **-a** option is set then base64 process the data on one line.

-k password

the password to derive the key from. This is for compatibility with previous versions of OpenSSL. Superseded by the **-pass** argument.

-kfile filename

read the password to derive the key from the first line of **filename**. This is for compatibility with previous versions of OpenSSL. Superseded by the **-pass** argument.

-nosalt

do not use a salt

-salt

use salt (randomly generated or provide with **-S** option) when encrypting (this is the default).

-S salt

the actual salt to use: this must be represented as a string of hex digits.

-K key

the actual key to use: this must be represented as a string comprised only of hex digits. If only the key is specified, the IV must additionally specified using the **-iv** option. When both a key and a password are specified, the key given with the **-K** option will be used and the IV generated from the password will be taken. It probably does not make much sense to specify both key and password.

-iv IV

the actual IV to use: this must be represented as a string comprised only of hex digits. When only the key is specified using the **-K** option, the IV must explicitly be defined. When a password is being specified using one of the other options, the IV is generated from this password.

-p

print out the key and IV used.

-P

print out the key and IV used then immediately exit: don't do any encryption or decryption.

-bufsize number

set the buffer size for I/O

-nopad

disable standard block padding

-debug

debug the BIOs used for I/O.

-z

Compress or decompress clear text using zlib before encryption or after decryption. This option exists only if OpenSSL with compiled with zlib or zlib-dynamic option.

-none

Use NULL cipher (no encryption or decryption of input).

NOTES

The program can be called either as **openssl ciphername** or **openssl enc -ciphername**. But the first form doesn't work with engine-provided ciphers, because this form is processed before the configuration file is read and any ENGINEs loaded.

Engines which provide entirely new encryption algorithms (such as ccgost engine which provides gost89 algorithm) should be configured in the configuration file. Engines, specified in the command line using -engine options can only be used for hadrware-assisted implementations of ciphers, which are supported by OpenSSL core or other engine, specified in the configuration file.

When enc command lists supported ciphers, ciphers provided by engines, specified in the configuration files are listed too.

A password will be prompted for to derive the key and IV if necessary.

The **-salt** option should **ALWAYS** be used if the key is being derived from a password unless you want compatibility with previous versions of OpenSSL and SSLeay.

Without the **-salt** option it is possible to perform efficient dictionary attacks on the password and to attack stream cipher encrypted data. The reason for this is that without the salt the same password always generates the same encryption key. When the salt is being used the first eight bytes of the encrypted data are reserved for the salt: it is generated at random when encrypting a file and read from the encrypted file when it is decrypted.

Some of the ciphers do not have large keys and others have security implications if not used correctly. A beginner is advised to just use a strong block cipher in CBC mode such as bf or des3.

All the block ciphers normally use PKCS#5 padding also known as standard block padding: this allows a rudimentary integrity or password check to be performed. However since the chance of random data passing the test is better than 1 in 256 it isn't a very good test.

If padding is disabled then the input data must be a multiple of the cipher block length.

All RC2 ciphers have the same key and effective key length.

Blowfish and RC5 algorithms use a 128 bit key.

SUPPORTED CIPHERS

Note that some of these ciphers can be disabled at compile time and some are available only if an appropriate engine is configured in the configuration file. The output of the **enc** command run with unsupported options (for example **openssl enc -help**) includes a list of ciphers, supported by your versesion of OpenSSL, including ones provided by configured engines.

The **enc** program does not support authenticated encryption modes like CCM and GCM. The utility does not store or retrieve the authentication tag.

```

```
rc5-cbc            RC5 cipher in CBC mode
rc5                Alias for rc5-cbc
rc5-cfb            RC5 cipher in CFB mode
rc5-ecb            RC5 cipher in ECB mode
rc5-ofb            RC5 cipher in OFB mode

aes-[128|192|256]-cbc  128/192/256 bit AES in CBC mode
aes-[128|192|256]      Alias for aes-[128|192|256]-cbc
aes-[128|192|256]-cfb  128/192/256 bit AES in 128 bit CFB mode
aes-[128|192|256]-cfb1 128/192/256 bit AES in 1 bit CFB mode
aes-[128|192|256]-cfb8 128/192/256 bit AES in 8 bit CFB mode
aes-[128|192|256]-ecb  128/192/256 bit AES in ECB mode
aes-[128|192|256]-ofb  128/192/256 bit AES in OFB mode
```

EXAMPLES

Just base64 encode a binary file:

```
openssl base64 -in file.bin -out file.b64
```

Decode the same file

```
openssl base64 -d -in file.b64 -out file.bin
```

Encrypt a file using triple DES in CBC mode using a prompted password:

```
openssl des3 -salt -in file.txt -out file.des3
```

Decrypt a file using a supplied password:

```
openssl des3 -d -salt -in file.des3 -out file.txt -k mypassword
```

Encrypt a file then base64 encode it (so it can be sent via mail for example) using Blowfish in CBC mode:

```
openssl bf -a -salt -in file.txt -out file.bf
```

Base64 decode a file then decrypt it:

```
openssl bf -d -salt -a -in file.bf -out file.txt
```

Decrypt some data using a supplied 40 bit RC4 key:

```
openssl rc4-40 -in file.rc4 -out file.txt -K 0102030405
```

BUGS

The **-A** option when used with large files doesn't work properly.

There should be an option to allow an iteration count to be included.

The **enc** program only supports a fixed number of algorithms with certain parameters. So if, for example, you want to use RC2 with a 76 bit key or RC4 with an 84 bit key you can't use this program.

Name

errstr — lookup error codes

Synopsis

```
openssl errstr error_code
```

DESCRIPTION

Sometimes an application will not load error message and only numerical forms will be available. The **errstr** utility can be used to display the meaning of the hex code. The hex code is the hex digits after the second colon.

EXAMPLE

The error code:

```
27594:error:2006D080:lib(32):func(109):reason(128):bss_file.c:107:
```

can be displayed with:

```
openssl errstr 2006D080
```

to produce the error message:

```
error:2006D080:BIO routines:BIO_new_file:no such file
```

SEE ALSO

err(3), ERR_load_crypto_strings(3), SSL_load_error_strings(3)

Name

gendsa — generate a DSA private key from a set of parameters

Synopsis

```
opensslgendsa
[-out filename]
[-aes128]
[-aes192]
[-aes256]
[-camellia128]
[-camellia192]
[-camellia256]
[-des]
[-des3]
[-idea]
[-rand file(s)]
[-engine id]
[paramfile]
```

DESCRIPTION

The **gendsa** command generates a DSA private key from a DSA parameter file (which will be typically generated by the **openssl dsaparam** command).

OPTIONS

-aes128|-aes192|-aes256|-camellia128|-camellia192|-camellia256|-des|-des3|-idea

These options encrypt the private key with specified cipher before outputting it. A pass phrase is prompted for. If none of these options is specified no encryption is used.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-engine id

specifying an engine (by its unique **id** string) will cause **gendsa** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

paramfile

This option specifies the DSA parameter file to use. The parameters in this file determine the size of the private key. DSA parameters can be generated and examined using the **openssl dsaparam** command.

NOTES

DSA key generation is little more than random number generation so it is much quicker that RSA key generation for example.

SEE ALSO

dsaparam(1), dsa(1), genrsa(1), rsa(1)

Name

genpkey — generate a private key

Synopsis

```
opensslgenpkey
[-out filename]
[-outform PEM|DER]
[-pass arg]
[-cipher]
[-engine id]
[-paramfile file]
[-algorithm alg]
[-pkeyopt opt:value]
[-genparam]
[-text]
```

DESCRIPTION

The **genpkey** command generates a private key.

OPTIONS

-out filename

the output filename. If this argument is not specified then standard output is used.

-outform DER|PEM

This specifies the output format DER or PEM.

-pass arg

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-cipher

This option encrypts the private key with the supplied cipher. Any algorithm name accepted by EVP_get_cipherbyname() is acceptable such as **des3**.

-engine id

specifying an engine (by its unique **id** string) will cause **genpkey** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms. If used this option should precede all other options.

-algorithm alg

public key algorithm to use such as RSA, DSA or DH. If used this option must precede any **-pkeyopt** options. The options **-paramfile** and **-algorithm** are mutually exclusive.

-pkeyopt opt:value

set the public key algorithm option **opt** to **value**. The precise set of options supported depends on the public key algorithm used and its implementation. See **KEY GENERATION OPTIONS** below for more details.

-genparam

generate a set of parameters instead of a private key. If used this option must precede and **-algorithm**, **-paramfile** or **-pkeyopt** options.

-paramfile filename

Some public key algorithms generate a private key based on a set of parameters. They can be supplied using this option. If this option is used the public key algorithm used is determined by the parameters. If used this option must precede and **-pkeyopt** options. The options **-paramfile** and **-algorithm** are mutually exclusive.

-text

Print an (unencrypted) text representation of private and public keys and parameters along with the PEM or DER structure.

KEY GENERATION OPTIONS

The options supported by each algorith and indeed each implementation of an algorithm can vary. The options for the OpenSSL implementations are detailed below.

RSA KEY GENERATION OPTIONS

rsa_keygen_bits:numbits

The number of bits in the generated key. If not specified 1024 is used.

rsa_keygen_pubexp:value

The RSA public exponent value. This can be a large decimal or hexadecimal value if preceded by **0x**. Default value is 65537.

DSA PARAMETER GENERATION OPTIONS

dsa_paramgen_bits:numbits

The number of bits in the generated parameters. If not specified 1024 is used.

DH PARAMETER GENERATION OPTIONS

dh_paramgen_prime_len:numbits

The number of bits in the prime parameter **p**.

dh_paramgen_generator:value

The value to use for the generator **g**.

EC PARAMETER GENERATION OPTIONS

ec_paramgen_curve:curve

the EC curve to use.

GOST2001 KEY GENERATION AND PARAMETER OPTIONS

Gost 2001 support is not enabled by default. To enable this algorithm, one should load the ccgost engine in the OpenSSL configuration file. See README.gost file in the engines/ccgost directiry of the source distribution for more details.

Use of a parameter file for the GOST R 34.10 algorithm is optional. Parameters can be specified during key generation directly as well as during generation of parameter file.

paramset:name

Specifies GOST R 34.10-2001 parameter set according to RFC 4357. Parameter set can be specified using abbreviated name, object short name or numeric OID. Following parameter sets are supported:

paramset	OID	Usage
A	1.2.643.2.2.35.1	Signature
B	1.2.643.2.2.35.2	Signature
C	1.2.643.2.2.35.3	Signature
XA	1.2.643.2.2.36.0	Key exchange
XB	1.2.643.2.2.36.1	Key exchange
test	1.2.643.2.2.35.0	Test purposes

NOTES

The use of the genpkey program is encouraged over the algorithm specific utilities because additional algorithm options and ENGINE provided algorithms can be used.

EXAMPLES

Generate an RSA private key using default parameters:

```
openssl genpkey -algorithm RSA -out key.pem
```

Encrypt output private key using 128 bit AES and the passphrase "hello":

```
openssl genpkey -algorithm RSA -out key.pem -aes-128-cbc -pass pass:hello
```

Generate a 2048 bit RSA key using 3 as the public exponent:

```
openssl genpkey -algorithm RSA -out key.pem -pkeyopt rsa_keygen_bits:2048 \
                                               -pkeyopt rsa_keygen_pubexp:3
```

Generate 1024 bit DSA parameters:

```
openssl genpkey -genparam -algorithm DSA -out dsap.pem \
                                               -pkeyopt dsa_paramgen_bits:1024
```

Generate DSA key from parameters:

```
openssl genpkey -paramfile dsap.pem -out dsakey.pem
```

Generate 1024 bit DH parameters:

```
openssl genpkey -genparam -algorithm DH -out dhp.pem \
                                       -pkeyopt dh_paramgen_prime_len:1024
```

Generate DH key from parameters:

```
openssl genpkey -paramfile dhp.pem -out dhkey.pem
```

Name

genrsa — generate an RSA private key

Synopsis

```
opensslgenrsa
[-out filename]
[-passout arg]
[-aes128]
[-aes192]
[-aes256]
[-camellia128]
[-camellia192]
[-camellia256]
[-des]
[-des3]
[-idea]
[-f4]
[-3]
[-rand file(s)]
[-engine id]
[numbits]
```

DESCRIPTION

The **genrsa** command generates an RSA private key.

OPTIONS

-out filename

the output filename. If this argument is not specified then standard output is used.

-passout arg

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-aes128|-aes192|-aes256|-camellia128|-camellia192|-camellia256|-des|-des3|-idea

These options encrypt the private key with specified cipher before outputting it. If none of these options is specified no encryption is used. If encryption is used a pass phrase is prompted for if it is not supplied via the **-passout** argument.

-F4|-3

the public exponent to use, either 65537 or 3. The default is 65537.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-engine id

specifying an engine (by its unique **id** string) will cause **genrsa** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

numbits

the size of the private key to generate in bits. This must be the last option specified. The default is 512.

NOTES

RSA private key generation essentially involves the generation of two prime numbers. When generating a private key various symbols will be output to indicate the progress of the generation. A **.** represents each number which has passed an initial sieve test, **+** means a number has passed a single round of the Miller-Rabin primality test. A newline means that the number has passed all the prime tests (the actual number depends on the key size).

Because key generation is a random process the time taken to generate a key may vary somewhat.

BUGS

A quirk of the prime generation algorithm is that it cannot generate small primes. Therefore the number of bits should not be less that 64. For typical private keys this will not matter because for security reasons they will be much larger (typically 1024 bits).

SEE ALSO

gendsa(1)

Name

nseq — create or examine a netscape certificate sequence

Synopsis

```
opensslnseq
[-in filename]
[-out filename]
[-toseq]
```

DESCRIPTION

The **nseq** command takes a file containing a Netscape certificate sequence and prints out the certificates contained in it or takes a file of certificates and converts it into a Netscape certificate sequence.

COMMAND OPTIONS

-in filename

This specifies the input filename to read or standard input if this option is not specified.

-out filename

specifies the output filename or standard output by default.

-toseq

normally a Netscape certificate sequence will be input and the output is the certificates contained in it. With the **-toseq** option the situation is reversed: a Netscape certificate sequence is created from a file of certificates.

EXAMPLES

Output the certificates in a Netscape certificate sequence

```
openssl nseq -in nseq.pem -out certs.pem
```

Create a Netscape certificate sequence

```
openssl nseq -in certs.pem -toseq -out nseq.pem
```

NOTES

The **PEM** encoded form uses the same headers and footers as a certificate:

```
-----BEGIN CERTIFICATE-----
-----END CERTIFICATE-----
```

A Netscape certificate sequence is a Netscape specific form that can be sent to browsers as an alternative to the standard PKCS#7 format when several certificates are sent to the browser: for example during certificate enrollment. It is used by Netscape certificate server for example.

BUGS

This program needs a few more options: like allowing DER or PEM input and output files and allowing multiple certificate files to be used.

DESCRIPTION

The Online Certificate Status Protocol (OCSP) enables applications to determine the (revocation) state of an identified certificate (RFC 2560).

The **ocsp** command performs many common OCSP tasks. It can be used to print out requests and responses, create requests and send queries to an OCSP responder and behave like a mini OCSP server itself.

OCSP CLIENT OPTIONS

-out filename

specify output filename, default is standard output.

-issuer filename

This specifies the current issuer certificate. This option can be used multiple times. The certificate specified in **filename** must be in PEM format. This option **MUST** come before any **-cert** options.

-cert filename

Add the certificate **filename** to the request. The issuer certificate is taken from the previous **issuer** option, or an error occurs if no issuer certificate is specified.

-serial num

Same as the **cert** option except the certificate with serial number **num** is added to the request. The serial number is interpreted as a decimal integer unless preceded by **0x**. Negative integers can also be specified by preceding the value by a **-** sign.

-signer filename, **-signkey filename**

Sign the OCSP request using the certificate specified in the **signer** option and the private key specified by the **signkey** option. If the **signkey** option is not present then the private key is read from the same file as the certificate. If neither option is specified then the OCSP request is not signed.

-sign_other filename

Additional certificates to include in the signed request.

-nonce, **-no_nonce**

Add an OCSP nonce extension to a request or disable OCSP nonce addition. Normally if an OCSP request is input using the **respin** option no nonce is added: using the **nonce** option will force addition of a nonce. If an OCSP request is being created (using **cert** and **serial** options) a nonce is automatically added specifying **no_nonce** overrides this.

-req_text, **-resp_text**, **-text**

print out the text form of the OCSP request, response or both respectively.

-reqout file, **-respout file**

write out the DER encoded certificate request or response to **file**.

-reqin file, **-respin file**

read OCSP request or response file from **file**. These option are ignored if OCSP request or response creation is implied by other options (for example with **serial**, **cert** and **host** options).

-url responder_url

specify the responder URL. Both HTTP and HTTPS (SSL/TLS) URLs can be specified.

-host hostname:port, **-path pathname**

if the **host** option is present then the OCSP request is sent to the host **hostname** on port **port**. **path** specifies the HTTP path name to use or "/" by default.

-timeout seconds

connection timeout to the OCSP responder in seconds

-CAfile file, **-CApath pathname**

file or pathname containing trusted CA certificates. These are used to verify the signature on the OCSP response.

-no_alt_chains

See **verify** manual page for details.

-verify_other file

file containing additional certificates to search when attempting to locate the OCSP response signing certificate. Some responders omit the actual signer's certificate from the response: this option can be used to supply the necessary certificate in such cases.

-trust_other

the certificates specified by the **-verify_other** option should be explicitly trusted and no additional checks will be performed on them. This is useful when the complete responder certificate chain is not available or trusting a root CA is not appropriate.

-VAfile file

file containing explicitly trusted responder certificates. Equivalent to the **-verify_other** and **-trust_other** options.

-noverify

don't attempt to verify the OCSP response signature or the nonce values. This option will normally only be used for debugging since it disables all verification of the responders certificate.

-no_intern

ignore certificates contained in the OCSP response when searching for the signers certificate. With this option the signers certificate must be specified with either the **-verify_other** or **-VAfile** options.

-no_signature_verify

don't check the signature on the OCSP response. Since this option tolerates invalid signatures on OCSP responses it will normally only be used for testing purposes.

-no_cert_verify

don't verify the OCSP response signers certificate at all. Since this option allows the OCSP response to be signed by any certificate it should only be used for testing purposes.

-no_chain

do not use certificates in the response as additional untrusted CA certificates.

-no_explicit

do not explicitly trust the root CA if it is set to be trusted for OCSP signing.

-no_cert_checks

don't perform any additional checks on the OCSP response signers certificate. That is do not make any checks to see if the signers certificate is authorised to provide the necessary status information: as a result this option should only be used for testing purposes.

-validity_period nsec, **-status_age age**

these options specify the range of times, in seconds, which will be tolerated in an OCSP response. Each certificate status response includes a **notBefore** time and an optional **notAfter** time. The current time should fall between these two values, but the interval between the two times may be only a few seconds. In practice the OCSP responder and clients clocks may not be precisely synchronised and so such a check may fail. To avoid this the **-validity_period** option can be used to specify an acceptable error range in seconds, the default value is 5 minutes.

If the **notAfter** time is omitted from a response then this means that new status information is immediately available. In this case the age of the **notBefore** field is checked to see it is not older than **age** seconds old. By default this additional check is not performed.

-md5|-sha1|-sha256|-ripemod160|…

this option sets digest algorithm to use for certificate identification in the OCSP request. By default SHA-1 is used.

OCSP SERVER OPTIONS

-index indexfile

indexfile is a text index file in **ca** format containing certificate revocation information.

If the **index** option is specified the **ocsp** utility is in responder mode, otherwise it is in client mode. The request(s) the responder processes can be either specified on the command line (using **issuer** and **serial** options), supplied in a file (using the **respin** option) or via external OCSP clients (if **port** or **url** is specified).

If the **index** option is present then the **CA** and **rsigner** options must also be present.

-CA file

CA certificate corresponding to the revocation information in **indexfile**.

-rsigner file

The certificate to sign OCSP responses with.

-rother file

Additional certificates to include in the OCSP response.

-resp_no_certs

Don't include any certificates in the OCSP response.

-resp_key_id

Identify the signer certificate using the key ID, default is to use the subject name.

-rkey file

The private key to sign OCSP responses with: if not present the file specified in the **rsigner** option is used.

-port portnum

Port to listen for OCSP requests on. The port may also be specified using the **url** option.

-nrequest number

The OCSP server will exit after receiving **number** requests, default unlimited.

-nmin minutes, **-ndays days**

Number of minutes or days when fresh revocation information is available: used in the **nextUpdate** field. If neither option is present then the **nextUpdate** field is omitted meaning fresh revocation information is immediately available.

OCSP Response verification.

OCSP Response follows the rules specified in RFC2560.

Initially the OCSP responder certificate is located and the signature on the OCSP request checked using the responder certificate's public key.

Then a normal certificate verify is performed on the OCSP responder certificate building up a certificate chain in the process. The locations of the trusted certificates used to build the chain can be specified by the **CAfile** and **CApath** options or they will be looked for in the standard OpenSSL certificates directory.

If the initial verify fails then the OCSP verify process halts with an error.

Otherwise the issuing CA certificate in the request is compared to the OCSP responder certificate: if there is a match then the OCSP verify succeeds.

Otherwise the OCSP responder certificate's CA is checked against the issuing CA certificate in the request. If there is a match and the OCSPSigning extended key usage is present in the OCSP responder certificate then the OCSP verify succeeds.

Otherwise, if **-no_explicit** is **not** set the root CA of the OCSP responders CA is checked to see if it is trusted for OCSP signing. If it is the OCSP verify succeeds.

If none of these checks is successful then the OCSP verify fails.

What this effectively means if that if the OCSP responder certificate is authorised directly by the CA it is issuing revocation information about (and it is correctly configured) then verification will succeed.

If the OCSP responder is a "global responder" which can give details about multiple CAs and has its own separate certificate chain then its root CA can be trusted for OCSP signing. For example:

```
openssl x509 -in ocspCA.pem -addtrust OCSPSigning -out trustedCA.pem
```

Alternatively the responder certificate itself can be explicitly trusted with the **-VAfile** option.

NOTES

As noted, most of the verify options are for testing or debugging purposes. Normally only the **-CApath**, **-CAfile** and (if the responder is a 'global VA') **-VAfile** options need to be used.

The OCSP server is only useful for test and demonstration purposes: it is not really usable as a full OCSP responder. It contains only a very simple HTTP request handling and can only handle the POST form of OCSP queries. It also handles requests serially meaning it cannot respond to new requests until it has processed the current one. The text index file format of revocation is also inefficient for large quantities of revocation data.

It is possible to run the **ocsp** application in responder mode via a CGI script using the **respin** and **respout** options.

EXAMPLES

Create an OCSP request and write it to a file:

```
openssl ocsp -issuer issuer.pem -cert c1.pem -cert c2.pem -reqout req.der
```

Send a query to an OCSP responder with URL http://ocsp.myhost.com/ save the response to a file and print it out in text form

```
openssl ocsp -issuer issuer.pem -cert c1.pem -cert c2.pem \
    -url http://ocsp.myhost.com/ -resp_text -respout resp.der
```

Read in an OCSP response and print out text form:

```
openssl ocsp -respin resp.der -text
```

OCSP server on port 8888 using a standard **ca** configuration, and a separate responder certificate. All requests and responses are printed to a file.

```
openssl ocsp -index demoCA/index.txt -port 8888 -rsigner rcert.pem -CA demoCA/cacert.pem \
       -text -out log.txt
```

As above but exit after processing one request:

```
openssl ocsp -index demoCA/index.txt -port 8888 -rsigner rcert.pem -CA demoCA/cacert.pem \
    -nrequest 1
```

Query status information using internally generated request:

```
openssl ocsp -index demoCA/index.txt -rsigner rcert.pem -CA demoCA/cacert.pem \
    -issuer demoCA/cacert.pem -serial 1
```

Query status information using request read from a file, write response to a second file.

```
openssl ocsp -index demoCA/index.txt -rsigner rcert.pem -CA demoCA/cacert.pem \
    -reqin req.der -respout resp.der
```

HISTORY

The -no_alt_chains options was first added to OpenSSL 1.0.1n and 1.0.2b.

Name

passwd — compute password hashes

Synopsis

```
openssl passwd
[-crypt]
[-1]
[-apr1]
[-salt string]
[-in file]
[-stdin]
[-noverify]
[-quiet]
[-table]
{password}
```

DESCRIPTION

The **passwd** command computes the hash of a password typed at run-time or the hash of each password in a list. The password list is taken from the named file for option **-in file**, from stdin for option **-stdin**, or from the command line, or from the terminal otherwise. The Unix standard algorithm **crypt** and the MD5-based BSD password algorithm **1** and its Apache variant **apr1** are available.

OPTIONS

-crypt

Use the **crypt** algorithm (default).

-1

Use the MD5 based BSD password algorithm **1**.

-apr1

Use the **apr1** algorithm (Apache variant of the BSD algorithm).

-salt *string*

Use the specified salt. When reading a password from the terminal, this implies **-noverify**.

-in *file*

Read passwords from *file*.

-stdin

Read passwords from **stdin**.

-noverify

Don't verify when reading a password from the terminal.

-quiet

Don't output warnings when passwords given at the command line are truncated.

-table

In the output list, prepend the cleartext password and a TAB character to each password hash.

EXAMPLES

openssl passwd -crypt -salt xx password prints **xxj31ZMTZzkVA**.

openssl passwd -1 -salt xxxxxxxx password prints **$1$xxxxxxxx$UYCIxa628.9qXjpQCjM4a.**.

openssl passwd -apr1 -salt xxxxxxxx password prints **$apr1$xxxxxxxx$dxHfLAsjHkDRmG83UXe8K0**.

[-CAfile file]
[-CApath dir]
[-CSP name]
```

DESCRIPTION

The **pkcs12** command allows PKCS#12 files (sometimes referred to as PFX files) to be created and parsed. PKCS#12 files are used by several programs including Netscape, MSIE and MS Outlook.

COMMAND OPTIONS

There are a lot of options the meaning of some depends of whether a PKCS#12 file is being created or parsed. By default a PKCS#12 file is parsed. A PKCS#12 file can be created by using the **-export** option (see below).

PARSING OPTIONS

-in filename

This specifies filename of the PKCS#12 file to be parsed. Standard input is used by default.

-out filename

The filename to write certificates and private keys to, standard output by default. They are all written in PEM format.

-passin arg

the PKCS#12 file (i.e. input file) password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-passout arg

pass phrase source to encrypt any outputted private keys with. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-password arg

With -export, -password is equivalent to -passout. Otherwise, -password is equivalent to -passin.

-noout

this option inhibits output of the keys and certificates to the output file version of the PKCS#12 file.

-clcerts

only output client certificates (not CA certificates).

-cacerts

only output CA certificates (not client certificates).

-nocerts

no certificates at all will be output.

-nokeys

no private keys will be output.

-info

output additional information about the PKCS#12 file structure, algorithms used and iteration counts.

-des

use DES to encrypt private keys before outputting.

-des3

use triple DES to encrypt private keys before outputting, this is the default.

-idea

use IDEA to encrypt private keys before outputting.

-aes128, **-aes192**, **-aes256**

use AES to encrypt private keys before outputting.

-camellia128, **-camellia192**, **-camellia256**

use Camellia to encrypt private keys before outputting.

-nodes

don't encrypt the private keys at all.

-nomacver

don't attempt to verify the integrity MAC before reading the file.

-twopass

prompt for separate integrity and encryption passwords: most software always assumes these are the same so this option will render such PKCS#12 files unreadable.

FILE CREATION OPTIONS

-export

This option specifies that a PKCS#12 file will be created rather than parsed.

-out filename

This specifies filename to write the PKCS#12 file to. Standard output is used by default.

-in filename

The filename to read certificates and private keys from, standard input by default. They must all be in PEM format. The order doesn't matter but one private key and its corresponding certificate should be present. If additional certificates are present they will also be included in the PKCS#12 file.

-inkey filename

file to read private key from. If not present then a private key must be present in the input file.

-name friendlyname

This specifies the "friendly name" for the certificate and private key. This name is typically displayed in list boxes by software importing the file.

-certfile filename

A filename to read additional certificates from.

-caname friendlyname

This specifies the "friendly name" for other certificates. This option may be used multiple times to specify names for all certificates in the order they appear. Netscape ignores friendly names on other certificates whereas MSIE displays them.

-pass arg, **-passout arg**

the PKCS#12 file (i.e. output file) password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-passin password

pass phrase source to decrypt any input private keys with. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-chain

if this option is present then an attempt is made to include the entire certificate chain of the user certificate. The standard CA store is used for this search. If the search fails it is considered a fatal error.

-descert

encrypt the certificate using triple DES, this may render the PKCS#12 file unreadable by some "export grade" software. By default the private key is encrypted using triple DES and the certificate using 40 bit RC2.

-keypbe alg, **-certpbe alg**

these options allow the algorithm used to encrypt the private key and certificates to be selected. Any PKCS#5 v1.5 or PKCS#12 PBE algorithm name can be used (see **NOTES** section for more information). If a a cipher name (as output by the **list-cipher-algorithms** command is specified then it is used with PKCS#5 v2.0. For interoperability reasons it is advisable to only use PKCS#12 algorithms.

-keyex|-keysig

specifies that the private key is to be used for key exchange or just signing. This option is only interpreted by MSIE and similar MS software. Normally "export grade" software will only allow 512 bit RSA keys to be used for encryption purposes but arbitrary length keys for signing. The **-keysig** option marks the key for signing only. Signing only keys can be used for S/MIME signing, authenticode (ActiveX control signing) and SSL client authentication, however due to a bug only MSIE 5.0 and later support the use of signing only keys for SSL client authentication.

-macalg digest

specify the MAC digest algorithm. If not included them SHA1 will be used.

-nomaciter, **-noiter**

these options affect the iteration counts on the MAC and key algorithms. Unless you wish to produce files compatible with MSIE 4.0 you should leave these options alone.

To discourage attacks by using large dictionaries of common passwords the algorithm that derives keys from passwords can have an iteration count applied to it: this causes a certain part of the algorithm to be repeated and slows it down. The MAC is used to check the file integrity but since it will normally have the same password as the keys and certificates it could also be attacked. By default both MAC and encryption iteration counts are set to 2048, using these options the MAC and encryption iteration counts can be set to 1, since this reduces the file security you should not use these options unless you really have to. Most software supports both MAC and key iteration counts. MSIE 4.0 doesn't support MAC iteration counts so it needs the **-nomaciter** option.

-maciter

This option is included for compatibility with previous versions, it used to be needed to use MAC iterations counts but they are now used by default.

-nomac

don't attempt to provide the MAC integrity.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-CAfile file

CA storage as a file.

-CApath dir

CA storage as a directory. This directory must be a standard certificate directory: that is a hash of each subject name (using **x509 -hash**) should be linked to each certificate.

-CSP name

write **name** as a Microsoft CSP name.

NOTES

Although there are a large number of options most of them are very rarely used. For PKCS#12 file parsing only **-in** and **-out** need to be used for PKCS#12 file creation **-export** and **-name** are also used.

If none of the **-clcerts**, **-cacerts** or **-nocerts** options are present then all certificates will be output in the order they appear in the input PKCS#12 files. There is no guarantee that the first certificate present is the one corresponding to the private key. Certain software which requires a private key and certificate and assumes the first certificate in the file is the one corresponding to the private key: this may not always be the case. Using the **-clcerts** option will solve this problem by only outputting the certificate corresponding to the private key. If the CA certificates are required then they can be output to a separate file using the **-nokeys -cacerts** options to just output CA certificates.

The **-keypbe** and **-certpbe** algorithms allow the precise encryption algorithms for private keys and certificates to be specified. Normally the defaults are fine but occasionally software can't handle triple DES encrypted private keys, then the option **-keypbe PBE-SHA1-RC2-40** can be used to reduce the private key encryption to 40 bit RC2. A complete description of all algorithms is contained in the **pkcs8** manual page.

EXAMPLES

Parse a PKCS#12 file and output it to a file:

```
openssl pkcs12 -in file.p12 -out file.pem
```

Output only client certificates to a file:

```
openssl pkcs12 -in file.p12 -clcerts -out file.pem
```

Don't encrypt the private key:

```
openssl pkcs12 -in file.p12 -out file.pem -nodes
```

Print some info about a PKCS#12 file:

```
openssl pkcs12 -in file.p12 -info -noout
```

Create a PKCS#12 file:

```
openssl pkcs12 -export -in file.pem -out file.p12 -name "My Certificate"
```

Include some extra certificates:

```
openssl pkcs12 -export -in file.pem -out file.p12 -name "My Certificate" \
 -certfile othercerts.pem
```

BUGS

Some would argue that the PKCS#12 standard is one big bug :-)

Versions of OpenSSL before 0.9.6a had a bug in the PKCS#12 key generation routines. Under rare circumstances this could produce a PKCS#12 file encrypted with an invalid key. As a result some PKCS#12 files which triggered this bug from other implementations (MSIE or Netscape) could not be decrypted by OpenSSL and similarly OpenSSL could produce PKCS#12 files which could not be decrypted by other implementations. The chances of producing such a file are relatively small: less than 1 in 256.

A side effect of fixing this bug is that any old invalidly encrypted PKCS#12 files cannot no longer be parsed by the fixed version. Under such circumstances the **pkcs12** utility will report that the MAC is OK but fail with a decryption error when extracting private keys.

This problem can be resolved by extracting the private keys and certificates from the PKCS#12 file using an older version of OpenSSL and recreating the PKCS#12 file from the keys and certificates using a newer version of OpenSSL. For example:

```
old-openssl -in bad.p12 -out keycerts.pem
openssl -in keycerts.pem -export -name "My PKCS#12 file" -out fixed.p12
```

SEE ALSO

pkcs8(1)

Name

pkcs7 — PKCS#7 utility

Synopsis

```
opensslpkcs7
[-inform PEM|DER]
[-outform PEM|DER]
[-in filename]
[-out filename]
[-print_certs]
[-text]
[-noout]
[-engine id]
```

DESCRIPTION

The **pkcs7** command processes PKCS#7 files in DER or PEM format.

COMMAND OPTIONS

-inform DER|PEM

This specifies the input format. **DER** format is DER encoded PKCS#7 v1.5 structure.**PEM** (the default) is a base64 encoded version of the DER form with header and footer lines.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read from or standard input if this option is not specified.

-out filename

specifies the output filename to write to or standard output by default.

-print_certs

prints out any certificates or CRLs contained in the file. They are preceded by their subject and issuer names in one line format.

-text

prints out certificates details in full rather than just subject and issuer names.

-noout

don't output the encoded version of the PKCS#7 structure (or certificates is **-print_certs** is set).

-engine id

specifying an engine (by its unique **id** string) will cause **pkcs7** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

EXAMPLES

Convert a PKCS#7 file from PEM to DER:

```
openssl pkcs7 -in file.pem -outform DER -out file.der
```

Output all certificates in a file:

```
openssl pkcs7 -in file.pem -print_certs -out certs.pem
```

NOTES

The PEM PKCS#7 format uses the header and footer lines:

```
-----BEGIN PKCS7-----
-----END PKCS7-----
```

For compatibility with some CAs it will also accept:

```
-----BEGIN CERTIFICATE-----
-----END CERTIFICATE-----
```

RESTRICTIONS

There is no option to print out all the fields of a PKCS#7 file.

This PKCS#7 routines only understand PKCS#7 v 1.5 as specified in RFC2315 they cannot currently parse, for example, the new CMS as described in RFC2630.

Name

pkcs8 — PKCS#8 format private key conversion tool

Synopsis

```
opensslpkcs8
[-topk8]
[-inform PEM|DER]
[-outform PEM|DER]
[-in filename]
[-passin arg]
[-out filename]
[-passout arg]
[-noiter]
[-nocrypt]
[-nooct]
[-embed]
[-nsdb]
[-v2 alg]
[-v1 alg]
[-engine id]
```

DESCRIPTION

The **pkcs8** command processes private keys in PKCS#8 format. It can handle both unencrypted PKCS#8 PrivateKeyInfo format and EncryptedPrivateKeyInfo format with a variety of PKCS#5 (v1.5 and v2.0) and PKCS#12 algorithms.

COMMAND OPTIONS

-topk8

Normally a PKCS#8 private key is expected on input and a traditional format private key will be written. With the **-topk8** option the situation is reversed: it reads a traditional format private key and writes a PKCS#8 format key.

-inform DER|PEM

This specifies the input format. If a PKCS#8 format key is expected on input then either a **DER** or **PEM** encoded version of a PKCS#8 key will be expected. Otherwise the **DER** or **PEM** format of the traditional format private key is used.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read a key from or standard input if this option is not specified. If the key is encrypted a pass phrase will be prompted for.

-passin arg

the input file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-out filename

This specifies the output filename to write a key to or standard output by default. If any encryption options are set then a pass phrase will be prompted for. The output filename should **not** be the same as the input filename.

-passout arg

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-nocrypt

PKCS#8 keys generated or input are normally PKCS#8 EncryptedPrivateKeyInfo structures using an appropriate password based encryption algorithm. With this option an unencrypted PrivateKeyInfo structure is expected or output. This option does not encrypt private keys at all and should only be used when absolutely necessary. Certain software such as some versions of Java code signing software used unencrypted private keys.

-nooct

This option generates RSA private keys in a broken format that some software uses. Specifically the private key should be enclosed in a OCTET STRING but some software just includes the structure itself without the surrounding OCTET STRING.

-embed

This option generates DSA keys in a broken format. The DSA parameters are embedded inside the PrivateKey structure. In this form the OCTET STRING contains an ASN1 SEQUENCE consisting of two structures: a SEQUENCE containing the parameters and an ASN1 INTEGER containing the private key.

-nsdb

This option generates DSA keys in a broken format compatible with Netscape private key databases. The PrivateKey contains a SEQUENCE consisting of the public and private keys respectively.

-v2 alg

This option enables the use of PKCS#5 v2.0 algorithms. Normally PKCS#8 private keys are encrypted with the password based encryption algorithm called **pbeWithMD5AndDES-CBC** this uses 56 bit DES encryption but it was the strongest encryption algorithm supported in PKCS#5 v1.5. Using the **-v2** option PKCS#5 v2.0 algorithms are used which can use any encryption algorithm such as 168 bit triple DES or 128 bit RC2 however not many implementations support PKCS#5 v2.0 yet. If you are just using private keys with OpenSSL then this doesn't matter.

The **alg** argument is the encryption algorithm to use, valid values include **des**, **des3** and **rc2**. It is recommended that **des3** is used.

-v1 alg

This option specifies a PKCS#5 v1.5 or PKCS#12 algorithm to use. A complete list of possible algorithms is included below.

-engine id

specifying an engine (by its unique **id** string) will cause **pkcs8** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

NOTES

The encrypted form of a PEM encode PKCS#8 files uses the following headers and footers:

```
-----BEGIN ENCRYPTED PRIVATE KEY-----
-----END ENCRYPTED PRIVATE KEY-----
```

The unencrypted form uses:

```
-----BEGIN PRIVATE KEY-----
-----END PRIVATE KEY-----
```

Private keys encrypted using PKCS#5 v2.0 algorithms and high iteration counts are more secure that those encrypted using the traditional SSLeay compatible formats. So if additional security is considered important the keys should be converted.

The default encryption is only 56 bits because this is the encryption that most current implementations of PKCS#8 will support.

Some software may use PKCS#12 password based encryption algorithms with PKCS#8 format private keys: these are handled automatically but there is no option to produce them.

It is possible to write out DER encoded encrypted private keys in PKCS#8 format because the encryption details are included at an ASN1 level whereas the traditional format includes them at a PEM level.

PKCS#5 v1.5 and PKCS#12 algorithms.

Various algorithms can be used with the **-v1** command line option, including PKCS#5 v1.5 and PKCS#12. These are described in more detail below.

PBE-MD2-DES PBE-MD5-DES

> These algorithms were included in the original PKCS#5 v1.5 specification. They only offer 56 bits of protection since they both use DES.

PBE-SHA1-RC2-64 PBE-MD2-RC2-64 PBE-MD5-RC2-64 PBE-SHA1-DES

> These algorithms are not mentioned in the original PKCS#5 v1.5 specification but they use the same key derivation algorithm and are supported by some software. They are mentioned in PKCS#5 v2.0. They use either 64 bit RC2 or 56 bit DES.

PBE-SHA1-RC4-128 PBE-SHA1-RC4-40 PBE-SHA1-3DES PBE-SHA1-2DES PBE-SHA1-RC2-128 PBE-SHA1-RC2-40

> These algorithms use the PKCS#12 password based encryption algorithm and allow strong encryption algorithms like triple DES or 128 bit RC2 to be used.

EXAMPLES

Convert a private from traditional to PKCS#5 v2.0 format using triple DES:

```
openssl pkcs8 -in key.pem -topk8 -v2 des3 -out enckey.pem
```

Convert a private key to PKCS#8 using a PKCS#5 1.5 compatible algorithm (DES):

```
openssl pkcs8 -in key.pem -topk8 -out enckey.pem
```

Convert a private key to PKCS#8 using a PKCS#12 compatible algorithm (3DES):

```
openssl pkcs8 -in key.pem -topk8 -out enckey.pem -v1 PBE-SHA1-3DES
```

Read a DER unencrypted PKCS#8 format private key:

```
openssl pkcs8 -inform DER -nocrypt -in key.der -out key.pem
```

Convert a private key from any PKCS#8 format to traditional format:

```
openssl pkcs8 -in pk8.pem -out key.pem
```

STANDARDS

Test vectors from this PKCS#5 v2.0 implementation were posted to the pkcs-tng mailing list using triple DES, DES and RC2 with high iteration counts, several people confirmed that they could decrypt the private keys produced and Therefore it can be assumed that the PKCS#5 v2.0 implementation is reasonably accurate at least as far as these algorithms are concerned.

The format of PKCS#8 DSA (and other) private keys is not well documented: it is hidden away in PKCS#11 v2.01, section 11.9. OpenSSL's default DSA PKCS#8 private key format complies with this standard.

BUGS

There should be an option that prints out the encryption algorithm in use and other details such as the iteration count.

PKCS#8 using triple DES and PKCS#5 v2.0 should be the default private key format for OpenSSL: for compatibility several of the utilities use the old format at present.

Name

pkey — public or private key processing tool

Synopsis

```
opensslpkey
[-inform PEM|DER]
[-outform PEM|DER]
[-in filename]
[-passin arg]
[-out filename]
[-passout arg]
[-cipher]
[-text]
[-text_pub]
[-noout]
[-pubin]
[-pubout]
[-engine id]
```

DESCRIPTION

The **pkey** command processes public or private keys. They can be converted between various forms and their components printed out.

COMMAND OPTIONS

-inform DER|PEM

This specifies the input format DER or PEM.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read a key from or standard input if this option is not specified. If the key is encrypted a pass phrase will be prompted for.

-passin arg

the input file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-out filename

This specifies the output filename to write a key to or standard output if this option is not specified. If any encryption options are set then a pass phrase will be prompted for. The output filename should **not** be the same as the input filename.

-passout password

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-cipher

These options encrypt the private key with the supplied cipher. Any algorithm name accepted by EVP_get_cipherbyname() is acceptable such as **des3**.

-text

prints out the various public or private key components in plain text in addition to the encoded version.

-text_pub

print out only public key components even if a private key is being processed.

-noout

do not output the encoded version of the key.

-pubin

by default a private key is read from the input file: with this option a public key is read instead.

-pubout

by default a private key is output: with this option a public key will be output instead. This option is automatically set if the input is a public key.

-engine id

specifying an engine (by its unique **id** string) will cause **pkey** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

EXAMPLES

To remove the pass phrase on an RSA private key:

```
openssl pkey -in key.pem -out keyout.pem
```

To encrypt a private key using triple DES:

```
openssl pkey -in key.pem -des3 -out keyout.pem
```

To convert a private key from PEM to DER format:

```
openssl pkey -in key.pem -outform DER -out keyout.der
```

To print out the components of a private key to standard output:

```
openssl pkey -in key.pem -text -noout
```

To print out the public components of a private key to standard output:

```
openssl pkey -in key.pem -text_pub -noout
```

To just output the public part of a private key:

```
openssl pkey -in key.pem -pubout -out pubkey.pem
```

SEE ALSO

Name

pkeyparam — public key algorithm parameter processing tool

Synopsis

```
opensslpkeyparam
[-in filename]
[-out filename]
[-text]
[-noout]
[-engine id]
```

DESCRIPTION

The **pkey** command processes public or private keys. They can be converted between various forms and their components printed out.

COMMAND OPTIONS

-in filename

This specifies the input filename to read parameters from or standard input if this option is not specified.

-out filename

This specifies the output filename to write parameters to or standard output if this option is not specified.

-text

prints out the parameters in plain text in addition to the encoded version.

-noout

do not output the encoded version of the parameters.

-engine id

specifying an engine (by its unique **id** string) will cause **pkeyparam** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

EXAMPLE

Print out text version of parameters:

```
openssl pkeyparam -in param.pem -text
```

NOTES

There are no **-inform** or **-outform** options for this command because only PEM format is supported because the key type is determined by the PEM headers.

Name

pkeyutl — public key algorithm utility

Synopsis

```
opensslpkeyutl
[-in file]
[-out file]
[-sigfile file]
[-inkey file]
[-keyform PEM|DER]
[-passin arg]
[-peerkey file]
[-peerform PEM|DER]
[-pubin]
[-certin]
[-rev]
[-sign]
[-verify]
[-verifyrecover]
[-encrypt]
[-decrypt]
[-derive]
[-pkeyopt opt:value]
[-hexdump]
[-asn1parse]
[-engine id]
```

DESCRIPTION

The **pkeyutl** command can be used to perform public key operations using any supported algorithm.

COMMAND OPTIONS

-in filename

This specifies the input filename to read data from or standard input if this option is not specified.

-out filename

specifies the output filename to write to or standard output by default.

-inkey file

the input key file, by default it should be a private key.

-keyform PEM|DER

the key format PEM, DER or ENGINE.

-passin arg

the input key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-peerkey file

the peer key file, used by key derivation (agreement) operations.

-peerform PEM|DER

the peer key format PEM, DER or ENGINE.

-engine id

specifying an engine (by its unique **id** string) will cause **pkeyutl** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

-pubin

the input file is a public key.

-certin

the input is a certificate containing a public key.

-rev

reverse the order of the input buffer. This is useful for some libraries (such as CryptoAPI) which represent the buffer in little endian format.

-sign

sign the input data and output the signed result. This requires a private key.

-verify

verify the input data against the signature file and indicate if the verification succeeded or failed.

-verifyrecover

verify the input data and output the recovered data.

-encrypt

encrypt the input data using a public key.

-decrypt

decrypt the input data using a private key.

-derive

derive a shared secret using the peer key.

-hexdump

hex dump the output data.

-asn1parse

asn1parse the output data, this is useful when combined with the **-verifyrecover** option when an ASN1 structure is signed.

NOTES

The operations and options supported vary according to the key algorithm and its implementation. The OpenSSL operations and options are indicated below.

Unless otherwise mentioned all algorithms support the **digest:alg** option which specifies the digest in use for sign, verify and verifyrecover operations. The value **alg** should represent a digest name as used in the EVP_get_digestbyname() function for example **sha1**.

RSA ALGORITHM

The RSA algorithm supports encrypt, decrypt, sign, verify and verifyrecover operations in general. Some padding modes only support some of these operations however.

-rsa_padding_mode:mode

This sets the RSA padding mode. Acceptable values for **mode** are **pkcs1** for PKCS#1 padding, **sslv23** for SSLv23 padding, **none** for no padding, **oaep** for **OAEP** mode, **x931** for X9.31 mode and **pss** for PSS.

In PKCS#1 padding if the message digest is not set then the supplied data is signed or verified directly instead of using a **DigestInfo** structure. If a digest is set then the a **DigestInfo** structure is used and its the length must correspond to the digest type.

For **oeap** mode only encryption and decryption is supported.

For **x931** if the digest type is set it is used to format the block data otherwise the first byte is used to specify the X9.31 digest ID. Sign, verify and verifyrecover are can be performed in this mode.

For **pss** mode only sign and verify are supported and the digest type must be specified.

rsa_pss_saltlen:len

For **pss** mode only this option specifies the salt length. Two special values are supported: -1 sets the salt length to the digest length. When signing -2 sets the salt length to the maximum permissible value. When verifying -2 causes the salt length to be automatically determined based on the **PSS** block structure.

DSA ALGORITHM

The DSA algorithm supports signing and verification operations only. Currently there are no additional options other than **digest**. Only the SHA1 digest can be used and this digest is assumed by default.

DH ALGORITHM

The DH algorithm only supports the derivation operation and no additional options.

EC ALGORITHM

The EC algorithm supports sign, verify and derive operations. The sign and verify operations use ECDSA and derive uses ECDH. Currently there are no additional options other than **digest**. Only the SHA1 digest can be used and this digest is assumed by default.

EXAMPLES

Sign some data using a private key:

```
openssl pkeyutl -sign -in file -inkey key.pem -out sig
```

Recover the signed data (e.g. if an RSA key is used):

```
openssl pkeyutl -verifyrecover -in sig -inkey key.pem
```

Verify the signature (e.g. a DSA key):

```
openssl pkeyutl -verify -in file -sigfile sig -inkey key.pem
```

Sign data using a message digest value (this is currently only valid for RSA):

```
openssl pkeyutl -sign -in file -inkey key.pem -out sig -pkeyopt digest:sha256
```

Derive a shared secret value:

```
openssl pkeyutl -derive -inkey key.pem -peerkey pubkey.pem -out secret
```

Name

rand — generate pseudo-random bytes

Synopsis

```
openssl rand
[-out file]
[-rand file(s)]
[-base64]
[-hex]
num
```

DESCRIPTION

The **rand** command outputs *num* pseudo-random bytes after seeding the random number generator once. As in other **openssl** command line tools, PRNG seeding uses the file *$HOME/***.rnd** or **.rnd** in addition to the files given in the **-rand** option. A new *$HOME*/**.rnd** or **.rnd** file will be written back if enough seeding was obtained from these sources.

OPTIONS

-out *file*

Write to *file* instead of standard output.

-rand *file(s)*

Use specified file or files or EGD socket (see RAND_egd(3)) for seeding the random number generator. Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-base64

Perform base64 encoding on the output.

-hex

Show the output as a hex string.

SEE ALSO

RAND_bytes(3)

[-nameopt]
[-reqopt]
[-subject]
[-subj arg]
[-batch]
[-verbose]
[-engine id]
```

DESCRIPTION

The **req** command primarily creates and processes certificate requests in PKCS#10 format. It can additionally create self signed certificates for use as root CAs for example.

COMMAND OPTIONS

-inform DER|PEM

> This specifies the input format. The **DER** option uses an ASN1 DER encoded form compatible with the PKCS#10. The **PEM** form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines.

-outform DER|PEM

> This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read a request from or standard input if this option is not specified. A request is only read if the creation options (**-new** and **-newkey**) are not specified.

-passin arg

the input file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-out filename

This specifies the output filename to write to or standard output by default.

-passout arg

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-text

prints out the certificate request in text form.

-subject

prints out the request subject (or certificate subject if **-x509** is specified)

-pubkey

outputs the public key.

-noout

this option prevents output of the encoded version of the request.

-modulus

this option prints out the value of the modulus of the public key contained in the request.

-verify

verifies the signature on the request.

-new

this option generates a new certificate request. It will prompt the user for the relevant field values. The actual fields prompted for and their maximum and minimum sizes are specified in the configuration file and any requested extensions.

If the **-key** option is not used it will generate a new RSA private key using information specified in the configuration file.

-subj arg

Replaces subject field of input request with specified data and outputs modified request. The arg must be formatted as */type0=value0/type1=value1/type2=...*, characters may be escaped by \ (backslash), no spaces are skipped.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-newkey arg

this option creates a new certificate request and a new private key. The argument takes one of several forms. **rsa:nbits**, where **nbits** is the number of bits, generates an RSA key **nbits** in size. If **nbits** is omitted, i.e. **-newkey rsa** specified, the default key size, specified in the configuration file is used.

All other algorithms support the **-newkey alg:file** form, where file may be an algorithm parameter file, created by the **genpkey -genparam** command or and X.509 certificate for a key with approriate algorithm.

param:file generates a key using the parameter file or certificate **file**, the algorithm is determined by the parameters. **algname:file** use algorithm **algname** and parameter file **file**: the two algorithms must match or an error occurs. **algname** just uses algorithm **algname**, and parameters, if neccessary should be specified via **-pkeyopt** parameter.

dsa:filename generates a DSA key using the parameters in the file **filename**. **ec:filename** generates EC key (usable both with ECDSA or ECDH algorithms), **gost2001:filename** generates GOST R 34.10-2001 key (requires **ccgost** engine configured in the configuration file). If just **gost2001** is specified a parameter set should be specified by **-pkeyopt paramset:X**

-pkeyopt opt:value

set the public key algorithm option **opt** to **value**. The precise set of options supported depends on the public key algorithm used and its implementation. See **KEY GENERATION OPTIONS** in the **genpkey** manual page for more details.

-key filename

This specifies the file to read the private key from. It also accepts PKCS#8 format private keys for PEM format files.

-keyform PEM|DER

the format of the private key file specified in the **-key** argument. PEM is the default.

-keyout filename

this gives the filename to write the newly created private key to. If this option is not specified then the filename present in the configuration file is used.

-nodes

if this option is specified then if a private key is created it will not be encrypted.

-[digest]

this specifies the message digest to sign the request with (such as **-md5**, **-sha1**). This overrides the digest algorithm specified in the configuration file.

Some public key algorithms may override this choice. For instance, DSA signatures always use SHA1, GOST R 34.10 signatures always use GOST R 34.11-94 (**-md_gost94**).

-config filename

this allows an alternative configuration file to be specified, this overrides the compile time filename or any specified in the **OPENSSL_CONF** environment variable.

-subj arg

sets subject name for new request or supersedes the subject name when processing a request. The arg must be formatted as */type0=value0/type1=value1/type2=…*, characters may be escaped by \ (backslash), no spaces are skipped.

-multivalue-rdn

this option causes the -subj argument to be interpreted with full support for multivalued RDNs. Example:

/DC=org/DC=OpenSSL/DC=users/UID=123456+CN=John Doe

If -multi-rdn is not used then the UID value is *123456+CN=John Doe*.

-x509

this option outputs a self signed certificate instead of a certificate request. This is typically used to generate a test certificate or a self signed root CA. The extensions added to the certificate (if any) are specified in the configuration file. Unless specified using the **set_serial** option **0** will be used for the serial number.

-days n

when the **-x509** option is being used this specifies the number of days to certify the certificate for. The default is 30 days.

-set_serial n

serial number to use when outputting a self signed certificate. This may be specified as a decimal value or a hex value if preceded by **0x**. It is possible to use negative serial numbers but this is not recommended.

-extensions section
-reqexts section

these options specify alternative sections to include certificate extensions (if the **-x509** option is present) or certificate request extensions. This allows several different sections to be used in the same configuration file to specify requests for a variety of purposes.

-utf8

this option causes field values to be interpreted as UTF8 strings, by default they are interpreted as ASCII. This means that the field values, whether prompted from a terminal or obtained from a configuration file, must be valid UTF8 strings.

-nameopt option

option which determines how the subject or issuer names are displayed. The **option** argument can be a single option or multiple options separated by commas. Alternatively the **-nameopt** switch may be used more than once to set multiple options. See the x509(1) manual page for details.

-reqopt

customise the output format used with **-text**. The **option** argument can be a single option or multiple options separated by commas.

See discission of the **-certopt** parameter in the **x509** command.

-asn1-kludge

by default the **req** command outputs certificate requests containing no attributes in the correct PKCS#10 format. However certain CAs will only accept requests containing no attributes in an invalid form: this option produces this invalid format.

More precisely the **Attributes** in a PKCS#10 certificate request are defined as a **SET OF Attribute**. They are **not OPTIONAL** so if no attributes are present then they should be encoded as an empty **SET OF**. The invalid form does not include the empty **SET OF** whereas the correct form does.

It should be noted that very few CAs still require the use of this option.

-no-asn1-kludge

Reverses effect of **-asn1-kludge**

-newhdr

Adds the word **NEW** to the PEM file header and footer lines on the outputted request. Some software (Netscape certificate server) and some CAs need this.

-batch

non-interactive mode.

-verbose

print extra details about the operations being performed.

-engine id

specifying an engine (by its unique **id** string) will cause **req** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

-keygen_engine id

specifies an engine (by its unique **id** string) which would be used for key generation operations.

CONFIGURATION FILE FORMAT

The configuration options are specified in the **req** section of the configuration file. As with all configuration files if no value is specified in the specific section (i.e. **req**) then the initial unnamed or **default** section is searched too.

The options available are described in detail below.

input_password output_password

The passwords for the input private key file (if present) and the output private key file (if one will be created). The command line options **passin** and **passout** override the configuration file values.

default_bits

This specifies the default key size in bits. If not specified then 512 is used. It is used if the **-new** option is used. It can be overridden by using the **-newkey** option.

default_keyfile

This is the default filename to write a private key to. If not specified the key is written to standard output. This can be overridden by the **-keyout** option.

oid_file

This specifies a file containing additional **OBJECT IDENTIFIERS**. Each line of the file should consist of the numerical form of the object identifier followed by white space then the short name followed by white space and finally the long name.

oid_section

This specifies a section in the configuration file containing extra object identifiers. Each line should consist of the short name of the object identifier followed by **=** and the numerical form. The short and long names are the same when this option is used.

RANDFILE

This specifies a filename in which random number seed information is placed and read from, or an EGD socket (see RAND_egd(3)). It is used for private key generation.

encrypt_key

If this is set to **no** then if a private key is generated it is **not** encrypted. This is equivalent to the **-nodes** command line option. For compatibility **encrypt_rsa_key** is an equivalent option.

default_md

This option specifies the digest algorithm to use. Possible values include **md5 sha1 mdc2**. If not present then MD5 is used. This option can be overridden on the command line.

string_mask

This option masks out the use of certain string types in certain fields. Most users will not need to change this option.

It can be set to several values **default** which is also the default option uses PrintableStrings, T61Strings and BMPStrings if the **pkix** value is used then only PrintableStrings and BMPStrings will be used. This follows the PKIX recommendation in RFC2459. If the **utf8only** option is used then only UTF8Strings will be used: this is the PKIX recommendation in RFC2459 after 2003. Finally the **nombstr** option just uses PrintableStrings and T61Strings: certain software has problems with BMPStrings and UTF8Strings: in particular Netscape.

req_extensions

this specifies the configuration file section containing a list of extensions to add to the certificate request. It can be overridden by the **-reqexts** command line switch. See the x509v3_config(5) manual page for details of the extension section format.

x509_extensions

this specifies the configuration file section containing a list of extensions to add to certificate generated when the **-x509** switch is used. It can be overridden by the **-extensions** command line switch.

prompt

if set to the value **no** this disables prompting of certificate fields and just takes values from the config file directly. It also changes the expected format of the **distinguished_name** and **attributes** sections.

utf8

if set to the value **yes** then field values to be interpreted as UTF8 strings, by default they are interpreted as ASCII. This means that the field values, whether prompted from a terminal or obtained from a configuration file, must be valid UTF8 strings.

attributes

this specifies the section containing any request attributes: its format is the same as **distinguished_name**. Typically these may contain the challengePassword or unstructuredName types. They are currently ignored by OpenSSL's request signing utilities but some CAs might want them.

distinguished_name

This specifies the section containing the distinguished name fields to prompt for when generating a certificate or certificate request. The format is described in the next section.

DISTINGUISHED NAME AND ATTRIBUTE SECTION FORMAT

There are two separate formats for the distinguished name and attribute sections. If the **prompt** option is set to **no** then these sections just consist of field names and values: for example,

```
CN=My Name
OU=My Organization
```

```
emailAddress=someone@somewhere.org
```

This allows external programs (e.g. GUI based) to generate a template file with all the field names and values and just pass it to **req**. An example of this kind of configuration file is contained in the **EXAMPLES** section.

Alternatively if the **prompt** option is absent or not set to **no** then the file contains field prompting information. It consists of lines of the form:

```
fieldName="prompt"
fieldName_default="default field value"
fieldName_min= 2
fieldName_max= 4
```

"fieldName" is the field name being used, for example commonName (or CN). The "prompt" string is used to ask the user to enter the relevant details. If the user enters nothing then the default value is used if no default value is present then the field is omitted. A field can still be omitted if a default value is present if the user just enters the '.' character.

The number of characters entered must be between the fieldName_min and fieldName_max limits: there may be additional restrictions based on the field being used (for example countryName can only ever be two characters long and must fit in a PrintableString).

Some fields (such as organizationName) can be used more than once in a DN. This presents a problem because configuration files will not recognize the same name occurring twice. To avoid this problem if the fieldName contains some characters followed by a full stop they will be ignored. So for example a second organizationName can be input by calling it "1.organizationName".

The actual permitted field names are any object identifier short or long names. These are compiled into OpenSSL and include the usual values such as commonName, countryName, localityName, organizationName, organizationalUnitName, stateOrProvinceName. Additionally emailAddress is include as well as name, surname, givenName initials and dnQualifier.

Additional object identifiers can be defined with the **oid_file** or **oid_section** options in the configuration file. Any additional fields will be treated as though they were a DirectoryString.

EXAMPLES

Examine and verify certificate request:

```
openssl req -in req.pem -text -verify -noout
```

Create a private key and then generate a certificate request from it:

```
openssl genrsa -out key.pem 1024
openssl req -new -key key.pem -out req.pem
```

The same but just using req:

```
openssl req -newkey rsa:1024 -keyout key.pem -out req.pem
```

Generate a self signed root certificate:

```
openssl req -x509 -newkey rsa:1024 -keyout key.pem -out req.pem
```

Example of a file pointed to by the **oid_file** option:

```
1.2.3.4        shortName       A longer Name
1.2.3.6        otherName       Other longer Name
```

Example of a section pointed to by **oid_section** making use of variable expansion:

```
testoid1=1.2.3.5
testoid2=${testoid1}.6
```

Sample configuration file prompting for field values:

```
[ req ]
default_bits           = 1024
default_keyfile        = privkey.pem
distinguished_name     = req_distinguished_name
attributes             = req_attributes
x509_extensions        = v3_ca

dirstring_type = nobmp

[ req_distinguished_name ]
countryName                    = Country Name (2 letter code)
countryName_default            = AU
countryName_min                = 2
countryName_max                = 2

localityName                   = Locality Name (eg, city)

organizationalUnitName         = Organizational Unit Name (eg, section)

commonName                     = Common Name (eg, YOUR name)
commonName_max                 = 64

emailAddress                   = Email Address
emailAddress_max               = 40

[ req_attributes ]
challengePassword              = A challenge password
challengePassword_min          = 4
challengePassword_max          = 20

[ v3_ca ]

subjectKeyIdentifier=hash
authorityKeyIdentifier=keyid:always,issuer:always
basicConstraints = CA:true
```

Sample configuration containing all field values:

```
RANDFILE               = $ENV::HOME/.rnd

[ req ]
default_bits           = 1024
default_keyfile        = keyfile.pem
distinguished_name     = req_distinguished_name
attributes             = req_attributes
prompt                 = no
output_password        = mypass

[ req_distinguished_name ]
C                      = GB
ST                     = Test State or Province
L                      = Test Locality
O                      = Organization Name
OU                     = Organizational Unit Name
CN                     = Common Name
emailAddress           = test@email.address

[ req_attributes ]
challengePassword              = A challenge password
```

NOTES

The header and footer lines in the **PEM** format are normally:

```
-----BEGIN CERTIFICATE REQUEST-----
-----END CERTIFICATE REQUEST-----
```

some software (some versions of Netscape certificate server) instead needs:

```
-----BEGIN NEW CERTIFICATE REQUEST-----
-----END NEW CERTIFICATE REQUEST-----
```

which is produced with the **-newhdr** option but is otherwise compatible. Either form is accepted transparently on input.

The certificate requests generated by **Xenroll** with MSIE have extensions added. It includes the **keyUsage** extension which determines the type of key (signature only or general purpose) and any additional OIDs entered by the script in an extendedKeyUsage extension.

DIAGNOSTICS

The following messages are frequently asked about:

```
Using configuration from /some/path/openssl.cnf
Unable to load config info
```

This is followed some time later by…

```
unable to find 'distinguished_name' in config
problems making Certificate Request
```

The first error message is the clue: it can't find the configuration file! Certain operations (like examining a certificate request) don't need a configuration file so its use isn't enforced. Generation of certificates or requests however does need a configuration file. This could be regarded as a bug.

Another puzzling message is this:

```
Attributes:
    a0:00
```

this is displayed when no attributes are present and the request includes the correct empty **SET OF** structure (the DER encoding of which is 0xa0 0x00). If you just see:

```
Attributes:
```

then the **SET OF** is missing and the encoding is technically invalid (but it is tolerated). See the description of the command line option **-asn1-kludge** for more information.

ENVIRONMENT VARIABLES

The variable **OPENSSL_CONF** if defined allows an alternative configuration file location to be specified, it will be overridden by the **-config** command line switch if it is present. For compatibility reasons the **SSLEAY_CONF** environment variable serves the same purpose but its use is discouraged.

BUGS

OpenSSL's handling of T61Strings (aka TeletexStrings) is broken: it effectively treats them as ISO-8859-1 (Latin 1), Netscape and MSIE have similar behaviour. This can cause problems if you need characters that aren't available in PrintableStrings and you don't want to or can't use BMPStrings.

As a consequence of the T61String handling the only correct way to represent accented characters in OpenSSL is to use a BMPString: unfortunately Netscape currently chokes on these. If you have to use accented characters with Netscape and MSIE then you currently need to use the invalid T61String form.

The current prompting is not very friendly. It doesn't allow you to confirm what you've just entered. Other things like extensions in certificate requests are statically defined in the configuration file. Some of these: like an email address in subjectAltName should be input by the user.

[-pubin]
[-pubout]
[-RSAPublicKey_in]
[-RSAPublicKey_out]
[-engine id]
```

DESCRIPTION

The **rsa** command processes RSA keys. They can be converted between various forms and their components printed out. **Note** this command uses the traditional SSLeay compatible format for private key encryption: newer applications should use the more secure PKCS#8 format using the **pkcs8** utility.

COMMAND OPTIONS

-inform DER|NET|PEM

This specifies the input format. The **DER** option uses an ASN1 DER encoded form compatible with the PKCS#1 RSAPrivateKey or SubjectPublicKeyInfo format. The **PEM** form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines. On input PKCS#8 format private keys are also accepted. The **NET** form is a format is described in the **NOTES** section.

-outform DER|NET|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read a key from or standard input if this option is not specified. If the key is encrypted a pass phrase will be prompted for.

-passin arg

the input file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-out filename

This specifies the output filename to write a key to or standard output if this option is not specified. If any encryption options are set then a pass phrase will be prompted for. The output filename should **not** be the same as the input filename.

-passout password

the output file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-sgckey

use the modified NET algorithm used with some versions of Microsoft IIS and SGC keys.

-aes128|-aes192|-aes256|-camellia128|-camellia192|-camellia256|-des|-des3|-idea

These options encrypt the private key with the specified cipher before outputting it. A pass phrase is prompted for. If none of these options is specified the key is written in plain text. This means that using the **rsa** utility to read in an encrypted key with no encryption option can be used to remove the pass phrase from a key, or by setting the encryption options it can be use to add or change the pass phrase. These options can only be used with PEM format output files.

-text

prints out the various public or private key components in plain text in addition to the encoded version.

-noout

this option prevents output of the encoded version of the key.

-modulus

this option prints out the value of the modulus of the key.

-check

this option checks the consistency of an RSA private key.

-pubin

by default a private key is read from the input file: with this option a public key is read instead.

-pubout

by default a private key is output: with this option a public key will be output instead. This option is automatically set if the input is a public key.

-RSAPublicKey_in, **-RSAPublicKey_out**

like **-pubin** and **-pubout** except **RSAPublicKey** format is used instead.

-engine id

specifying an engine (by its unique **id** string) will cause **rsa** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

NOTES

The PEM private key format uses the header and footer lines:

```
-----BEGIN RSA PRIVATE KEY-----
-----END RSA PRIVATE KEY-----
```

The PEM public key format uses the header and footer lines:

```
-----BEGIN PUBLIC KEY-----
-----END PUBLIC KEY-----
```

The PEM **RSAPublicKey** format uses the header and footer lines:

```
-----BEGIN RSA PUBLIC KEY-----
-----END RSA PUBLIC KEY-----
```

The **NET** form is a format compatible with older Netscape servers and Microsoft IIS .key files, this uses unsalted RC4 for its encryption. It is not very secure and so should only be used when necessary.

Some newer version of IIS have additional data in the exported .key files. To use these with the utility, view the file with a binary editor and look for the string "private-key", then trace back to the byte sequence 0x30, 0x82 (this is an ASN1 SEQUENCE). Copy all the data from this point onwards to another file and use that as the input to the **rsa** utility with the **-inform NET** option. If you get an error after entering the password try the **-sgckey** option.

EXAMPLES

To remove the pass phrase on an RSA private key:

```
openssl rsa -in key.pem -out keyout.pem
```

To encrypt a private key using triple DES:

```
openssl rsa -in key.pem -des3 -out keyout.pem
```

To convert a private key from PEM to DER format:

```
openssl rsa -in key.pem -outform DER -out keyout.der
```

To print out the components of a private key to standard output:

```
openssl rsa -in key.pem -text -noout
```

To just output the public part of a private key:

```
openssl rsa -in key.pem -pubout -out pubkey.pem
```

Output the public part of a private key in **RSAPublicKey** format:

```
openssl rsa -in key.pem -RSAPublicKey_out -out pubkey.pem
```

BUGS

The command line password arguments don't currently work with **NET** format.

There should be an option that automatically handles .key files, without having to manually edit them.

Name

rsautl — RSA utility

Synopsis

```
opensslrsautl
[-in file]
[-out file]
[-inkey file]
[-pubin]
[-certin]
[-sign]
[-verify]
[-encrypt]
[-decrypt]
[-pkcs]
[-ssl]
[-raw]
[-hexdump]
[-asn1parse]
```

DESCRIPTION

The **rsautl** command can be used to sign, verify, encrypt and decrypt data using the RSA algorithm.

COMMAND OPTIONS

-in filename

This specifies the input filename to read data from or standard input if this option is not specified.

-out filename

specifies the output filename to write to or standard output by default.

-inkey file

the input key file, by default it should be an RSA private key.

-pubin

the input file is an RSA public key.

-certin

the input is a certificate containing an RSA public key.

-sign

sign the input data and output the signed result. This requires and RSA private key.

-verify

verify the input data and output the recovered data.

-encrypt

encrypt the input data using an RSA public key.

-decrypt

decrypt the input data using an RSA private key.

-pkcs, -oaep, -ssl, -raw

the padding to use: PKCS#1 v1.5 (the default), PKCS#1 OAEP, special padding used in SSL v2 backwards compatible handshakes, or no padding, respectively. For signatures, only **-pkcs** and **-raw** can be used.

-hexdump

hex dump the output data.

-asn1parse

asn1parse the output data, this is useful when combined with the **-verify** option.

NOTES

rsautl because it uses the RSA algorithm directly can only be used to sign or verify small pieces of data.

EXAMPLES

Sign some data using a private key:

```
openssl rsautl -sign -in file -inkey key.pem -out sig
```

Recover the signed data

```
openssl rsautl -verify -in sig -inkey key.pem
```

Examine the raw signed data:

```
openssl rsautl -verify -in file -inkey key.pem -raw -hexdump

0000 - 00 01 ff ff ff ff ff ff-ff ff ff ff ff ff ff ff   ……..........
0010 - ff ff ff ff ff ff ff ff-ff ff ff ff ff ff ff ff   ……..........
0020 - ff ff ff ff ff ff ff ff-ff ff ff ff ff ff ff ff   ……..........
0030 - ff ff ff ff ff ff ff ff-ff ff ff ff ff ff ff ff   ……..........
0040 - ff ff ff ff ff ff ff ff-ff ff ff ff ff ff ff ff   ……..........
0050 - ff ff ff ff ff ff ff ff-ff ff ff ff ff ff ff ff   ……..........
0060 - ff ff ff ff ff ff ff ff-ff ff ff ff ff ff ff ff   ……..........
0070 - ff ff ff ff 00 68 65 6c-6c 6f 20 77 6f 72 6c 64   …..hello world
```

The PKCS#1 block formatting is evident from this. If this was done using encrypt and decrypt the block would have been of type 2 (the second byte) and random padding data visible instead of the 0xff bytes.

It is possible to analyse the signature of certificates using this utility in conjunction with **asn1parse**. Consider the self signed example in certs/pca-cert.pem . Running **asn1parse** as follows yields:

```
openssl asn1parse -in pca-cert.pem

  0:d=0  hl=4 l= 742 cons: SEQUENCE
  4:d=1  hl=4 l= 591 cons:  SEQUENCE
  8:d=2  hl=2 l=   3 cons:   cont [ 0 ]
 10:d=3  hl=2 l=   1 prim:    INTEGER           :02
 13:d=2  hl=2 l=   1 prim:   INTEGER           :00
 16:d=2  hl=2 l=  13 cons:   SEQUENCE
 18:d=3  hl=2 l=   9 prim:    OBJECT            :md5WithRSAEncryption
 29:d=3  hl=2 l=   0 prim:    NULL
 31:d=2  hl=2 l=  92 cons:   SEQUENCE
 33:d=3  hl=2 l=  11 cons:    SET
 35:d=4  hl=2 l=   9 cons:     SEQUENCE
 37:d=5  hl=2 l=   3 prim:      OBJECT            :countryName
 42:d=5  hl=2 l=   2 prim:      PRINTABLESTRING   :AU
….
599:d=1  hl=2 l=  13 cons:  SEQUENCE
601:d=2  hl=2 l=   9 prim:   OBJECT            :md5WithRSAEncryption
612:d=2  hl=2 l=   0 prim:   NULL
614:d=1  hl=3 l= 129 prim:  BIT STRING
```

The final BIT STRING contains the actual signature. It can be extracted with:

```
openssl asn1parse -in pca-cert.pem -out sig -noout -strparse 614
```

The certificate public key can be extracted with:

```
openssl x509 -in test/testx509.pem -pubkey -noout >pubkey.pem
```

The signature can be analysed with:

```
openssl rsautl -in sig -verify -asn1parse -inkey pubkey.pem -pubin

 0:d=0  hl=2 l=  32 cons: SEQUENCE
 2:d=1  hl=2 l=  12 cons:  SEQUENCE
 4:d=2  hl=2 l=   8 prim:   OBJECT            :md5
14:d=2  hl=2 l=   0 prim:   NULL
16:d=1  hl=2 l=  16 prim:  OCTET STRING
   0000 - f3 46 9e aa 1a 4a 73 c9-37 ea 93 00 48 25 08 b5   .F…Js.7…H%..
```

This is the parsed version of an ASN1 DigestInfo structure. It can be seen that the digest used was md5. The actual part of the certificate that was signed can be extracted with:

```
openssl asn1parse -in pca-cert.pem -out tbs -noout -strparse 4
```

and its digest computed with:

```
openssl md5 -c tbs
MD5(tbs)= f3:46:9e:aa:1a:4a:73:c9:37:ea:93:00:48:25:08:b5
```

which it can be seen agrees with the recovered value above.

DESCRIPTION

The **s_client** command implements a generic SSL/TLS client which connects to a remote host using SSL/TLS. It is a *very* useful diagnostic tool for SSL servers.

OPTIONS

-connect host:port

> This specifies the host and optional port to connect to. If not specified then an attempt is made to connect to the local host on port 4433.

-servername name

Set the TLS SNI (Server Name Indication) extension in the ClientHello message.

-cert certname

The certificate to use, if one is requested by the server. The default is not to use a certificate.

-certform format

The certificate format to use: DER or PEM. PEM is the default.

-key keyfile

The private key to use. If not specified then the certificate file will be used.

-keyform format

The private format to use: DER or PEM. PEM is the default.

-pass arg

the private key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-verify depth

The verify depth to use. This specifies the maximum length of the server certificate chain and turns on server certificate verification. Currently the verify operation continues after errors so all the problems with a certificate chain can be seen. As a side effect the connection will never fail due to a server certificate verify failure.

-verify_return_error

Return verification errors instead of continuing. This will typically abort the handshake with a fatal error.

-CApath directory

The directory to use for server certificate verification. This directory must be in "hash format", see **verify** for more information. These are also used when building the client certificate chain.

-CAfile file

A file containing trusted certificates to use during server authentication and to use when attempting to build the client certificate chain.

-purpose, -ignore_critical, -issuer_checks, -crl_check, -crl_check_all, -policy_check, -extended_crl, -x509_strict, -policy, -check_ss_sig, -no_alt_chains

Set various certificate chain valiadition option. See the **verify** manual page for details.

-reconnect

reconnects to the same server 5 times using the same session ID, this can be used as a test that session caching is working.

-pause

pauses 1 second between each read and write call.

-showcerts

display the whole server certificate chain: normally only the server certificate itself is displayed.

-prexit

print session information when the program exits. This will always attempt to print out information even if the connection fails. Normally information will only be printed out once if the connection succeeds. This option is useful because the cipher in use may be renegotiated or the connection may fail because a client certificate is required or is requested only after an attempt is made to access a certain URL. Note: the output produced by this option is not always accurate because a connection might never have been established.

-state

prints out the SSL session states.

-debug

print extensive debugging information including a hex dump of all traffic.

-msg

show all protocol messages with hex dump.

-nbio_test

tests non-blocking I/O

-nbio

turns on non-blocking I/O

-crlf

this option translated a line feed from the terminal into CR+LF as required by some servers.

-ign_eof

inhibit shutting down the connection when end of file is reached in the input.

-quiet

inhibit printing of session and certificate information. This implicitly turns on **-ign_eof** as well.

-no_ign_eof

shut down the connection when end of file is reached in the input. Can be used to override the implicit **-ign_eof** after **-quiet**.

-psk_identity identity

Use the PSK identity **identity** when using a PSK cipher suite.

-psk key

Use the PSK key **key** when using a PSK cipher suite. The key is given as a hexadecimal number without leading 0x, for example -psk 1a2b3c4d.

-ssl2, **-ssl3**, **-tls1**, **-tls1_1**, **-tls1_2**, **-no_ssl2**, **-no_ssl3**, **-no_tls1**, **-no_tls1_1**, **-no_tls1_2**

These options require or disable the use of the specified SSL or TLS protocols. By default the initial handshake uses a *version-flexible* method which will negotiate the highest mutually supported protocol version.

-bugs

there are several known bug in SSL and TLS implementations. Adding this option enables various workarounds.

-cipher cipherlist

this allows the cipher list sent by the client to be modified. Although the server determines which cipher suite is used it should take the first supported cipher in the list sent by the client. See the **ciphers** command for more information.

-serverpref

use the server's cipher preferences; only used for SSLV2.

-starttls protocol

send the protocol-specific message(s) to switch to TLS for communication. **protocol** is a keyword for the intended protocol. Currently, the only supported keywords are "smtp", "pop3", "imap", and "ftp".

-tlsextdebug

print out a hex dump of any TLS extensions received from the server.

-no_ticket

disable RFC4507bis session ticket support.

-sess_out filename

output SSL session to **filename**

-sess_in sess.pem

load SSL session from **filename**. The client will attempt to resume a connection from this session.

-engine id

specifying an engine (by its unique **id** string) will cause **s_client** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-status

sends a certificate status request to the server (OCSP stapling). The server response (if any) is printed out.

-nextprotoneg protocols

enable Next Protocol Negotiation TLS extension and provide a list of comma-separated protocol names that the client should advertise support for. The list should contain most wanted protocols first. Protocol names are printable ASCII strings, for example "http/1.1" or "spdy/3". Empty list of protocols is treated specially and will cause the client to advertise support for the TLS extension but disconnect just after reciving ServerHello with a list of server supported protocols.

CONNECTED COMMANDS

If a connection is established with an SSL server then any data received from the server is displayed and any key presses will be sent to the server. When used interactively (which means neither **-quiet** nor **-ign_eof** have been given), the session will be renegotiated if the line begins with an **R**, and if the line begins with a **Q** or if end of file is reached, the connection will be closed down.

NOTES

s_client can be used to debug SSL servers. To connect to an SSL HTTP server the command:

```
openssl s_client -connect servername:443
```

would typically be used (https uses port 443). If the connection succeeds then an HTTP command can be given such as "GET /" to retrieve a web page.

If the handshake fails then there are several possible causes, if it is nothing obvious like no client certificate then the **-bugs**, **-ssl2**, **-ssl3**, **-tls1**, **-no_ssl2**, **-no_ssl3**, **-no_tls1** options can be tried in case it is a buggy server. In particular you should play with these options **before** submitting a bug report to an OpenSSL mailing list.

A frequent problem when attempting to get client certificates working is that a web client complains it has no certificates or gives an empty list to choose from. This is normally because the server is not sending the clients certificate authority in its "acceptable CA list" when it requests a certificate. By using **s_client** the CA list can be viewed and checked. However some servers only request client authentication after a specific URL is requested. To obtain the list in this case it is necessary to use the **-prexit** option and send an HTTP request for an appropriate page.

If a certificate is specified on the command line using the **-cert** option it will not be used unless the server specifically requests a client certificate. Therefor merely including a client certificate on the command line is no guarantee that the certificate works.

If there are problems verifying a server certificate then the **-showcerts** option can be used to show the whole chain.

Since the SSLv23 client hello cannot include compression methods or extensions these will only be supported if its use is disabled, for example by using the **-no_sslv2** option.

The **s_client** utility is a test tool and is designed to continue the handshake after any certificate verification errors. As a result it will accept any certificate chain (trusted or not) sent by the peer. None test applications should **not** do this as it makes them vulnerable to a MITM attack. This behaviour can be changed by with the **-verify_return_error** option: any verify errors are then returned aborting the handshake.

BUGS

Because this program has a lot of options and also because some of the techniques used are rather old, the C source of s_client is rather hard to read and not a model of how things should be done. A typical SSL client program would be much simpler.

The **-prexit** option is a bit of a hack. We should really report information whenever a session is renegotiated.

DESCRIPTION

The **s_server** command implements a generic SSL/TLS server which listens for connections on a given port using SSL/TLS.

OPTIONS

-accept port

the TCP port to listen on for connections. If not specified 4433 is used.

-context id

sets the SSL context id. It can be given any string value. If this option is not present a default value will be used.

-cert certname

The certificate to use, most servers cipher suites require the use of a certificate and some require a certificate with a certain public key type: for example the DSS cipher suites require a certificate containing a DSS (DSA) key. If not specified then the filename "server.pem" will be used.

-certform format

The certificate format to use: DER or PEM. PEM is the default.

-key keyfile

The private key to use. If not specified then the certificate file will be used.

-keyform format

The private format to use: DER or PEM. PEM is the default.

-pass arg

the private key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-dcert filename, **-dkey keyname**

specify an additional certificate and private key, these behave in the same manner as the **-cert** and **-key** options except there is no default if they are not specified (no additional certificate and key is used). As noted above some cipher suites require a certificate containing a key of a certain type. Some cipher suites need a certificate carrying an RSA key and some a DSS (DSA) key. By using RSA and DSS certificates and keys a server can support clients which only support RSA or DSS cipher suites by using an appropriate certificate.

-dcertform format, **-dkeyform format**, **-dpass arg**

additional certificate and private key format and passphrase respectively.

-nocert

if this option is set then no certificate is used. This restricts the cipher suites available to the anonymous ones (currently just anonymous DH).

-dhparam filename

the DH parameter file to use. The ephemeral DH cipher suites generate keys using a set of DH parameters. If not specified then an attempt is made to load the parameters from the server certificate file. If this fails then a static set of parameters hard coded into the s_server program will be used.

-no_dhe

if this option is set then no DH parameters will be loaded effectively disabling the ephemeral DH cipher suites.

-no_ecdhe

if this option is set then no ECDH parameters will be loaded effectively disabling the ephemeral ECDH cipher suites.

-no_tmp_rsa

certain export cipher suites sometimes use a temporary RSA key, this option disables temporary RSA key generation.

-verify depth, **-Verify depth**

The verify depth to use. This specifies the maximum length of the client certificate chain and makes the server request a certificate from the client. With the **-verify** option a certificate is requested but the client does not have to send one, with the **-Verify** option the client must supply a certificate or an error occurs.

If the ciphersuite cannot request a client certificate (for example an anonymous ciphersuite or PSK) this option has no effect.

-crl_check, **-crl_check_all**

Check the peer certificate has not been revoked by its CA. The CRL(s) are appended to the certificate file. With the **-crl_check_all** option all CRLs of all CAs in the chain are checked.

-CApath directory

The directory to use for client certificate verification. This directory must be in "hash format", see **verify** for more information. These are also used when building the server certificate chain.

-CAfile file

A file containing trusted certificates to use during client authentication and to use when attempting to build the server certificate chain. The list is also used in the list of acceptable client CAs passed to the client when a certificate is requested.

-no_alt_chains

See the **verify** manual page for details.

-state

prints out the SSL session states.

-debug

print extensive debugging information including a hex dump of all traffic.

-msg

show all protocol messages with hex dump.

-nbio_test

tests non blocking I/O

-nbio

turns on non blocking I/O

-crlf

this option translated a line feed from the terminal into CR+LF.

-quiet

inhibit printing of session and certificate information.

-psk_hint hint

Use the PSK identity hint **hint** when using a PSK cipher suite.

-psk key

Use the PSK key **key** when using a PSK cipher suite. The key is given as a hexadecimal number without leading 0x, for example -psk 1a2b3c4d.

-ssl2, **-ssl3**, **-tls1**, **-tls1_1**, **-tls1_2**, **-no_ssl2**, **-no_ssl3**, **-no_tls1**, **-no_tls1_1**, **-no_tls1_2**

These options require or disable the use of the specified SSL or TLS protocols. By default the initial handshake uses a *version-flexible* method which will negotiate the highest mutually supported protocol version.

-bugs

there are several known bug in SSL and TLS implementations. Adding this option enables various workarounds.

-hack

this option enables a further workaround for some some early Netscape SSL code (?).

-cipher cipherlist

this allows the cipher list used by the server to be modified. When the client sends a list of supported ciphers the first client cipher also included in the server list is used. Because the client specifies the preference order, the order of the server cipherlist irrelevant. See the **ciphers** command for more information.

-serverpref

use the server's cipher preferences, rather than the client's preferences.

-tlsextdebug

print out a hex dump of any TLS extensions received from the server.

-no_ticket

disable RFC4507bis session ticket support.

-www

sends a status message back to the client when it connects. This includes lots of information about the ciphers used and various session parameters. The output is in HTML format so this option will normally be used with a web browser.

-WWW

emulates a simple web server. Pages will be resolved relative to the current directory, for example if the URL https://myhost/page.html is requested the file ./page.html will be loaded.

-HTTP

emulates a simple web server. Pages will be resolved relative to the current directory, for example if the URL https://myhost/page.html is requested the file ./page.html will be loaded. The files loaded are assumed to contain a complete and correct HTTP response (lines that are part of the HTTP response line and headers must end with CRLF).

-engine id

specifying an engine (by its unique **id** string) will cause **s_server** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

-id_prefix arg

generate SSL/TLS session IDs prefixed by **arg**. This is mostly useful for testing any SSL/TLS code (eg. proxies) that wish to deal with multiple servers, when each of which might be generating a unique range of session IDs (eg. with a certain prefix).

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

-status

enables certificate status request support (aka OCSP stapling).

-status_verbose

enables certificate status request support (aka OCSP stapling) and gives a verbose printout of the OCSP response.

-status_timeout nsec

sets the timeout for OCSP response to **nsec** seconds.

-status_url url

sets a fallback responder URL to use if no responder URL is present in the server certificate. Without this option an error is returned if the server certificate does not contain a responder address.

-nextprotoneg protocols

enable Next Protocol Negotiation TLS extension and provide a comma-separated list of supported protocol names. The list should contain most wanted protocols first. Protocol names are printable ASCII strings, for example "http/1.1" or "spdy/3".

CONNECTED COMMANDS

If a connection request is established with an SSL client and neither the **-www** nor the **-WWW** option has been used then normally any data received from the client is displayed and any key presses will be sent to the client.

Certain single letter commands are also recognized which perform special operations: these are listed below.

q end the current SSL connection but still accept new connections.

Q end the current SSL connection and exit.

r renegotiate the SSL session.

R renegotiate the SSL session and request a client certificate.

P send some plain text down the underlying TCP connection: this should cause the client to disconnect due to a protocol violation.

S print out some session cache status information.

NOTES

s_server can be used to debug SSL clients. To accept connections from a web browser the command:

```
openssl s_server -accept 443 -www
```

can be used for example.

Most web browsers (in particular Netscape and MSIE) only support RSA cipher suites, so they cannot connect to servers which don't use a certificate carrying an RSA key or a version of OpenSSL with RSA disabled.

Although specifying an empty list of CAs when requesting a client certificate is strictly speaking a protocol violation, some SSL clients interpret this to mean any CA is acceptable. This is useful for debugging purposes.

The session parameters can printed out using the **sess_id** program.

BUGS

Because this program has a lot of options and also because some of the techniques used are rather old, the C source of s_server is rather hard to read and not a model of how things should be done. A typical SSL server program would be much simpler.

The output of common ciphers is wrong: it just gives the list of ciphers that OpenSSL recognizes and the client supports.

There should be a way for the **s_server** program to print out details of any unknown cipher suites a client says it supports.

HISTORY

The -no_alt_chains options was first added to OpenSSL 1.0.1n and 1.0.2b.

Name

s_time — SSL/TLS performance timing program

Synopsis

```
openssls_time
[-connect host:port]
[-www page]
[-cert filename]
[-key filename]
[-CApath directory]
[-CAfile filename]
[-reuse]
[-new]
[-verify depth]
[-nbio]
[-time seconds]
[-ssl2]
[-ssl3]
[-bugs]
[-cipher cipherlist]
```

DESCRIPTION

The **s_time** command implements a generic SSL/TLS client which connects to a remote host using SSL/TLS. It can request a page from the server and includes the time to transfer the payload data in its timing measurements. It measures the number of connections within a given timeframe, the amount of data transferred (if any), and calculates the average time spent for one connection.

OPTIONS

-connect host:port

This specifies the host and optional port to connect to.

-www page

This specifies the page to GET from the server. A value of '/' gets the index.htm[l] page. If this parameter is not specified, then **s_time** will only perform the handshake to establish SSL connections but not transfer any payload data.

-cert certname

The certificate to use, if one is requested by the server. The default is not to use a certificate. The file is in PEM format.

-key keyfile

The private key to use. If not specified then the certificate file will be used. The file is in PEM format.

-verify depth

The verify depth to use. This specifies the maximum length of the server certificate chain and turns on server certificate verification. Currently the verify operation continues after errors so all the problems with a certificate chain can be seen. As a side effect the connection will never fail due to a server certificate verify failure.

-CApath directory

The directory to use for server certificate verification. This directory must be in "hash format", see **verify** for more information. These are also used when building the client certificate chain.

-CAfile file

A file containing trusted certificates to use during server authentication and to use when attempting to build the client certificate chain.

-new

performs the timing test using a new session ID for each connection. If neither **-new** nor **-reuse** are specified, they are both on by default and executed in sequence.

-reuse

performs the timing test using the same session ID; this can be used as a test that session caching is working. If neither **-new** nor **-reuse** are specified, they are both on by default and executed in sequence.

-nbio

turns on non-blocking I/O.

-ssl2, **-ssl3**

these options disable the use of certain SSL or TLS protocols. By default the initial handshake uses a method which should be compatible with all servers and permit them to use SSL v3, SSL v2 or TLS as appropriate. The timing program is not as rich in options to turn protocols on and off as the s_client(1) program and may not connect to all servers.

Unfortunately there are a lot of ancient and broken servers in use which cannot handle this technique and will fail to connect. Some servers only work if TLS is turned off with the **-ssl3** option; others will only support SSL v2 and may need the **-ssl2** option.

-bugs

there are several known bug in SSL and TLS implementations. Adding this option enables various workarounds.

-cipher cipherlist

this allows the cipher list sent by the client to be modified. Although the server determines which cipher suite is used it should take the first supported cipher in the list sent by the client. See the ciphers(1) command for more information.

-time length

specifies how long (in seconds) **s_time** should establish connections and optionally transfer payload data from a server. Server and client performance and the link speed determine how many connections **s_time** can establish.

NOTES

s_time can be used to measure the performance of an SSL connection. To connect to an SSL HTTP server and get the default page the command

```
openssl s_time -connect servername:443 -www / -CApath yourdir -CAfile yourfile.pem \
    -cipher commoncipher [-ssl3]
```

would typically be used (https uses port 443). 'commoncipher' is a cipher to which both client and server can agree, see the ciphers(1) command for details.

If the handshake fails then there are several possible causes, if it is nothing obvious like no client certificate then the **-bugs**, **-ssl2**, **-ssl3** options can be tried in case it is a buggy server. In particular you should play with these options **before** submitting a bug report to an OpenSSL mailing list.

A frequent problem when attempting to get client certificates working is that a web client complains it has no certificates or gives an empty list to choose from. This is normally because the server is not sending the clients certificate authority in its "acceptable

CA list" when it requests a certificate. By using s_client(1) the CA list can be viewed and checked. However some servers only request client authentication after a specific URL is requested. To obtain the list in this case it is necessary to use the **-prexit** option of s_client(1) and send an HTTP request for an appropriate page.

If a certificate is specified on the command line using the **-cert** option it will not be used unless the server specifically requests a client certificate. Therefor merely including a client certificate on the command line is no guarantee that the certificate works.

BUGS

Because this program does not have all the options of the s_client(1) program to turn protocols on and off, you may not be able to measure the performance of all protocols with all servers.

The **-verify** option should really exit if the server verification fails.

SEE ALSO

s_client(1), s_server(1), ciphers(1)

Name

sess_id — SSL/TLS session handling utility

Synopsis

```
opensslsess_id
[-inform PEM|DER]
[-outform PEM|DER]
[-in filename]
[-out filename]
[-text]
[-noout]
[-context ID]
```

DESCRIPTION

The **sess_id** process the encoded version of the SSL session structure and optionally prints out SSL session details (for example the SSL session master key) in human readable format. Since this is a diagnostic tool that needs some knowledge of the SSL protocol to use properly, most users will not need to use it.

-inform DER|PEM

This specifies the input format. The **DER** option uses an ASN1 DER encoded format containing session details. The precise format can vary from one version to the next. The **PEM** form is the default format: it consists of the **DER** format base64 encoded with additional header and footer lines.

-outform DER|PEM

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read session information from or standard input by default.

-out filename

This specifies the output filename to write session information to or standard output if this option is not specified.

-text

prints out the various public or private key components in plain text in addition to the encoded version.

-cert

if a certificate is present in the session it will be output using this option, if the **-text** option is also present then it will be printed out in text form.

-noout

this option prevents output of the encoded version of the session.

-context ID

this option can set the session id so the output session information uses the supplied ID. The ID can be any string of characters. This option wont normally be used.

OUTPUT

Typical output:

```
SSL-Session:
    Protocol  : TLSv1
    Cipher    : 0016
    Session-ID: 871E62626C554CE95488823752CBD5F3673A3EF3DCE9C67BD916C809914B40ED
    Session-ID-ctx: 01000000
    Master-Key: A7CEFC571974BE02CAC305269DC59F76EA9F0B180CB6642697A68251F2D2BB57E51DBBB4C7885573192AE9AEE220FACD
    Key-Arg   : None
    Start Time: 948459261
    Timeout   : 300 (sec)
    Verify return code 0 (ok)
```

Theses are described below in more detail.

Protocol

this is the protocol in use TLSv1, SSLv3 or SSLv2.

Cipher

the cipher used this is the actual raw SSL or TLS cipher code, see the SSL or TLS specifications for more information.

Session-ID

the SSL session ID in hex format.

Session-ID-ctx

the session ID context in hex format.

Master-Key

this is the SSL session master key.

Key-Arg

the key argument, this is only used in SSL v2.

Start Time

this is the session start time represented as an integer in standard Unix format.

Timeout

the timeout in seconds.

Verify return code

this is the return code when an SSL client certificate is verified.

NOTES

The PEM encoded session format uses the header and footer lines:

```
-----BEGIN SSL SESSION PARAMETERS-----
-----END SSL SESSION PARAMETERS-----
```

Since the SSL session output contains the master key it is possible to read the contents of an encrypted session using this information. Therefore appropriate security precautions should be taken if the information is being output by a "real" application. This is however strongly discouraged and should only be used for debugging purposes.

BUGS

The cipher and start time should be printed out in human readable form.

[cert.pem]…
```

DESCRIPTION

The **smime** command handles S/MIME mail. It can encrypt, decrypt, sign and verify S/MIME messages.

COMMAND OPTIONS

There are six operation options that set the type of operation to be performed. The meaning of the other options varies according to the operation type.

-encrypt

encrypt mail for the given recipient certificates. Input file is the message to be encrypted. The output file is the encrypted mail in MIME format.

Note that no revocation check is done for the recipient cert, so if that key has been compromised, others may be able to decrypt the text.

-decrypt

decrypt mail using the supplied certificate and private key. Expects an encrypted mail message in MIME format for the input file. The decrypted mail is written to the output file.

-sign

sign mail using the supplied certificate and private key. Input file is the message to be signed. The signed message in MIME format is written to the output file.

-verify

verify signed mail. Expects a signed mail message on input and outputs the signed data. Both clear text and opaque signing is supported.

-pk7out

takes an input message and writes out a PEM encoded PKCS#7 structure.

-resign

resign a message: take an existing message and one or more new signers.

-in filename

the input message to be encrypted or signed or the MIME message to be decrypted or verified.

-inform SMIME|PEM|DER

this specifies the input format for the PKCS#7 structure. The default is **SMIME** which reads an S/MIME format message. **PEM** and **DER** format change this to expect PEM and DER format PKCS#7 structures instead. This currently only affects the input format of the PKCS#7 structure, if no PKCS#7 structure is being input (for example with **-encrypt** or **-sign**) this option has no effect.

-out filename

the message text that has been decrypted or verified or the output MIME format message that has been signed or verified.

-outform SMIME|PEM|DER

this specifies the output format for the PKCS#7 structure. The default is **SMIME** which write an S/MIME format message. **PEM** and **DER** format change this to write PEM and DER format PKCS#7 structures instead. This currently only affects the output format of the PKCS#7 structure, if no PKCS#7 structure is being output (for example with **-verify** or **-decrypt**) this option has no effect.

-stream -indef -noindef

the **-stream** and **-indef** options are equivalent and enable streaming I/O for encoding operations. This permits single pass processing of data without the need to hold the entire contents in memory, potentially supporting very large files. Streaming is automatically set for S/MIME signing with detached data if the output format is **SMIME** it is currently off by default for all other operations.

-noindef

disable streaming I/O where it would produce and indefinite length constructed encoding. This option currently has no effect. In future streaming will be enabled by default on all relevant operations and this option will disable it.

-content filename

This specifies a file containing the detached content, this is only useful with the **-verify** command. This is only usable if the PKCS#7 structure is using the detached signature form where the content is not included. This option will override any content if the input format is S/MIME and it uses the multipart/signed MIME content type.

-text

this option adds plain text (text/plain) MIME headers to the supplied message if encrypting or signing. If decrypting or verifying it strips off text headers: if the decrypted or verified message is not of MIME type text/plain then an error occurs.

-CAfile file

a file containing trusted CA certificates, only used with **-verify**.

-CApath dir

a directory containing trusted CA certificates, only used with **-verify**. This directory must be a standard certificate directory: that is a hash of each subject name (using **x509 -hash**) should be linked to each certificate.

-md digest

digest algorithm to use when signing or resigning. If not present then the default digest algorithm for the signing key will be used (usually SHA1).

-[cipher]

the encryption algorithm to use. For example DES (56 bits) - **-des**, triple DES (168 bits) - **-des3**, EVP_get_cipherbyname() function) can also be used preceded by a dash, for example **-aes_128_cbc**. See **enc** for list of ciphers supported by your version of OpenSSL.

If not specified triple DES is used. Only used with **-encrypt**.

-nointern

when verifying a message normally certificates (if any) included in the message are searched for the signing certificate. With this option only the certificates specified in the **-certfile** option are used. The supplied certificates can still be used as untrusted CAs however.

-noverify

do not verify the signers certificate of a signed message.

-nochain

do not do chain verification of signers certificates: that is don't use the certificates in the signed message as untrusted CAs.

-nosigs

don't try to verify the signatures on the message.

-nocerts

when signing a message the signer's certificate is normally included with this option it is excluded. This will reduce the size of the signed message but the verifier must have a copy of the signers certificate available locally (passed using the **-certfile** option for example).

-noattr

normally when a message is signed a set of attributes are included which include the signing time and supported symmetric algorithms. With this option they are not included.

-binary

normally the input message is converted to "canonical" format which is effectively using CR and LF as end of line: as required by the S/MIME specification. When this option is present no translation occurs. This is useful when handling binary data which may not be in MIME format.

-nodetach

when signing a message use opaque signing: this form is more resistant to translation by mail relays but it cannot be read by mail agents that do not support S/MIME. Without this option cleartext signing with the MIME type multipart/signed is used.

-certfile file

allows additional certificates to be specified. When signing these will be included with the message. When verifying these will be searched for the signers certificates. The certificates should be in PEM format.

-signer file

a signing certificate when signing or resigning a message, this option can be used multiple times if more than one signer is required. If a message is being verified then the signers certificates will be written to this file if the verification was successful.

-recip file

the recipients certificate when decrypting a message. This certificate must match one of the recipients of the message or an error occurs.

-inkey file

the private key to use when signing or decrypting. This must match the corresponding certificate. If this option is not specified then the private key must be included in the certificate file specified with the **-recip** or **-signer** file. When signing this option can be used multiple times to specify successive keys.

-passin arg

the private key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-rand file(s)

a file or files containing random data used to seed the random number generator, or an EGD socket (see RAND_egd(3)). Multiple files can be specified separated by a OS-dependent character. The separator is **;** for MS-Windows, **,** for OpenVMS, and **:** for all others.

cert.pem…

one or more certificates of message recipients: used when encrypting a message.

-to, -from, -subject

the relevant mail headers. These are included outside the signed portion of a message so they may be included manually. If signing then many S/MIME mail clients check the signers certificate's email address matches that specified in the From: address.

-purpose, -ignore_critical, -issuer_checks, -crl_check, -crl_check_all, -policy_check, -extended_crl, -x509_strict, -policy -check_ss_sig -no_alt_chains

Set various options of certificate chain verification. See **verify** manual page for details.

NOTES

The MIME message must be sent without any blank lines between the headers and the output. Some mail programs will automatically add a blank line. Piping the mail directly to sendmail is one way to achieve the correct format.

The supplied message to be signed or encrypted must include the necessary MIME headers or many S/MIME clients wont display it properly (if at all). You can use the **-text** option to automatically add plain text headers.

A "signed and encrypted" message is one where a signed message is then encrypted. This can be produced by encrypting an already signed message: see the examples section.

This version of the program only allows one signer per message but it will verify multiple signers on received messages. Some S/MIME clients choke if a message contains multiple signers. It is possible to sign messages "in parallel" by signing an already signed message.

The options **-encrypt** and **-decrypt** reflect common usage in S/MIME clients. Strictly speaking these process PKCS#7 enveloped data: PKCS#7 encrypted data is used for other purposes.

The **-resign** option uses an existing message digest when adding a new signer. This means that attributes must be present in at least one existing signer using the same message digest or this operation will fail.

The **-stream** and **-indef** options enable experimental streaming I/O support. As a result the encoding is BER using indefinite length constructed encoding and no longer DER. Streaming is supported for the **-encrypt** operation and the **-sign** operation if the content is not detached.

Streaming is always used for the **-sign** operation with detached data but since the content is no longer part of the PKCS#7 structure the encoding remains DER.

EXIT CODES

0 the operation was completely successfully.

1 an error occurred parsing the command options.

2 one of the input files could not be read.

3 an error occurred creating the PKCS#7 file or when reading the MIME message.

4 an error occurred decrypting or verifying the message.

5 the message was verified correctly but an error occurred writing out the signers certificates.

EXAMPLES

Create a cleartext signed message:

```
openssl smime -sign -in message.txt -text -out mail.msg \
       -signer mycert.pem
```

Create an opaque signed message:

```
openssl smime -sign -in message.txt -text -out mail.msg -nodetach \
       -signer mycert.pem
```

Create a signed message, include some additional certificates and read the private key from another file:

```
openssl smime -sign -in in.txt -text -out mail.msg \
       -signer mycert.pem -inkey mykey.pem -certfile mycerts.pem
```

Create a signed message with two signers:

```
openssl smime -sign -in message.txt -text -out mail.msg \
       -signer mycert.pem -signer othercert.pem
```

Send a signed message under Unix directly to sendmail, including headers:

```
openssl smime -sign -in in.txt -text -signer mycert.pem \
       -from steve@openssl.org -to someone@somewhere \
       -subject "Signed message" | sendmail someone@somewhere
```

Verify a message and extract the signer's certificate if successful:

```
openssl smime -verify -in mail.msg -signer user.pem -out signedtext.txt
```

Send encrypted mail using triple DES:

```
openssl smime -encrypt -in in.txt -from steve@openssl.org \
       -to someone@somewhere -subject "Encrypted message" \
       -des3 user.pem -out mail.msg
```

Sign and encrypt mail:

```
openssl smime -sign -in ml.txt -signer my.pem -text \
       | openssl smime -encrypt -out mail.msg \
       -from steve@openssl.org -to someone@somewhere \
       -subject "Signed and Encrypted message" -des3 user.pem
```

Note: the encryption command does not include the **-text** option because the message being encrypted already has MIME headers.

Decrypt mail:

```
openssl smime -decrypt -in mail.msg -recip mycert.pem -inkey key.pem
```

The output from Netscape form signing is a PKCS#7 structure with the detached signature format. You can use this program to verify the signature by line wrapping the base64 encoded structure and surrounding it with:

```
-----BEGIN PKCS7-----
-----END PKCS7-----
```

and using the command:

```
openssl smime -verify -inform PEM -in signature.pem -content content.txt
```

Alternatively you can base64 decode the signature and use:

```
openssl smime -verify -inform DER -in signature.der -content content.txt
```

Create an encrypted message using 128 bit Camellia:

```
openssl smime -encrypt -in plain.txt -camellia128 -out mail.msg cert.pem
```

Add a signer to an existing message:

```
openssl smime -resign -in mail.msg -signer newsign.pem -out mail2.msg
```

BUGS

The MIME parser isn't very clever: it seems to handle most messages that I've thrown at it but it may choke on others.

The code currently will only write out the signer's certificate to a file: if the signer has a separate encryption certificate this must be manually extracted. There should be some heuristic that determines the correct encryption certificate.

Ideally a database should be maintained of a certificates for each email address.

The code doesn't currently take note of the permitted symmetric encryption algorithms as supplied in the SMIMECapabilities signed attribute. This means the user has to manually include the correct encryption algorithm. It should store the list of permitted ciphers in a database and only use those.

No revocation checking is done on the signer's certificate.

The current code can only handle S/MIME v2 messages, the more complex S/MIME v3 structures may cause parsing errors.

HISTORY

The use of multiple **-signer** options and the **-resign** command were first added in OpenSSL 1.0.0

The -no_alt_chains options was first added to OpenSSL 1.0.1n and 1.0.2b.

Name

speed — test library performance

Synopsis

```
openssl speed
[-engine id]
[md2]
[mdc2]
[md5]
[hmac]
[sha1]
[rmd160]
[idea-cbc]
[rc2-cbc]
[rc5-cbc]
[bf-cbc]
[des-cbc]
[des-ede3]
[rc4]
[rsa512]
[rsa1024]
[rsa2048]
[rsa4096]
[dsa512]
[dsa1024]
[dsa2048]
[idea]
[rc2]
[des]
[rsa]
[blowfish]
```

DESCRIPTION

This command is used to test the performance of cryptographic algorithms.

OPTIONS

-engine id

specifying an engine (by its unique **id** string) will cause **speed** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

[zero or more test algorithms]

If any options are given, **speed** tests those algorithms, otherwise all of the above are tested.

Name

spkac — SPKAC printing and generating utility

Synopsis

```
opensslspkac
[-in filename]
[-out filename]
[-key keyfile]
[-passin arg]
[-challenge string]
[-pubkey]
[-spkac spkacname]
[-spksect section]
[-noout]
[-verify]
[-engine id]
```

DESCRIPTION

The **spkac** command processes Netscape signed public key and challenge (SPKAC) files. It can print out their contents, verify the signature and produce its own SPKACs from a supplied private key.

COMMAND OPTIONS

-in filename

This specifies the input filename to read from or standard input if this option is not specified. Ignored if the **-key** option is used.

-out filename

specifies the output filename to write to or standard output by default.

-key keyfile

create an SPKAC file using the private key in **keyfile**. The **-in**, **-noout**, **-spksect** and **-verify** options are ignored if present.

-passin password

the input file password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-challenge string

specifies the challenge string if an SPKAC is being created.

-spkac spkacname

allows an alternative name form the variable containing the SPKAC. The default is "SPKAC". This option affects both generated and input SPKAC files.

-spksect section

allows an alternative name form the section containing the SPKAC. The default is the default section.

-noout

don't output the text version of the SPKAC (not used if an SPKAC is being created).

-pubkey

output the public key of an SPKAC (not used if an SPKAC is being created).

-verify

verifies the digital signature on the supplied SPKAC.

-engine id

specifying an engine (by its unique **id** string) will cause **spkac** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

EXAMPLES

Print out the contents of an SPKAC:

```
openssl spkac -in spkac.cnf
```

Verify the signature of an SPKAC:

```
openssl spkac -in spkac.cnf -noout -verify
```

Create an SPKAC using the challenge string "hello":

```
openssl spkac -key key.pem -challenge hello -out spkac.cnf
```

Example of an SPKAC, (long lines split up for clarity):

```
SPKAC=MIG5MGUwXDANBgkqhkiG9w0BAQEFAANLADBIAkEA1cCoq2Wa3Ixs47uI7F\
PVwHVIPDx5yso105Y6zpozam135a8R0CpoRvkkigIyXfcCjiVi5oWk+6FfPaD03u\
PFoQIDAQABFgVoZWxsbzANBgkqhkiG9w0BAQQFAANBAFpQtY/FojdwkJh1bEIYuc\
2EeM2KHTWPEepWYeawvHD0gQ3DngSC75YCWnnDdq+NQ3F+X4deMx9AaEglZtULwV\
4=
```

NOTES

A created SPKAC with suitable DN components appended can be fed into the **ca** utility.

SPKACs are typically generated by Netscape when a form is submitted containing the **KEYGEN** tag as part of the certificate enrollment process.

The challenge string permits a primitive form of proof of possession of private key. By checking the SPKAC signature and a random challenge string some guarantee is given that the user knows the private key corresponding to the public key being certified. This is important in some applications. Without this it is possible for a previous SPKAC to be used in a "replay attack".

```

DESCRIPTION

The **ts** command is a basic Time Stamping Authority (TSA) client and server application as specified in RFC 3161 (Time-Stamp Protocol, TSP). A TSA can be part of a PKI deployment and its role is to provide long term proof of the existence of a certain datum before a particular time. Here is a brief description of the protocol:

1. The TSA client computes a one-way hash value for a data file and sends the hash to the TSA.

2. The TSA attaches the current date and time to the received hash value, signs them and sends the time stamp token back to the client. By creating this token the TSA certifies the existence of the original data file at the time of response generation.

3. The TSA client receives the time stamp token and verifies the signature on it. It also checks if the token contains the same hash value that it had sent to the TSA.

There is one DER encoded protocol data unit defined for transporting a time stamp request to the TSA and one for sending the time stamp response back to the client. The **ts** command has three main functions: creating a time stamp request based on a data file, creating a time stamp response based on a request, verifying if a response corresponds to a particular request or a data file.

There is no support for sending the requests/responses automatically over HTTP or TCP yet as suggested in RFC 3161. The users must send the requests either by ftp or e-mail.

OPTIONS

Time Stamp Request generation

The **-query** switch can be used for creating and printing a time stamp request with the following options:

-rand file:file…

The files containing random data for seeding the random number generator. Multiple files can be specified, the separator is **;** for MS-Windows, **,** for VMS and **:** for all other platforms. (Optional)

-config configfile

The configuration file to use, this option overrides the **OPENSSL_CONF** environment variable. Only the OID section of the config file is used with the **-query** command. (Optional)

-data file_to_hash

The data file for which the time stamp request needs to be created. stdin is the default if neither the **-data** nor the **-digest** parameter is specified. (Optional)

-digest digest_bytes

It is possible to specify the message imprint explicitly without the data file. The imprint must be specified in a hexadecimal format, two characters per byte, the bytes optionally separated by colons (e.g. 1A:F6:01:… or 1AF601…). The number of bytes must match the message digest algorithm in use. (Optional)

-md2|-md4|-md5|-sha|-sha1|-mdc2|-ripemd160|…

The message digest to apply to the data file, it supports all the message digest algorithms that are supported by the openssl **dgst** command. The default is SHA-1. (Optional)

-policy object_id

The policy that the client expects the TSA to use for creating the time stamp token. Either the dotted OID notation or OID names defined in the config file can be used. If no policy is requested the TSA will use its own default policy. (Optional)

-no_nonce

No nonce is specified in the request if this option is given. Otherwise a 64 bit long pseudo-random none is included in the request. It is recommended to use nonce to protect against replay-attacks. (Optional)

-cert

The TSA is expected to include its signing certificate in the response. (Optional)

-in request.tsq

This option specifies a previously created time stamp request in DER format that will be printed into the output file. Useful when you need to examine the content of a request in human-readable

format. (Optional)

-out request.tsq

Name of the output file to which the request will be written. Default is stdout. (Optional)

-text

If this option is specified the output is human-readable text format instead of DER. (Optional)

Time Stamp Response generation

A time stamp response (TimeStampResp) consists of a response status and the time stamp token itself (ContentInfo), if the token generation was successful. The **-reply** command is for creating a time stamp response or time stamp token based on a request and printing the response/token in human-readable format. If **-token_out** is not specified the output is always a time stamp response (TimeStampResp), otherwise it is a time stamp token (ContentInfo).

-config configfile

The configuration file to use, this option overrides the **OPENSSL_CONF** environment variable. See **CONFIGURATION FILE OPTIONS** for configurable variables. (Optional)

-section tsa_section

The name of the config file section conatining the settings for the response generation. If not specified the default TSA section is used, see **CONFIGURATION FILE OPTIONS** for details. (Optional)

-queryfile request.tsq

The name of the file containing a DER encoded time stamp request. (Optional)

-passin password_src

Specifies the password source for the private key of the TSA. See **PASS PHRASE ARGUMENTS** in openssl(1). (Optional)

-signer tsa_cert.pem

The signer certificate of the TSA in PEM format. The TSA signing certificate must have exactly one extended key usage assigned to it: timeStamping. The extended key usage must also be critical, otherwise the certificate is going to be refused. Overrides the **signer_cert** variable of the config file. (Optional)

-inkey private.pem

The signer private key of the TSA in PEM format. Overrides the **signer_key** config file option. (Optional)

-chain certs_file.pem

The collection of certificates in PEM format that will all be included in the response in addition to the signer certificate if the **-cert** option was used for the request. This file is supposed to contain the certificate chain for the signer certificate from its issuer upwards. The **-reply** command does not build a certificate chain automatically. (Optional)

-policy object_id

The default policy to use for the response unless the client explicitly requires a particular TSA policy. The OID can be specified either in dotted notation or with its name. Overrides the **default_policy** config file option. (Optional)

-in response.tsr

Specifies a previously created time stamp response or time stamp token (if **-token_in** is also specified) in DER format that will be written to the output file. This option does not require a request, it is useful e.g. when you need to examine the content of a response or token or you want to extract the time stamp token from a response. If the input is a token and the output is a time stamp response a default 'granted' status info is added to the token. (Optional)

-token_in

This flag can be used together with the **-in** option and indicates that the input is a DER encoded time stamp token (ContentInfo) instead of a time stamp response (TimeStampResp). (Optional)

-out response.tsr

The response is written to this file. The format and content of the file depends on other options (see **-text**, **-token_out**). The default is stdout. (Optional)

-token_out

The output is a time stamp token (ContentInfo) instead of time stamp response (TimeStampResp). (Optional)

-text

If this option is specified the output is human-readable text format instead of DER. (Optional)

-engine id

Specifying an engine (by its unique **id** string) will cause **ts** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms. Default is builtin. (Optional)

Time Stamp Response verification

The **-verify** command is for verifying if a time stamp response or time stamp token is valid and matches a particular time stamp request or data file. The **-verify** command does not use the configuration file.

-data file_to_hash

The response or token must be verified against file_to_hash. The file is hashed with the message digest algorithm specified in the token. The **-digest** and **-queryfile** options must not be specified with this one. (Optional)

-digest digest_bytes

The response or token must be verified against the message digest specified with this option. The number of bytes must match the message digest algorithm specified in the token. The **-data** and **-queryfile** options must not be specified with this one. (Optional)

-queryfile request.tsq

The original time stamp request in DER format. The **-data** and **-digest** options must not be specified with this one. (Optional)

-in response.tsr

The time stamp response that needs to be verified in DER format. (Mandatory)

-token_in

This flag can be used together with the **-in** option and indicates that the input is a DER encoded time stamp token (ContentInfo) instead of a time stamp response (TimeStampResp). (Optional)

-CApath trusted_cert_path

The name of the directory containing the trused CA certificates of the client. See the similar option of verify(1) for additional details. Either this option or **-CAfile** must be specified. (Optional)

-CAfile trusted_certs.pem

The name of the file containing a set of trusted self-signed CA certificates in PEM format. See the similar option of verify(1) for additional details. Either this option or **-CApath** must be specified. (Optional)

-untrusted cert_file.pem

Set of additional untrusted certificates in PEM format which may be needed when building the certificate chain for the TSA's signing certificate. This file must contain the TSA signing certificate and all intermediate CA certificates unless the response includes them. (Optional)

CONFIGURATION FILE OPTIONS

The **-query** and **-reply** commands make use of a configuration file defined by the **OPENSSL_CONF** environment variable. See config(5) for a general description of the syntax of the config file. The **-query** command uses only the symbolic OID names section and it can work without it. However, the **-reply** command needs the config file for its operation.

When there is a command line switch equivalent of a variable the switch always overrides the settings in the config file.

tsa section, **default_tsa**

This is the main section and it specifies the name of another section that contains all the options for the **-reply** command. This default section can be overridden with the **-section** command line switch. (Optional)

oid_file

See ca(1) for description. (Optional)

oid_section

See ca(1) for description. (Optional)

RANDFILE

See ca(1) for description. (Optional)

serial

The name of the file containing the hexadecimal serial number of the last time stamp response created. This number is incremented by 1 for each response. If the file does not exist at the time of response generation a new file is created with serial number 1. (Mandatory)

crypto_device

Specifies the OpenSSL engine that will be set as the default for all available algorithms. The default value is builtin, you can specify any other engines supported by OpenSSL (e.g. use chil for the NCipher HSM). (Optional)

signer_cert

TSA signing certificate in PEM format. The same as the **-signer** command line option. (Optional)

certs

A file containing a set of PEM encoded certificates that need to be included in the response. The same as the **-chain** command line option. (Optional)

signer_key

The private key of the TSA in PEM format. The same as the **-inkey** command line option. (Optional)

default_policy

The default policy to use when the request does not mandate any policy. The same as the **-policy** command line option. (Optional)

other_policies

Comma separated list of policies that are also acceptable by the TSA and used only if the request explicitly specifies one of them. (Optional)

digests

The list of message digest algorithms that the TSA accepts. At least one algorithm must be specified. (Mandatory)

accuracy

The accuracy of the time source of the TSA in seconds, milliseconds and microseconds. E.g. secs:1, millisecs:500, microsecs:100. If any of the components is missing zero is assumed for that field. (Optional)

clock_precision_digits

Specifies the maximum number of digits, which represent the fraction of seconds, that need to be included in the time field. The trailing zeroes must be removed from the time, so there might actually be fewer digits, or no fraction of seconds at all. Supported only on UNIX platforms. The maximum value is 6, default is 0. (Optional)

ordering

If this option is yes the responses generated by this TSA can always be ordered, even if the time difference between two responses is less than the sum of their accuracies. Default is no. (Optional)

tsa_name

Set this option to yes if the subject name of the TSA must be included in the TSA name field of the response. Default is no. (Optional)

ess_cert_id_chain

The SignedData objects created by the TSA always contain the certificate identifier of the signing certificate in a signed attribute (see RFC 2634, Enhanced Security Services). If this option is set to yes and either the **certs** variable or the **-chain** option is specified then the certificate identifiers of the chain will also be included in the SigningCertificate signed attribute. If this variable is set to no, only the signing certificate identifier is included. Default is no. (Optional)

ENVIRONMENT VARIABLES

OPENSSL_CONF contains the path of the configuration file and can be overridden by the **-config** command line option.

EXAMPLES

All the examples below presume that **OPENSSL_CONF** is set to a proper configuration file, e.g. the example configuration file openssl/apps/openssl.cnf will do.

Time Stamp Request

To create a time stamp request for design1.txt with SHA-1 without nonce and policy and no certificate is required in the response:

```
openssl ts -query -data design1.txt -no_nonce \
      -out design1.tsq
```

To create a similar time stamp request with specifying the message imprint explicitly:

```
openssl ts -query -digest b7e5d3f93198b38379852f2c04e78d73abdd0f4b \
       -no_nonce -out design1.tsq
```

To print the content of the previous request in human readable format:

```
openssl ts -query -in design1.tsq -text
```

To create a time stamp request which includes the MD-5 digest of design2.txt, requests the signer certificate and nonce, specifies a policy id (assuming the tsa_policy1 name is defined in the OID section of the config file):

```
openssl ts -query -data design2.txt -md5 \
      -policy tsa_policy1 -cert -out design2.tsq
```

Time Stamp Response

Before generating a response a signing certificate must be created for the TSA that contains the **timeStamping** critical extended key usage extension without any other key usage extensions. You can add the 'extendedKeyUsage = critical,timeStamping' line to the user certificate section of the config file to generate a proper certificate. See req(1), ca(1), x509(1) for instructions. The examples below assume that cacert.pem contains the certificate of the CA, tsacert.pem is the signing certificate issued by cacert.pem and tsakey.pem is the private key of the TSA.

To create a time stamp response for a request:

```
openssl ts -reply -queryfile design1.tsq -inkey tsakey.pem \
      -signer tsacert.pem -out design1.tsr
```

If you want to use the settings in the config file you could just write:

```
openssl ts -reply -queryfile design1.tsq -out design1.tsr
```

To print a time stamp reply to stdout in human readable format:

```
openssl ts -reply -in design1.tsr -text
```

To create a time stamp token instead of time stamp response:

```
openssl ts -reply -queryfile design1.tsq -out design1_token.der -token_out
```

To print a time stamp token to stdout in human readable format:

```
openssl ts -reply -in design1_token.der -token_in -text -token_out
```

To extract the time stamp token from a response:

```
openssl ts -reply -in design1.tsr -out design1_token.der -token_out
```

To add 'granted' status info to a time stamp token thereby creating a valid response:

```
openssl ts -reply -in design1_token.der -token_in -out design1.tsr
```

Time Stamp Verification

To verify a time stamp reply against a request:

```
openssl ts -verify -queryfile design1.tsq -in design1.tsr \
      -CAfile cacert.pem -untrusted tsacert.pem
```

To verify a time stamp reply that includes the certificate chain:

```
openssl ts -verify -queryfile design2.tsq -in design2.tsr \
      -CAfile cacert.pem
```

To verify a time stamp token against the original data file: openssl ts -verify -data design2.txt -in design2.tsr \ -CAfile cacert.pem

To verify a time stamp token against a message imprint: openssl ts -verify -digest b7e5d3f93198b38379852f2c04e78d73abdd0f4b \ -in design2.tsr -CAfile cacert.pem

You could also look at the 'test' directory for more examples.

BUGS

If you find any bugs or you have suggestions please write to Zoltan Glozik <zglozik@opentsa.org>. Known issues:

- No support for time stamps over SMTP, though it is quite easy to implement an automatic e-mail based TSA with procmail and perl. HTTP server support is provided in the form of a separate apache module. HTTP client support is provided by tsget(1). Pure TCP/IP protocol is not supported.

- The file containing the last serial number of the TSA is not locked when being read or written. This is a problem if more than one instance of openssl(1) is trying to create a time stamp response at the same time. This is not an issue when using the apache server module, it does proper locking.

- Look for the FIXME word in the source files.

- The source code should really be reviewed by somebody else, too.

- More testing is needed, I have done only some basic tests (see test/testtsa).

Name

verify — Utility to verify certificates.

Synopsis

```
opensslverify
[-CApath directory]
[-CAfile file]
[-purpose purpose]
[-policy arg]
[-ignore_critical]
[-crl_check]
[-crl_check_all]
[-policy_check]
[-explicit_policy]
[-inhibit_any]
[-inhibit_map]
[-x509_strict]
[-extended_crl]
[-use_deltas]
[-policy_print]
[-no_alt_chains]
[-allow_proxy_certs]
[-untrusted file]
[-help]
[-issuer_checks]
[-attime timestamp]
[-verbose]
[-]
[certificates]
```

DESCRIPTION

The **verify** command verifies certificate chains.

COMMAND OPTIONS

-CApath directory

A directory of trusted certificates. The certificates should have names of the form: hash.0 or have symbolic links to them of this form ("hash" is the hashed certificate subject name: see the **-hash** option of the **x509** utility). Under Unix the **c_rehash** script will automatically create symbolic links to a directory of certificates.

-CAfile file A file of trusted certificates. The file should contain multiple certificates in PEM format concatenated together.

-untrusted file

A file of untrusted certificates. The file should contain multiple certificates in PEM format concatenated together.

-purpose purpose

The intended use for the certificate. If this option is not specified, **verify** will not consider certificate purpose during chain verification. Currently accepted uses are **sslclient**, **sslserver**, **nssslserver**, **smimesign**, **smimeencrypt**. See the **VERIFY OPERATION** section for more information.

-help

Print out a usage message.

-verbose

Print extra information about the operations being performed.

-issuer_checks

Print out diagnostics relating to searches for the issuer certificate of the current certificate. This shows why each candidate issuer certificate was rejected. The presence of rejection messages does not itself imply that anything is wrong; during the normal verification process, several rejections may take place.

-attime timestamp

Perform validation checks using time specified by **timestamp** and not current system time. **timestamp** is the number of seconds since 01.01.1970 (UNIX time).

-policy arg

Enable policy processing and add **arg** to the user-initial-policy-set (see RFC5280). The policy **arg** can be an object name an OID in numeric form. This argument can appear more than once.

-policy_check

Enables certificate policy processing.

-explicit_policy

Set policy variable require-explicit-policy (see RFC5280).

-inhibit_any

Set policy variable inhibit-any-policy (see RFC5280).

-inhibit_map

Set policy variable inhibit-policy-mapping (see RFC5280).

-no_alt_chains

When building a certificate chain, if the first certificate chain found is not trusted, then OpenSSL will continue to check to see if an alternative chain can be found that is trusted. With this option that behaviour is suppressed so that only the first chain found is ever used. Using this option will force the behaviour to match that of previous OpenSSL versions.

-allow_proxy_certs

Allow the verification of proxy certificates.

-policy_print

Print out diagnostics related to policy processing.

-crl_check

Checks end entity certificate validity by attempting to look up a valid CRL. If a valid CRL cannot be found an error occurs.

-crl_check_all

Checks the validity of **all** certificates in the chain by attempting to look up valid CRLs.

-ignore_critical

Normally if an unhandled critical extension is present which is not supported by OpenSSL the certificate is rejected (as required by RFC5280). If this option is set critical extensions are ignored.

-x509_strict

For strict X.509 compliance, disable non-compliant workarounds for broken certificates.

-extended_crl

Enable extended CRL features such as indirect CRLs and alternate CRL signing keys.

-use_deltas

Enable support for delta CRLs.

-check_ss_sig

Verify the signature on the self-signed root CA. This is disabled by default because it doesn't add any security.

-

Indicates the last option. All arguments following this are assumed to be certificate files. This is useful if the first certificate filename begins with a **-**.

certificates

One or more certificates to verify. If no certificates are given, **verify** will attempt to read a certificate from standard input. Certificates must be in PEM format.

VERIFY OPERATION

The **verify** program uses the same functions as the internal SSL and S/MIME verification, therefore this description applies to these verify operations too.

There is one crucial difference between the verify operations performed by the **verify** program: wherever possible an attempt is made to continue after an error whereas normally the verify operation would halt on the first error. This allows all the problems with a certificate chain to be determined.

The verify operation consists of a number of separate steps.

Firstly a certificate chain is built up starting from the supplied certificate and ending in the root CA. It is an error if the whole chain cannot be built up. The chain is built up by looking up the issuers certificate of the current certificate. If a certificate is found which is its own issuer it is assumed to be the root CA.

The process of 'looking up the issuers certificate' itself involves a number of steps. In versions of OpenSSL before 0.9.5a the first certificate whose subject name matched the issuer of the current certificate was assumed to be the issuers certificate. In OpenSSL 0.9.6 and later all certificates whose subject name matches the issuer name of the current certificate are subject to further tests. The relevant authority key identifier components of the current certificate (if present) must match the subject key identifier (if present) and issuer and serial number of the candidate issuer, in addition the keyUsage extension of the candidate issuer (if present) must permit certificate signing.

The lookup first looks in the list of untrusted certificates and if no match is found the remaining lookups are from the trusted certificates. The root CA is always looked up in the trusted certificate list: if the certificate to verify is a root certificate then an exact match must be found in the trusted list.

The second operation is to check every untrusted certificate's extensions for consistency with the supplied purpose. If the **-purpose** option is not included then no checks are done. The supplied or "leaf" certificate must have extensions compatible with the supplied purpose and all other certificates must also be valid CA certificates. The precise extensions required are described in more detail in the **CERTIFICATE EXTENSIONS** section of the **x509** utility.

The third operation is to check the trust settings on the root CA. The root CA should be trusted for the supplied purpose. For compatibility with previous versions of SSLeay and OpenSSL a certificate with no trust settings is considered to be valid for all purposes.

The final operation is to check the validity of the certificate chain. The validity period is checked against the current system time and the notBefore and notAfter dates in the certificate. The certificate signatures are also checked at this point.

If all operations complete successfully then certificate is considered valid. If any operation fails then the certificate is not valid.

DIAGNOSTICS

When a verify operation fails the output messages can be somewhat cryptic. The general form of the error message is:

```
server.pem: /C=AU/ST=Queensland/O=CryptSoft Pty Ltd/CN=Test CA (1024 bit)
error 24 at 1 depth lookup:invalid CA certificate
```

The first line contains the name of the certificate being verified followed by the subject name of the certificate. The second line contains the error number and the depth. The depth is number of the certificate being verified when a problem was detected starting with zero for the certificate being verified itself then 1 for the CA that signed the certificate and so on. Finally a text version of the error number is presented.

An exhaustive list of the error codes and messages is shown below, this also includes the name of the error code as defined in the header file x509_vfy.h Some of the error codes are defined but never returned: these are described as "unused".

0 X509_V_OK: ok

the operation was successful.

2 X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT: unable to get issuer certificate

the issuer certificate of a looked up certificate could not be found. This normally means the list of trusted certificates is not complete.

3 X509_V_ERR_UNABLE_TO_GET_CRL: unable to get certificate CRL

the CRL of a certificate could not be found.

4 X509_V_ERR_UNABLE_TO_DECRYPT_CERT_SIGNATURE: unable to decrypt certificate's signature

the certificate signature could not be decrypted. This means that the actual signature value could not be determined rather than it not matching the expected value, this is only meaningful for RSA keys.

5 X509_V_ERR_UNABLE_TO_DECRYPT_CRL_SIGNATURE: unable to decrypt CRL's signature

the CRL signature could not be decrypted: this means that the actual signature value could not be determined rather than it not matching the expected value. Unused.

6 X509_V_ERR_UNABLE_TO_DECODE_ISSUER_PUBLIC_KEY: unable to decode issuer public key

the public key in the certificate SubjectPublicKeyInfo could not be read.

7 X509_V_ERR_CERT_SIGNATURE_FAILURE: certificate signature failure

the signature of the certificate is invalid.

8 X509_V_ERR_CRL_SIGNATURE_FAILURE: CRL signature failure

the signature of the certificate is invalid.

9 X509_V_ERR_CERT_NOT_YET_VALID: certificate is not yet valid

the certificate is not yet valid: the notBefore date is after the current time.

10 X509_V_ERR_CERT_HAS_EXPIRED: certificate has expired

the certificate has expired: that is the notAfter date is before the current time.

11 X509_V_ERR_CRL_NOT_YET_VALID: CRL is not yet valid

the CRL is not yet valid.

12 X509_V_ERR_CRL_HAS_EXPIRED: CRL has expired

the CRL has expired.

13 X509_V_ERR_ERROR_IN_CERT_NOT_BEFORE_FIELD: format error in certificate's notBefore field

the certificate notBefore field contains an invalid time.

14 X509_V_ERR_ERROR_IN_CERT_NOT_AFTER_FIELD: format error in certificate's notAfter field

the certificate notAfter field contains an invalid time.

15 X509_V_ERR_ERROR_IN_CRL_LAST_UPDATE_FIELD: format error in CRL's lastUpdate field

the CRL lastUpdate field contains an invalid time.

16 X509_V_ERR_ERROR_IN_CRL_NEXT_UPDATE_FIELD: format error in CRL's nextUpdate field

the CRL nextUpdate field contains an invalid time.

17 X509_V_ERR_OUT_OF_MEM: out of memory

an error occurred trying to allocate memory. This should never happen.

18 X509_V_ERR_DEPTH_ZERO_SELF_SIGNED_CERT: self signed certificate

the passed certificate is self signed and the same certificate cannot be found in the list of trusted certificates.

19 X509_V_ERR_SELF_SIGNED_CERT_IN_CHAIN: self signed certificate in certificate chain

the certificate chain could be built up using the untrusted certificates but the root could not be found locally.

20 X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT_LOCALLY: unable to get local issuer certificate

the issuer certificate could not be found: this occurs if the issuer certificate of an untrusted certificate cannot be found.

21 X509_V_ERR_UNABLE_TO_VERIFY_LEAF_SIGNATURE: unable to verify the first certificate

no signatures could be verified because the chain contains only one certificate and it is not self signed.

22 X509_V_ERR_CERT_CHAIN_TOO_LONG: certificate chain too long

the certificate chain length is greater than the supplied maximum depth. Unused.

23 X509_V_ERR_CERT_REVOKED: certificate revoked

the certificate has been revoked.

24 X509_V_ERR_INVALID_CA: invalid CA certificate

a CA certificate is invalid. Either it is not a CA or its extensions are not consistent with the supplied purpose.

25 X509_V_ERR_PATH_LENGTH_EXCEEDED: path length constraint exceeded

the basicConstraints pathlength parameter has been exceeded.

26 X509_V_ERR_INVALID_PURPOSE: unsupported certificate purpose

the supplied certificate cannot be used for the specified purpose.

27 X509_V_ERR_CERT_UNTRUSTED: certificate not trusted

the root CA is not marked as trusted for the specified purpose.

28 X509_V_ERR_CERT_REJECTED: certificate rejected

the root CA is marked to reject the specified purpose.

29 X509_V_ERR_SUBJECT_ISSUER_MISMATCH: subject issuer mismatch

the current candidate issuer certificate was rejected because its subject name did not match the issuer name of the current certificate. Only displayed when the **-issuer_checks** option is set.

30 X509_V_ERR_AKID_SKID_MISMATCH: authority and subject key identifier mismatch

the current candidate issuer certificate was rejected because its subject key identifier was present and did not match the authority key identifier current certificate. Only displayed when the **-issuer_checks** option is set.

31 X509_V_ERR_AKID_ISSUER_SERIAL_MISMATCH: authority and issuer serial number mismatch

the current candidate issuer certificate was rejected because its issuer name and serial number was present and did not match the authority key identifier of the current certificate. Only displayed when the **-issuer_checks** option is set.

32 X509_V_ERR_KEYUSAGE_NO_CERTSIGN:key usage does not include certificate signing

the current candidate issuer certificate was rejected because its keyUsage extension does not permit certificate signing.

50 X509_V_ERR_APPLICATION_VERIFICATION: application verification failure

an application specific error. Unused.

BUGS

Although the issuer checks are a considerable improvement over the old technique they still suffer from limitations in the underlying X509_LOOKUP API. One consequence of this is that trusted certificates with matching subject name must either appear in a file (as specified by the **-CAfile** option) or a directory (as specified by **-CApath**. If they occur in both then only the certificates in the file will be recognised.

Previous versions of OpenSSL assume certificates with matching subject name are identical and mishandled them.

Previous versions of this documentation swapped the meaning of the **X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT** and **20 X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT_LOCALLY** error codes.

SEE ALSO

x509(1)

HISTORY

The -no_alt_chains options was first added to OpenSSL 1.0.1n and 1.0.2b.

Name

version — print OpenSSL version information

Synopsis

```
openssl version
[-a]
[-v]
[-b]
[-o]
[-f]
[-p]
[-d]
```

DESCRIPTION

This command is used to print out version information about OpenSSL.

OPTIONS

-a

all information, this is the same as setting all the other flags.

-v

the current OpenSSL version.

-b

the date the current version of OpenSSL was built.

-o

option information: various options set when the library was built.

-f

compilation flags.

-p

platform setting.

-d

OPENSSLDIR setting.

NOTES

The output of **openssl version -a** would typically be used when sending in a bug report.

HISTORY

The **-d** option was added in OpenSSL 0.9.7.

Name

x509 — Certificate display and signing utility

Synopsis

```
opensslx509
[-inform DER|PEM|NET]
[-outform DER|PEM|NET]
[-keyform DER|PEM]
[-CAform DER|PEM]
[-CAkeyform DER|PEM]

[-extensions section]
[-engine id]
```

DESCRIPTION

The **x509** command is a multi purpose certificate utility. It can be used to display certificate information, convert certificates to various forms, sign certificate requests like a "mini CA" or edit certificate trust settings.

Since there are a large number of options they will split up into various sections.

OPTIONS

INPUT, OUTPUT AND GENERAL PURPOSE OPTIONS

-inform DER|PEM|NET

This specifies the input format normally the command will expect an X509 certificate but this can change if other options such as **-req** are present. The DER format is the DER encoding of the certificate and PEM is the base64 encoding of the DER encoding with header and footer lines added. The NET option is an obscure Netscape server format that is now obsolete.

-outform DER|PEM|NET

This specifies the output format, the options have the same meaning as the **-inform** option.

-in filename

This specifies the input filename to read a certificate from or standard input if this option is not specified.

-out filename

This specifies the output filename to write to or standard output by default.

-md2|-md5|-sha1|-mdc2

the digest to use. This affects any signing or display option that uses a message digest, such as the **-fingerprint**, **-signkey** and **-CA** options. If not specified then SHA1 is used. If the key being used to sign with is a DSA key then this option has no effect: SHA1 is always used with DSA keys.

-engine id

specifying an engine (by its unique **id** string) will cause **x509** to attempt to obtain a functional reference to the specified engine, thus initialising it if needed. The engine will then be set as the default for all available algorithms.

DISPLAY OPTIONS

Note: the **-alias** and **-purpose** options are also display options but are described in the **TRUST SETTINGS** section.

-text

prints out the certificate in text form. Full details are output including the public key, signature algorithms, issuer and subject names, serial number any extensions present and any trust settings.

-certopt option

customise the output format used with **-text**. The **option** argument can be a single option or multiple options separated by commas. The **-certopt** switch may be also be used more than once to set multiple options. See the **TEXT OPTIONS** section for more information.

-noout

this option prevents output of the encoded version of the request.

-pubkey

outputs the the certificate's SubjectPublicKeyInfo block in PEM format.

-modulus

this option prints out the value of the modulus of the public key contained in the certificate.

-serial

outputs the certificate serial number.

-subject_hash

outputs the "hash" of the certificate subject name. This is used in OpenSSL to form an index to allow certificates in a directory to be looked up by subject name.

-issuer_hash

outputs the "hash" of the certificate issuer name.

-ocspid

outputs the OCSP hash values for the subject name and public key.

-hash

synonym for "-subject_hash" for backward compatibility reasons.

-subject_hash_old

outputs the "hash" of the certificate subject name using the older algorithm as used by OpenSSL versions before 1.0.0.

-issuer_hash_old

outputs the "hash" of the certificate issuer name using the older algorithm as used by OpenSSL versions before 1.0.0.

-subject

outputs the subject name.

-issuer

outputs the issuer name.

-nameopt option

option which determines how the subject or issuer names are displayed. The **option** argument can be a single option or multiple options separated by commas. Alternatively the **-nameopt** switch may be used more than once to set multiple options. See the **NAME OPTIONS** section for more information.

-email

outputs the email address(es) if any.

-ocsp_uri

outputs the OCSP responder address(es) if any.

-startdate

prints out the start date of the certificate, that is the notBefore date.

-enddate

prints out the expiry date of the certificate, that is the notAfter date.

-dates

prints out the start and expiry dates of a certificate.

-checkend arg

checks if the certificate expires within the next **arg** seconds and exits non-zero if yes it will expire or zero if not.

-fingerprint

prints out the digest of the DER encoded version of the whole certificate (see digest options).

-C

this outputs the certificate in the form of a C source file.

TRUST SETTINGS

Please note these options are currently experimental and may well change.

A **trusted certificate** is an ordinary certificate which has several additional pieces of information attached to it such as the permitted and prohibited uses of the certificate and an "alias".

Normally when a certificate is being verified at least one certificate must be "trusted". By default a trusted certificate must be stored locally and must be a root CA: any certificate chain ending in this CA is then usable for any purpose.

Trust settings currently are only used with a root CA. They allow a finer control over the purposes the root CA can be used for. For example a CA may be trusted for SSL client but not SSL server use.

See the description of the **verify** utility for more information on the meaning of trust settings.

Future versions of OpenSSL will recognize trust settings on any certificate: not just root CAs.

-trustout

this causes **x509** to output a **trusted** certificate. An ordinary or trusted certificate can be input but by default an ordinary certificate is output and any trust settings are discarded. With the **-trustout** option a trusted certificate is output. A trusted certificate is automatically output if any trust settings are modified.

-setalias arg

sets the alias of the certificate. This will allow the certificate to be referred to using a nickname for example "Steve's Certificate".

-alias

outputs the certificate alias, if any.

-clrtrust

clears all the permitted or trusted uses of the certificate.

-clrreject

clears all the prohibited or rejected uses of the certificate.

-addtrust arg

adds a trusted certificate use. Any object name can be used here but currently only **clientAuth** (SSL client use), **serverAuth** (SSL server use) and **emailProtection** (S/MIME email) are used. Other OpenSSL applications may define additional uses.

-addreject arg

adds a prohibited use. It accepts the same values as the **-addtrust** option.

-purpose

this option performs tests on the certificate extensions and outputs the results. For a more complete description see the **CERTIFICATE EXTENSIONS** section.

SIGNING OPTIONS

The **x509** utility can be used to sign certificates and requests: it can thus behave like a "mini CA".

-signkey filename

this option causes the input file to be self signed using the supplied private key.

If the input file is a certificate it sets the issuer name to the subject name (i.e. makes it self signed) changes the public key to the supplied value and changes the start and end dates. The start date is set to the current time and the end date is set to a value determined by the **-days** option. Any certificate extensions are retained unless the **-clrext** option is supplied.

If the input is a certificate request then a self signed certificate is created using the supplied private key using the subject name in the request.

-passin arg

the key password source. For more information about the format of **arg** see the **PASS PHRASE ARGUMENTS** section in openssl(1).

-clrext

delete any extensions from a certificate. This option is used when a certificate is being created from another certificate (for example with the **-signkey** or the **-CA** options). Normally all extensions are retained.

-keyform PEM|DER

specifies the format (DER or PEM) of the private key file used in the **-signkey** option.

-days arg

specifies the number of days to make a certificate valid for. The default is 30 days.

-x509toreq

converts a certificate into a certificate request. The **-signkey** option is used to pass the required private key.

-req

by default a certificate is expected on input. With this option a certificate request is expected instead.

-set_serial n

specifies the serial number to use. This option can be used with either the **-signkey** or **-CA** options. If used in conjunction with the **-CA** option the serial number file (as specified by the **-CAserial** or **-CAcreateserial** options) is not used.

The serial number can be decimal or hex (if preceded by **0x**). Negative serial numbers can also be specified but their use is not recommended.

-CA filename

specifies the CA certificate to be used for signing. When this option is present **x509** behaves like a "mini CA". The input file is signed by this CA using this option: that is its issuer name is set to the subject name of the CA and it is digitally signed using the CAs private key.

This option is normally combined with the **-req** option. Without the **-req** option the input is a certificate which must be self signed.

-CAkey filename

sets the CA private key to sign a certificate with. If this option is not specified then it is assumed that the CA private key is present in the CA certificate file.

-CAserial filename

sets the CA serial number file to use.

When the **-CA** option is used to sign a certificate it uses a serial number specified in a file. This file consist of one line containing an even number of hex digits with the serial number to use. After each use the serial number is incremented and written out to the file again.

The default filename consists of the CA certificate file base name with ".srl" appended. For example if the CA certificate file is called "mycacert.pem" it expects to find a serial number file called "mycacert.srl".

-CAcreateserial

with this option the CA serial number file is created if it does not exist: it will contain the serial number "02" and the certificate being signed will have the 1 as its serial number. Normally if the **-CA** option is specified and the serial number file does not exist it is an error.

-extfile filename

file containing certificate extensions to use. If not specified then no extensions are added to the certificate.

-extensions section

the section to add certificate extensions from. If this option is not specified then the extensions should either be contained in the unnamed (default) section or the default section should contain a variable called "extensions" which contains the section to use. See the x509v3_config(5) manual page for details of the extension section format.

NAME OPTIONS

The **nameopt** command line switch determines how the subject and issuer names are displayed. If no **nameopt** switch is present the default "oneline" format is used which is compatible with previous versions of OpenSSL. Each option is described in detail below, all options can be preceded by a **-** to turn the option off. Only the first four will normally be used.

compat

use the old format. This is equivalent to specifying no name options at all.

RFC2253

displays names compatible with RFC2253 equivalent to **esc_2253**, **esc_ctrl**, **esc_msb**, **utf8**, **dump_nostr**, **dump_unknown**, **dump_der**, **sep_comma_plus**, **dn_rev** and **sname**.

oneline

a oneline format which is more readable than RFC2253. It is equivalent to specifying the **esc_2253**, **esc_ctrl**, **esc_msb**, **utf8**, **dump_nostr**, **dump_der**, **use_quote**, **sep_comma_plus_space**, **space_eq** and **sname** options.

multiline

a multiline format. It is equivalent **esc_ctrl**, **esc_msb**, **sep_multiline**, **space_eq**, **lname** and **align**.

esc_2253

escape the "special" characters required by RFC2253 in a field That is **,+"<>;**. Additionally **#** is escaped at the beginning of a string and a space character at the beginning or end of a string.

esc_ctrl

escape control characters. That is those with ASCII values less than 0x20 (space) and the delete (0x7f) character. They are escaped using the RFC2253 \XX notation (where XX are two hex digits representing the character value).

esc_msb

escape characters with the MSB set, that is with ASCII values larger than 127.

use_quote

escapes some characters by surrounding the whole string with **"** characters, without the option all escaping is done with the \ character.

utf8

convert all strings to UTF8 format first. This is required by RFC2253. If you are lucky enough to have a UTF8 compatible terminal then the use of this option (and **not** setting **esc_msb**) may result in the correct display of multibyte (international) characters. Is this option is not present then multibyte characters larger than 0xff will be represented using the format \UXXXX for 16 bits and \WXXXXXXXX for 32 bits. Also if this option is off any UTF8Strings will be converted to their character form first.

ignore_type

this option does not attempt to interpret multibyte characters in any way. That is their content octets are merely dumped as though one octet represents each character. This is useful for diagnostic purposes but will result in rather odd looking output.

show_type

show the type of the ASN1 character string. The type precedes the field contents. For example "BMPSTRING: Hello World".

dump_der

when this option is set any fields that need to be hexdumped will be dumped using the DER encoding of the field. Otherwise just the content octets will be displayed. Both options use the RFC2253 **#XXXX...** format.

dump_nostr

dump non character string types (for example OCTET STRING) if this option is not set then non character string types will be displayed as though each content octet represents a single character.

dump_all

dump all fields. This option when used with **dump_der** allows the DER encoding of the structure to be unambiguously determined.

dump_unknown

dump any field whose OID is not recognised by OpenSSL.

sep_comma_plus, **sep_comma_plus_space**, **sep_semi_plus_space**, **sep_multiline**

these options determine the field separators. The first character is between RDNs and the second between multiple AVAs (multiple AVAs are very rare and their use is discouraged). The options ending in "space" additionally place a space after the separator to make it more readable. The **sep_multiline** uses a linefeed character for the RDN separator and a spaced **+** for the AVA separator. It also indents the fields by four characters. If no field separator is specified then **sep_comma_plus_space** is used by default.

dn_rev

reverse the fields of the DN. This is required by RFC2253. As a side effect this also reverses the order of multiple AVAs but this is permissible.

nofname, **sname**, **lname**, **oid**

these options alter how the field name is displayed. **nofname** does not display the field at all. **sname** uses the "short name" form (CN for commonName for example). **lname** uses the long form. **oid** represents the OID in numerical form and is useful for diagnostic purpose.

align

align field values for a more readable output. Only usable with **sep_multiline**.

space_eq

places spaces round the **=** character which follows the field name.

TEXT OPTIONS

As well as customising the name output format, it is also possible to customise the actual fields printed using the **certopt** options when the **text** option is present. The default behaviour is to print all fields.

compatible

use the old format. This is equivalent to specifying no output options at all.

no_header

don't print header information: that is the lines saying "Certificate" and "Data".

no_version

don't print out the version number.

no_serial

don't print out the serial number.

no_signame

don't print out the signature algorithm used.

no_validity

don't print the validity, that is the **notBefore** and **notAfter** fields.

no_subject

don't print out the subject name.

no_issuer

don't print out the issuer name.

no_pubkey

don't print out the public key.

no_sigdump

don't give a hexadecimal dump of the certificate signature.

no_aux

don't print out certificate trust information.

no_extensions

don't print out any X509V3 extensions.

ext_default

retain default extension behaviour: attempt to print out unsupported certificate extensions.

ext_error

print an error message for unsupported certificate extensions.

ext_parse

ASN1 parse unsupported extensions.

ext_dump

hex dump unsupported extensions.

ca_default

the value used by the **ca** utility, equivalent to **no_issuer**, **no_pubkey**, **no_header**, **no_version**, **no_sigdump** and **no_signame**.

EXAMPLES

Note: in these examples the '\' means the example should be all on one line.

Display the contents of a certificate:

```
openssl x509 -in cert.pem -noout -text
```

Display the certificate serial number:

```
openssl x509 -in cert.pem -noout -serial
```

Display the certificate subject name:

```
openssl x509 -in cert.pem -noout -subject
```

Display the certificate subject name in RFC2253 form:

```
openssl x509 -in cert.pem -noout -subject -nameopt RFC2253
```

Display the certificate subject name in oneline form on a terminal supporting UTF8:

```
openssl x509 -in cert.pem -noout -subject -nameopt oneline,-esc_msb
```

Display the certificate MD5 fingerprint:

```
openssl x509 -in cert.pem -noout -fingerprint
```

Display the certificate SHA1 fingerprint:

```
openssl x509 -sha1 -in cert.pem -noout -fingerprint
```

Convert a certificate from PEM to DER format:

```
openssl x509 -in cert.pem -inform PEM -out cert.der -outform DER
```

Convert a certificate to a certificate request:

```
openssl x509 -x509toreq -in cert.pem -out req.pem -signkey key.pem
```

Convert a certificate request into a self signed certificate using extensions for a CA:

```
openssl x509 -req -in careq.pem -extfile openssl.cnf -extensions v3_ca \
       -signkey key.pem -out cacert.pem
```

Sign a certificate request using the CA certificate above and add user certificate extensions:

```
openssl x509 -req -in req.pem -extfile openssl.cnf -extensions v3_usr \
       -CA cacert.pem -CAkey key.pem -CAcreateserial
```

Set a certificate to be trusted for SSL client use and change set its alias to "Steve's Class 1 CA"

```
openssl x509 -in cert.pem -addtrust clientAuth \
       -setalias "Steve's Class 1 CA" -out trust.pem
```

NOTES

The PEM format uses the header and footer lines:

```
-----BEGIN CERTIFICATE-----
-----END CERTIFICATE-----
```

it will also handle files containing:

```
-----BEGIN X509 CERTIFICATE-----
-----END X509 CERTIFICATE-----
```

Trusted certificates have the lines

```
-----BEGIN TRUSTED CERTIFICATE-----
-----END TRUSTED CERTIFICATE-----
```

The conversion to UTF8 format used with the name options assumes that T61Strings use the ISO8859-1 character set. This is wrong but Netscape and MSIE do this as do many certificates. So although this is incorrect it is more likely to display the majority of certificates correctly.

The **-fingerprint** option takes the digest of the DER encoded certificate. This is commonly called a "fingerprint". Because of the nature of message digests the fingerprint of a certificate is unique to that certificate and two certificates with the same fingerprint can be considered to be the same.

The Netscape fingerprint uses MD5 whereas MSIE uses SHA1.

The **-email** option searches the subject name and the subject alternative name extension. Only unique email addresses will be printed out: it will not print the same address more than once.

CERTIFICATE EXTENSIONS

The **-purpose** option checks the certificate extensions and determines what the certificate can be used for. The actual checks done are rather complex and include various hacks and workarounds to handle broken certificates and software.

The same code is used when verifying untrusted certificates in chains so this section is useful if a chain is rejected by the verify code.

The basicConstraints extension CA flag is used to determine whether the certificate can be used as a CA. If the CA flag is true then it is a CA, if the CA flag is false then it is not a CA. **All** CAs should have the CA flag set to true.

If the basicConstraints extension is absent then the certificate is considered to be a "possible CA" other extensions are checked according to the intended use of the certificate. A warning is given in this case because the certificate should really not be regarded as a CA: however it is allowed to be a CA to work around some broken software.

If the certificate is a V1 certificate (and thus has no extensions) and it is self signed it is also assumed to be a CA but a warning is again given: this is to work around the problem of Verisign roots which are V1 self signed certificates.

If the keyUsage extension is present then additional restraints are made on the uses of the certificate. A CA certificate **must** have the keyCertSign bit set if the keyUsage extension is present.

The extended key usage extension places additional restrictions on the certificate uses. If this extension is present (whether critical or not) the key can only be used for the purposes specified.

A complete description of each test is given below. The comments about basicConstraints and keyUsage and V1 certificates above apply to **all** CA certificates.

SSL Client

> The extended key usage extension must be absent or include the "web client authentication" OID. keyUsage must be absent or it must have the digitalSignature bit set. Netscape certificate type must be absent or it must have the SSL client bit set.

SSL Client CA

> The extended key usage extension must be absent or include the "web client authentication" OID. Netscape certificate type must be absent or it must have the SSL CA bit set: this is used as a work around if the basicConstraints extension is absent.

SSL Server

> The extended key usage extension must be absent or include the "web server authentication" and/or one of the SGC OIDs. keyUsage must be absent or it must have the digitalSignature, the keyEncipherment set or both bits set. Netscape certificate type must be absent or have the SSL server bit set.

SSL Server CA

> The extended key usage extension must be absent or include the "web server authentication" and/or one of the SGC OIDs. Netscape certificate type must be absent or the SSL CA bit must be set: this is used as a work around if the basicConstraints extension is absent.

Netscape SSL Server

> For Netscape SSL clients to connect to an SSL server it must have the keyEncipherment bit set if the keyUsage extension is present. This isn't always valid because some cipher suites use the key for digital signing. Otherwise it is the same as a normal SSL server.

Common S/MIME Client Tests

The extended key usage extension must be absent or include the "email protection" OID. Netscape certificate type must be absent or should have the S/MIME bit set. If the S/MIME bit is not set in netscape certificate type then the SSL client bit is tolerated as an alternative but a warning is shown: this is because some Verisign certificates don't set the S/MIME bit.

S/MIME Signing

In addition to the common S/MIME client tests the digitalSignature bit must be set if the keyUsage extension is present.

S/MIME Encryption

In addition to the common S/MIME tests the keyEncipherment bit must be set if the keyUsage extension is present.

S/MIME CA

The extended key usage extension must be absent or include the "email protection" OID. Netscape certificate type must be absent or must have the S/MIME CA bit set: this is used as a work around if the basicConstraints extension is absent.

CRL Signing

The keyUsage extension must be absent or it must have the CRL signing bit set.

CRL Signing CA

The normal CA tests apply. Except in this case the basicConstraints extension must be present.

BUGS

Extensions in certificates are not transferred to certificate requests and vice versa.

It is possible to produce invalid certificates or requests by specifying the wrong private key or using inconsistent options in some cases: these should be checked.

There should be options to explicitly set such things as start and end dates rather than an offset from the current time.

The code to implement the verify behaviour described in the **TRUST SETTINGS** is currently being developed. It thus describes the intended behaviour rather than the current behaviour. It is hoped that it will represent reality in OpenSSL 0.9.5 and later.

SEE ALSO

HISTORY

Before OpenSSL 0.9.8, the default digest for RSA keys was MD5.

The hash algorithm used in the **-subject_hash** and **-issuer_hash** options before OpenSSL 1.0.0 was based on the deprecated MD5 algorithm and the encoding of the distinguished name. In OpenSSL 1.0.0 and later it is based on a canonical version of the DN using SHA1. This means that any directories using the old form must have their links rebuilt using **c_rehash** or similar.

Name

config — OpenSSL CONF library configuration files

DESCRIPTION

The OpenSSL CONF library can be used to read configuration files. It is used for the OpenSSL master configuration file **openssl.cnf** and in a few other places like **SPKAC** files and certificate extension files for the **x509** utility. OpenSSL applications can also use the CONF library for their own purposes.

A configuration file is divided into a number of sections. Each section starts with a line **[section_name]** and ends when a new section is started or end of file is reached. A section name can consist of alphanumeric characters and underscores.

The first section of a configuration file is special and is referred to as the **default** section this is usually unnamed and is from the start of file until the first named section. When a name is being looked up it is first looked up in a named section (if any) and then the default section.

The environment is mapped onto a section called **ENV**.

Comments can be included by preceding them with the **#** character

Each section in a configuration file consists of a number of name and value pairs of the form **name=value**

The **name** string can contain any alphanumeric characters as well as a few punctuation symbols such as **. , ;** and **_**.

The **value** string consists of the string following the **=** character until end of line with any leading and trailing white space removed.

The value string undergoes variable expansion. This can be done by including the form **$var** or **${var}**: this will substitute the value of the named variable in the current section. It is also possible to substitute a value from another section using the syntax **$section::name** or **${section::name}**. By using the form **$ENV::name** environment variables can be substituted. It is also possible to assign values to environment variables by using the name **ENV::name**, this will work if the program looks up environment variables using the **CONF** library instead of calling **getenv()** directly.

It is possible to escape certain characters by using any kind of quote or the \ character. By making the last character of a line a \ a **value** string can be spread across multiple lines. In addition the sequences **\n**, **\r**, **\b** and **\t** are recognized.

OPENSSL LIBRARY CONFIGURATION

In OpenSSL 0.9.7 and later applications can automatically configure certain aspects of OpenSSL using the master OpenSSL configuration file, or optionally an alternative configuration file. The **openssl** utility includes this functionality: any sub command uses the master OpenSSL configuration file unless an option is used in the sub command to use an alternative configuration file.

To enable library configuration the default section needs to contain an appropriate line which points to the main configuration section. The default name is **openssl_conf** which is used by the **openssl** utility. Other applications may use an alternative name such as **myapplicaton_conf**.

The configuration section should consist of a set of name value pairs which contain specific module configuration information. The **name** represents the name of the *configuration module* the meaning of the **value** is module specific: it may, for example, represent a further configuration section containing configuration module specific information. E.g.

```
openssl_conf = openssl_init

[openssl_init]

oid_section = new_oids
engines = engine_section
```

```
[new_oids]

… new oids here …

[engine_section]

… engine stuff here …
```

The features of each configuration module are described below.

ASN1 OBJECT CONFIGURATION MODULE

This module has the name **oid_section**. The value of this variable points to a section containing name value pairs of OIDs: the name is the OID short and long name, the value is the numerical form of the OID. Although some of the **openssl** utility sub commands already have their own ASN1 OBJECT section functionality not all do. By using the ASN1 OBJECT configuration module **all** the **openssl** utility sub commands can see the new objects as well as any compliant applications. For example:

```
[new_oids]

some_new_oid = 1.2.3.4
some_other_oid = 1.2.3.5
```

In OpenSSL 0.9.8 it is also possible to set the value to the long name followed by a comma and the numerical OID form. For example:

```
shortName = some object long name, 1.2.3.4
```

ENGINE CONFIGURATION MODULE

This ENGINE configuration module has the name **engines**. The value of this variable points to a section containing further ENGINE configuration information.

The section pointed to by **engines** is a table of engine names (though see **engine_id** below) and further sections containing configuration information specific to each ENGINE.

Each ENGINE specific section is used to set default algorithms, load dynamic, perform initialization and send ctrls. The actual operation performed depends on the *command* name which is the name of the name value pair. The currently supported commands are listed below.

For example:

```
[engine_section]

# Configure ENGINE named "foo"
foo = foo_section
# Configure ENGINE named "bar"
bar = bar_section

[foo_section]
… foo ENGINE specific commands …

[bar_section]
… "bar" ENGINE specific commands …
```

The command **engine_id** is used to give the ENGINE name. If used this command must be first. For example:

```
[engine_section]
# This would normally handle an ENGINE named "foo"
foo = foo_section

[foo_section]
# Override default name and use "myfoo" instead.
engine_id = myfoo
```

The command **dynamic_path** loads and adds an ENGINE from the given path. It is equivalent to sending the ctrls **SO_PATH** with the path argument followed by **LIST_ADD** with value 2 and **LOAD** to the dynamic ENGINE. If this is not the required behaviour then alternative ctrls can be sent directly to the dynamic ENGINE using ctrl commands.

The command **init** determines whether to initialize the ENGINE. If the value is **0** the ENGINE will not be initialized, if **1** and attempt it made to initialized the ENGINE immediately. If the **init** command is not present then an attempt will be made to initialize the ENGINE after all commands in its section have been processed.

The command **default_algorithms** sets the default algorithms an ENGINE will supply using the functions **ENGINE_set_default_string()**

If the name matches none of the above command names it is assumed to be a ctrl command which is sent to the ENGINE. The value of the command is the argument to the ctrl command. If the value is the string **EMPTY** then no value is sent to the command.

For example:

```
[engine_section]

# Configure ENGINE named "foo"
foo = foo_section

[foo_section]
# Load engine from DSO
dynamic_path = /some/path/fooengine.so
# A foo specific ctrl.
some_ctrl = some_value
# Another ctrl that doesn't take a value.
other_ctrl = EMPTY
# Supply all default algorithms
default_algorithms = ALL
```

EVP CONFIGURATION MODULE

This modules has the name **alg_section** which points to a section containing algorithm commands.

Currently the only algorithm command supported is **fips_mode** whose value should be a boolean string such as **on** or **off**. If the value is **on** this attempt to enter FIPS mode. If the call fails or the library is not FIPS capable then an error occurs.

For example:

```
alg_section = evp_settings

[evp_settings]

fips_mode = on
```

NOTES

If a configuration file attempts to expand a variable that doesn't exist then an error is flagged and the file will not load. This can happen if an attempt is made to expand an environment variable that doesn't exist. For example in a previous version of OpenSSL the default OpenSSL master configuration file used the value of **HOME** which may not be defined on non Unix systems and would cause an error.

This can be worked around by including a **default** section to provide a default value: then if the environment lookup fails the default value will be used instead. For this to work properly the default value must be defined earlier in the configuration file than the expansion. See the **EXAMPLES** section for an example of how to do this.

If the same variable exists in the same section then all but the last value will be silently ignored. In certain circumstances such as with DNs the same field may occur multiple times. This is usually worked around by ignoring any characters before an initial **.** e.g.

```
1.OU="My first OU"
```

```
2.OU="My Second OU"
```

EXAMPLES

Here is a sample configuration file using some of the features mentioned above.

```
# This is the default section.

HOME=/temp
RANDFILE= ${ENV::HOME}/.rnd
configdir=$ENV::HOME/config

[ section_one ]

# We are now in section one.

# Quotes permit leading and trailing whitespace
any = " any variable name "

other = A string that can \
cover several lines \
by including \\ characters

message = Hello World\n

[ section_two ]

greeting = $section_one::message
```

This next example shows how to expand environment variables safely.

Suppose you want a variable called **tmpfile** to refer to a temporary filename. The directory it is placed in can determined by the the **TEMP** or **TMP** environment variables but they may not be set to any value at all. If you just include the environment variable names and the variable doesn't exist then this will cause an error when an attempt is made to load the configuration file. By making use of the default section both values can be looked up with **TEMP** taking priority and **/tmp** used if neither is defined:

```
TMP=/tmp
# The above value is used if TMP isn't in the environment
TEMP=$ENV::TMP
# The above value is used if TEMP isn't in the environment
tmpfile=${ENV::TEMP}/tmp.filename
```

Simple OpenSSL library configuration example to enter FIPS mode:

```
# Default appname: should match "appname" parameter (if any)
# supplied to CONF_modules_load_file et al.
openssl_conf = openssl_conf_section

[openssl_conf_section]
# Configuration module list
alg_section = evp_sect

[evp_sect]
# Set to "yes" to enter FIPS mode if supported
fips_mode = yes
```

Note: in the above example you will get an error in non FIPS capable versions of OpenSSL.

More complex OpenSSL library configuration. Add OID and don't enter FIPS mode:

```
# Default appname: should match "appname" parameter (if any)
# supplied to CONF_modules_load_file et al.
openssl_conf = openssl_conf_section

[openssl_conf_section]
```

```
# Configuration module list
alg_section = evp_sect
oid_section = new_oids

[evp_sect]
# This will have no effect as FIPS mode is off by default.
# Set to "yes" to enter FIPS mode, if supported
fips_mode = no

[new_oids]
# New OID, just short name
newoid1 = 1.2.3.4.1
# New OID shortname and long name
newoid2 = New OID 2 long name, 1.2.3.4.2
```

The above examples can be used with with any application supporting library configuration if "openssl_conf" is modified to match the appropriate "appname".

For example if the second sample file above is saved to "example.cnf" then the command line:

```
OPENSSL_CONF=example.cnf openssl asn1parse -genstr OID:1.2.3.4.1
```

will output:

```
0:d=0  hl=2 l=   4 prim: OBJECT            :newoid1
```

showing that the OID "newoid1" has been added as "1.2.3.4.1".

BUGS

Currently there is no way to include characters using the octal **\nnn** form. Strings are all null terminated so nulls cannot form part of the value.

The escaping isn't quite right: if you want to use sequences like **\n** you can't use any quote escaping on the same line.

Files are loaded in a single pass. This means that an variable expansion will only work if the variables referenced are defined earlier in the file.

SEE ALSO

x509(1), req(1), ca(1)

Name

x509v3_config — X509 V3 certificate extension configuration format

DESCRIPTION

Several of the OpenSSL utilities can add extensions to a certificate or certificate request based on the contents of a configuration file.

Typically the application will contain an option to point to an extension section. Each line of the extension section takes the form:

```
extension_name=[critical,] extension_options
```

If **critical** is present then the extension will be critical.

The format of **extension_options** depends on the value of **extension_name**.

There are four main types of extension: *string* extensions, *multi-valued* extensions, *raw* and *arbitrary* extensions.

String extensions simply have a string which contains either the value itself or how it is obtained.

For example:

```
nsComment="This is a Comment"
```

Multi-valued extensions have a short form and a long form. The short form is a list of names and values:

```
basicConstraints=critical,CA:true,pathlen:1
```

The long form allows the values to be placed in a separate section:

```
basicConstraints=critical,@bs_section

[bs_section]

CA=true
pathlen=1
```

Both forms are equivalent.

The syntax of raw extensions is governed by the extension code: it can for example contain data in multiple sections. The correct syntax to use is defined by the extension code itself: check out the certificate policies extension for an example.

If an extension type is unsupported then the *arbitrary* extension syntax must be used, see the “ARBITRARY EXTENSIONS” section for more details.

STANDARD EXTENSIONS

The following sections describe each supported extension in detail.

Basic Constraints.

This is a multi valued extension which indicates whether a certificate is a CA certificate. The first (mandatory) name is **CA** followed by **TRUE** or **FALSE**. If **CA** is **TRUE** then an optional **pathlen** name followed by an non-negative value can be included.

For example:

```
basicConstraints=CA:TRUE

basicConstraints=CA:FALSE

basicConstraints=critical,CA:TRUE, pathlen:0
```

A CA certificate **must** include the basicConstraints value with the CA field set to TRUE. An end user certificate must either set CA to FALSE or exclude the extension entirely. Some software may require the inclusion of basicConstraints with CA set to FALSE for end entity certificates.

The pathlen parameter indicates the maximum number of CAs that can appear below this one in a chain. So if you have a CA with a pathlen of zero it can only be used to sign end user certificates and not further CAs.

Key Usage.

Key usage is a multi valued extension consisting of a list of names of the permitted key usages.

The supporte names are: digitalSignature, nonRepudiation, keyEncipherment, dataEncipherment, keyAgreement, keyCertSign, cRLSign, encipherOnly and decipherOnly.

Examples:

```
keyUsage=digitalSignature, nonRepudiation

keyUsage=critical, keyCertSign
```

Extended Key Usage.

This extensions consists of a list of usages indicating purposes for which the certificate public key can be used for,

These can either be object short names of the dotted numerical form of OIDs. While any OID can be used only certain values make sense. In particular the following PKIX, NS and MS values are meaningful:

```
Value                  Meaning
-----                  -------
serverAuth             SSL/TLS Web Server Authentication.
clientAuth             SSL/TLS Web Client Authentication.
codeSigning            Code signing.
emailProtection        E-mail Protection (S/MIME).
timeStamping           Trusted Timestamping
msCodeInd              Microsoft Individual Code Signing (authenticode)
msCodeCom              Microsoft Commercial Code Signing (authenticode)
msCTLSign              Microsoft Trust List Signing
msSGC                  Microsoft Server Gated Crypto
msEFS                  Microsoft Encrypted File System
nsSGC                  Netscape Server Gated Crypto
```

Examples:

```
extendedKeyUsage=critical,codeSigning,1.2.3.4
extendedKeyUsage=nsSGC,msSGC
```

Subject Key Identifier.

This is really a string extension and can take two possible values. Either the word **hash** which will automatically follow the guidelines in RFC3280 or a hex string giving the extension value to include. The use of the hex string is strongly discouraged.

Example:

```
subjectKeyIdentifier=hash
```

Authority Key Identifier.

The authority key identifier extension permits two options. keyid and issuer: both can take the optional value "always".

If the keyid option is present an attempt is made to copy the subject key identifier from the parent certificate. If the value "always" is present then an error is returned if the option fails.

The issuer option copies the issuer and serial number from the issuer certificate. This will only be done if the keyid option fails or is not included unless the "always" flag will always include the value.

Example:

```
authorityKeyIdentifier=keyid,issuer
```

Subject Alternative Name.

The subject alternative name extension allows various literal values to be included in the configuration file. These include **email** (an email address) **URI** a uniform resource indicator, **DNS** (a DNS domain name), **RID** (a registered ID: OBJECT IDENTIFIER), **IP** (an IP address), **dirName** (a distinguished name) and otherName.

The email option include a special 'copy' value. This will automatically include and email addresses contained in the certificate subject name in the extension.

The IP address used in the **IP** options can be in either IPv4 or IPv6 format.

The value of **dirName** should point to a section containing the distinguished name to use as a set of name value pairs. Multi values AVAs can be formed by prefacing the name with a **+** character.

otherName can include arbitrary data associated with an OID: the value should be the OID followed by a semicolon and the content in standard ASN1_generate_nconf(3) format.

Examples:

```
subjectAltName=email:copy,email:my@other.address,URI:http://my.url.here/
subjectAltName=IP:192.168.7.1
subjectAltName=IP:13::17
subjectAltName=email:my@other.address,RID:1.2.3.4
subjectAltName=otherName:1.2.3.4;UTF8:some other identifier

subjectAltName=dirName:dir_sect

[dir_sect]
C=UK
O=My Organization
OU=My Unit
CN=My Name
```

Issuer Alternative Name.

The issuer alternative name option supports all the literal options of subject alternative name. It does **not** support the email:copy option because that would not make sense. It does support an additional issuer:copy option that will copy all the subject alternative name values from the issuer certificate (if possible).

Example:

```
issuserAltName = issuer:copy
```

Authority Info Access.

The authority information access extension gives details about how to access certain information relating to the CA. Its syntax is accessOID;location where *location* has the same syntax as subject alternative name (except that email:copy is not supported). accessOID can be any valid OID but only certain values are meaningful, for example OCSP and caIssuers.

Example:

```
authorityInfoAccess = OCSP;URI:http://ocsp.my.host/
authorityInfoAccess = caIssuers;URI:http://my.ca/ca.html
```

CRL distribution points.

This is a multi-valued extension whose options can be either in name:value pair using the same form as subject alternative name or a single value representing a section name containing all the distribution point fields.

For a name:value pair a new DistributionPoint with the fullName field set to the given value both the cRLissuer and reasons fields are omitted in this case.

In the single option case the section indicated contains values for each field. In this section:

If the name is "fullname" the value field should contain the full name of the distribution point in the same format as subject alternative name.

If the name is "relativename" then the value field should contain a section name whose contents represent a DN fragment to be placed in this field.

The name "CRLIssuer" if present should contain a value for this field in subject alternative name format.

If the name is "reasons" the value field should consist of a comma separated field containing the reasons. Valid reasons are: "keyCompromise", "CACompromise", "affiliationChanged", "superseded", "cessationOfOperation", "certificateHold", "privilegeWithdrawn" and "AACompromise".

Simple examples:

```
crlDistributionPoints=URI:http://myhost.com/myca.crl
crlDistributionPoints=URI:http://my.com/my.crl,URI:http://oth.com/my.crl
```

Full distribution point example:

```
crlDistributionPoints=crldp1_section

[crldp1_section]

fullname=URI:http://myhost.com/myca.crl
CRLissuer=dirName:issuer_sect
reasons=keyCompromise, CACompromise

[issuer_sect]
C=UK
O=Organisation
CN=Some Name
```

Issuing Distribution Point

This extension should only appear in CRLs. It is a multi valued extension whose syntax is similar to the "section" pointed to by the CRL distribution points extension with a few differences.

The names "reasons" and "CRLissuer" are not recognized.

The name "onlysomereasons" is accepted which sets this field. The value is in the same format as the CRL distribution point "reasons" field.

The names "onlyuser", "onlyCA", "onlyAA" and "indirectCRL" are also accepted the values should be a boolean value (TRUE or FALSE) to indicate the value of the corresponding field.

Example:

```
issuingDistributionPoint=critical, @idp_section

[idp_section]
```

```
fullname=URI:http://myhost.com/myca.crl
indirectCRL=TRUE
onlysomereasons=keyCompromise, CACompromise

[issuer_sect]
C=UK
O=Organisation
CN=Some Name
```

Certificate Policies.

This is a *raw* extension. All the fields of this extension can be set by using the appropriate syntax.

If you follow the PKIX recommendations and just using one OID then you just include the value of that OID. Multiple OIDs can be set separated by commas, for example:

```
certificatePolicies= 1.2.4.5, 1.1.3.4
```

If you wish to include qualifiers then the policy OID and qualifiers need to be specified in a separate section: this is done by using the @section syntax instead of a literal OID value.

The section referred to must include the policy OID using the name policyIdentifier, cPSuri qualifiers can be included using the syntax:

```
CPS.nnn=value
```

userNotice qualifiers can be set using the syntax:

```
userNotice.nnn=@notice
```

The value of the userNotice qualifier is specified in the relevant section. This section can include explicitText, organization and noticeNumbers options. explicitText and organization are text strings, noticeNumbers is a comma separated list of numbers. The organization and noticeNumbers options (if included) must BOTH be present. If you use the userNotice option with IE5 then you need the 'ia5org' option at the top level to modify the encoding: otherwise it will not be interpreted properly.

Example:

```
certificatePolicies=ia5org,1.2.3.4,1.5.6.7.8,@polsect

[polsect]

policyIdentifier = 1.3.5.8
CPS.1="http://my.host.name/"
CPS.2="http://my.your.name/"
userNotice.1=@notice

[notice]

explicitText="Explicit Text Here"
organization="Organisation Name"
noticeNumbers=1,2,3,4
```

The **ia5org** option changes the type of the *organization* field. In RFC2459 it can only be of type DisplayText. In RFC3280 IA5String is also permissible. Some software (for example some versions of MSIE) may require ia5org.

Policy Constraints

This is a multi-valued extension which consisting of the names **requireExplicitPolicy** or **inhibitPolicyMapping** and a non negative intger value. At least one component must be present.

Example:

```
policyConstraints = requireExplicitPolicy:3
```

Inhibit Any Policy

This is a string extension whose value must be a non negative integer.

Example:

```
inhibitAnyPolicy = 2
```

Name Constraints

The name constraints extension is a multi-valued extension. The name should begin with the word **permitted** or **excluded** followed by a **;**. The rest of the name and the value follows the syntax of subjectAltName except email:copy is not supported and the **IP** form should consist of an IP addresses and subnet mask separated by a **/**.

Examples:

```
nameConstraints=permitted;IP:192.168.0.0/255.255.0.0

nameConstraints=permitted;email:.somedomain.com

nameConstraints=excluded;email:.com
```

OCSP No Check

The OCSP No Check extension is a string extension but its value is ignored.

Example:

```
noCheck = ignored
```

DEPRECATED EXTENSIONS

The following extensions are non standard, Netscape specific and largely obsolete. Their use in new applications is discouraged.

Netscape String extensions.

Netscape Comment (**nsComment**) is a string extension containing a comment which will be displayed when the certificate is viewed in some browsers.

Example:

```
nsComment = "Some Random Comment"
```

Other supported extensions in this category are: **nsBaseUrl**, **nsRevocationUrl**, **nsCaRevocationUrl**, **nsRenewalUrl**, **nsCaPolicyUrl** and **nsSslServerName**.

Netscape Certificate Type

This is a multi-valued extensions which consists of a list of flags to be included. It was used to indicate the purposes for which a certificate could be used. The basicConstraints, keyUsage and extended key usage extensions are now used instead.

Acceptable values for nsCertType are: **client**, **server**, **email**, **objsign**, **reserved**, **sslCA**, **emailCA**, **objCA**.

ARBITRARY EXTENSIONS

If an extension is not supported by the OpenSSL code then it must be encoded using the arbitrary extension format. It is also possible to use the arbitrary format for supported extensions. Extreme care should be taken to ensure that the data is formatted correctly for the given extension type.

There are two ways to encode arbitrary extensions.

The first way is to use the word ASN1 followed by the extension content using the same syntax as ASN1_generate_nconf(3). For example:

```
1.2.3.4=critical,ASN1:UTF8String:Some random data

1.2.3.4=ASN1:SEQUENCE:seq_sect

[seq_sect]

field1 = UTF8:field1
field2 = UTF8:field2
```

It is also possible to use the word DER to include the raw encoded data in any extension.

```
1.2.3.4=critical,DER:01:02:03:04
1.2.3.4=DER:01020304
```

The value following DER is a hex dump of the DER encoding of the extension Any extension can be placed in this form to override the default behaviour. For example:

```
basicConstraints=critical,DER:00:01:02:03
```

WARNING

There is no guarantee that a specific implementation will process a given extension. It may therefore be sometimes possible to use certificates for purposes prohibited by their extensions because a specific application does not recognize or honour the values of the relevant extensions.

The DER and ASN1 options should be used with caution. It is possible to create totally invalid extensions if they are not used carefully.

NOTES

If an extension is multi-value and a field value must contain a comma the long form must be used otherwise the comma would be misinterpreted as a field separator. For example:

```
subjectAltName=URI:ldap://somehost.com/CN=foo,OU=bar
```

will produce an error but the equivalent form:

```
subjectAltName=@subject_alt_section

[subject_alt_section]
subjectAltName=URI:ldap://somehost.com/CN=foo,OU=bar
```

is valid.

Due to the behaviour of the OpenSSL **conf** library the same field name can only occur once in a section. This means that:

```
subjectAltName=@alt_section

[alt_section]

email=steve@here
email=steve@there
```

will only recognize the last value. This can be worked around by using the form:

```
[alt_section]

```

```
email.1=steve@here
email.2=steve@there
```

HISTORY

The X509v3 extension code was first added to OpenSSL 0.9.2.

Policy mappings, inhibit any policy and name constraints support was added in OpenSSL 0.9.8

The **directoryName** and **otherName** option as well as the **ASN1** option for arbitrary extensions was added in OpenSSL 0.9.8

Cryptographic functions

Name

crypto — OpenSSL cryptographic library

Synopsis

DESCRIPTION

The OpenSSL **crypto** library implements a wide range of cryptographic algorithms used in various Internet standards. The services provided by this library are used by the OpenSSL implementations of SSL, TLS and S/MIME, and they have also been used to implement SSH, OpenPGP, and other cryptographic standards.

OVERVIEW

libcrypto consists of a number of sub-libraries that implement the individual algorithms.

The functionality includes symmetric encryption, public key cryptography and key agreement, certificate handling, cryptographic hash functions and a cryptographic pseudo-random number generator.

SYMMETRIC CIPHERS

blowfish(3), cast(3), des(3), idea(3), rc2(3), rc4(3), rc5(3)

PUBLIC KEY CRYPTOGRAPHY AND KEY AGREEMENT

dsa(3), dh(3), rsa(3)

CERTIFICATES

x509(3), x509v3(3)

AUTHENTICATION CODES
HASH FUNCTIONS

hmac(3), md2(3), md4(3), md5(3), mdc2(3), ripemd(3), sha(3)

AUXILIARY FUNCTIONS

err(3), threads(3), rand(3), OPENSSL_VERSION_NUMBER(3)

INPUT/OUTPUT
DATA ENCODING

asn1(3), bio(3), evp(3), pem(3), pkcs7(3), pkcs12(3)

INTERNAL FUNCTIONS

bn(3), buffer(3), lhash(3), objects(3), stack(3), txt_db(3)

NOTES

Some of the newer functions follow a naming convention using the numbers **0** and **1**. For example the functions:

```
int X509_CRL_add0_revoked(X509_CRL *crl, X509_REVOKED *rev);
int X509_add1_trust_object(X509 *x, ASN1_OBJECT *obj);
```

The **0** version uses the supplied structure pointer directly in the parent and it will be freed up when the parent is freed. In the above example **crl** would be freed but **rev** would not.

The **1** function uses a copy of the supplied structure pointer (or in some cases increases its link count) in the parent and so both (**x** and **obj** above) should be freed up.

SEE ALSO

openssl(1), ssl(3)

Name

ASN1_generate_nconf and ASN1_generate_v3 — ASN1 generation functions

Synopsis

```
#include  <openssl/asn1.h>
```

```
ASN1_TYPE *ASN1_generate_nconf(char *str, CONF *nconf);
ASN1_TYPE *ASN1_generate_v3(char *str, X509V3_CTX *cnf);
```

DESCRIPTION

These functions generate the ASN1 encoding of a string in an **ASN1_TYPE** structure.

str contains the string to encode **nconf** or **cnf** contains the optional configuration information where additional strings will be read from. **nconf** will typically come from a config file wherease **cnf** is obtained from an **X509V3_CTX** structure which will typically be used by X509 v3 certificate extension functions. **cnf** or **nconf** can be set to **NULL** if no additional configuration will be used.

GENERATION STRING FORMAT

The actual data encoded is determined by the string **str** and the configuration information. The general format of the string is:

[modifier,]type[:value]

That is zero or more comma separated modifiers followed by a type followed by an optional colon and a value. The formats of **type**, **value** and **modifier** are explained below.

SUPPORTED TYPES

The supported types are listed below. Unless otherwise specified only the **ASCII** format is permissible.

BOOLEAN
BOOL

This encodes a boolean type. The **value** string is mandatory and should be **TRUE** or **FALSE**. Additionally **TRUE**, **true**, **Y**, **y**, **YES**, **yes**, **FALSE**, **false**, **N**, **n**, **NO** and **no** are acceptable.

NULL

Encode the **NULL** type, the **value** string must not be present.

INTEGER
INT

Encodes an ASN1 **INTEGER** type. The **value** string represents the value of the integer, it can be prefaced by a minus sign and is normally interpreted as a decimal value unless the prefix **0x** is included.

ENUMERATED
ENUM

Encodes the ASN1 **ENUMERATED** type, it is otherwise identical to **INTEGER**.

OBJECT
OID

Encodes an ASN1 **OBJECT IDENTIFIER**, the **value** string can be a short name, a long name or numerical format.

UTCTIME
UTC

Encodes an ASN1 **UTCTime** structure, the value should be in the format **YYMMDDHHMMSSZ**.

GENERALIZEDTIME
GENTIME

Encodes an ASN1 **GeneralizedTime** structure, the value should be in the format **YYYYMMDDHHMMSSZ**.

OCTETSTRING
OCT

Encodes an ASN1 **OCTET STRING**. **value** represents the contents of this structure, the format strings **ASCII** and **HEX** can be used to specify the format of **value**.

BITSTRING
BITSTR

Encodes an ASN1 **BIT STRING**. **value** represents the contents of this structure, the format strings **ASCII**, **HEX** and **BITLIST** can be used to specify the format of **value**.

If the format is anything other than **BITLIST** the number of unused bits is set to zero.

UNIVERSALSTRING, **UNIV**, **IA5**, **IA5STRING**, **UTF8**, **UTF8String**, **BMP**, **BMPSTRING**, **VISIBLESTRING**, **VISIBLE**, **PRINTABLESTRING**, **PRINTABLE**, **T61**, **T61STRING**, **TELETEXSTRING**, **GeneralString**, **NUMERICSTRING**, **NUMERIC**

These encode the corresponding string types. **value** represents the contents of this structure. The format can be **ASCII** or **UTF8**.

SEQUENCE
SEQ
SET

Formats the result as an ASN1 **SEQUENCE** or **SET** type. **value** should be a section name which will contain the contents. The field names in the section are ignored and the values are in the generated string format. If **value** is absent then an empty SEQUENCE will be encoded.

MODIFIERS

Modifiers affect the following structure, they can be used to add EXPLICIT or IMPLICIT tagging, add wrappers or to change the string format of the final type and value. The supported formats are documented below.

EXPLICIT
EXP

Add an explicit tag to the following structure. This string should be followed by a colon and the tag value to use as a decimal value.

By following the number with **U**, **A**, **P** or **C** UNIVERSAL, APPLICATION, PRIVATE or CONTEXT SPECIFIC tagging can be used, the default is CONTEXT SPECIFIC.

IMPLICIT
IMP

This is the same as **EXPLICIT** except IMPLICIT tagging is used instead.

OCTWRAP
SEQWRAP
SETWRAP
BITWRAP

The following structure is surrounded by an OCTET STRING, a SEQUENCE, a SET or a BIT STRING respectively. For a BIT STRING the number of unused bits is set to zero.

FORMAT

This specifies the format of the ultimate value. It should be followed by a colon and one of the strings **ASCII**, **UTF8**, **HEX** or **BITLIST**.

If no format specifier is included then **ASCII** is used. If **UTF8** is specified then the value string must be a valid **UTF8** string. For **HEX** the output must be a set of hex digits. **BITLIST** (which is only valid for a BIT STRING) is a comma separated list of the indices of the set bits, all other bits are zero.

EXAMPLES

A simple IA5String:

```
IA5STRING:Hello World
```

An IA5String explicitly tagged:

```
EXPLICIT:0,IA5STRING:Hello World
```

An IA5String explicitly tagged using APPLICATION tagging:

```
EXPLICIT:0A,IA5STRING:Hello World
```

A BITSTRING with bits 1 and 5 set and all others zero:

```
FORMAT:BITLIST,BITSTRING:1,5
```

A more complex example using a config file to produce a SEQUENCE consiting of a BOOL an OID and a UTF8String:

```
asn1 = SEQUENCE:seq_section

[seq_section]

field1 = BOOLEAN:TRUE
field2 = OID:commonName
field3 = UTF8:Third field
```

This example produces an RSAPrivateKey structure, this is the key contained in the file client.pem in all OpenSSL distributions (note: the field names such as 'coeff' are ignored and are present just for clarity):

```
asn1=SEQUENCE:private_key
[private_key]
version=INTEGER:0

n=INTEGER:0xBB6FE79432CC6EA2D8F970675A5A87BFBE1AFF0BE63E879F2AFFB93644\
D4D2C6D000430DEC66ABF47829E74B8C5108623A1C0EE8BE217B3AD8D36D5EB4FCA1D9

e=INTEGER:0x010001

d=INTEGER:0x6F05EAD2F27FFAEC84BEC360C4B928FD5F3A9865D0FCAAD291E2A52F4A\
F810DC6373278C006A0ABBA27DC8C63BF97F7E666E27C5284D7D3B1FFFE16B7A87B51D

p=INTEGER:0xF3929B9435608F8A22C208D86795271D54EBDFB09DDEF539AB083DA912\
D4BD57
```

```
q=INTEGER:0xC50016F89DFF2561347ED1186A46E150E28BF2D0F539A1594BBD7FE467\
46EC4F

exp1=INTEGER:0x9E7D4326C924AFC1DEA40B45650134966D6F9DFA3A7F9D698CD4ABEA\
9C0A39B9

exp2=INTEGER:0xBA84003BB95355AFB7C50DF140C60513D0BA51D637272E355E397779\
E7B2458F

coeff=INTEGER:0x30B9E4F2AFA5AC679F920FC83F1F2DF1BAF1779CF989447FABC2F5\
628657053A
```

This example is the corresponding public key in a SubjectPublicKeyInfo structure:

```
# Start with a SEQUENCE
asn1=SEQUENCE:pubkeyinfo

# pubkeyinfo contains an algorithm identifier and the public key wrapped
# in a BIT STRING
[pubkeyinfo]
algorithm=SEQUENCE:rsa_alg
pubkey=BITWRAP,SEQUENCE:rsapubkey

# algorithm ID for RSA is just an OID and a NULL
[rsa_alg]
algorithm=OID:rsaEncryption
parameter=NULL

# Actual public key: modulus and exponent
[rsapubkey]
n=INTEGER:0xBB6FE79432CC6EA2D8F970675A5A87BFBE1AFF0BE63E879F2AFFB93644\
D4D2C6D000430DEC66ABF47829E74B8C5108623A1C0EE8BE217B3AD8D36D5EB4FCA1D9

e=INTEGER:0x010001
```

RETURN VALUES

ASN1_generate_nconf() and ASN1_generate_v3() return the encoded data as an **ASN1_TYPE** structure or **NULL** if an error occurred.

The error codes that can be obtained by ERR_get_error(3).

SEE ALSO

ERR_get_error(3)

HISTORY

ASN1_generate_nconf() and ASN1_generate_v3() were added to OpenSSL 0.9.8

Name

ASN1_OBJECT_new and ASN1_OBJECT_free — object allocation functions

Synopsis

```
#include  <openssl/asn1.h>
```

```
ASN1_OBJECT *ASN1_OBJECT_new(void);
void ASN1_OBJECT_free(ASN1_OBJECT *a);
```

DESCRIPTION

The ASN1_OBJECT allocation routines, allocate and free an ASN1_OBJECT structure, which represents an ASN1 OBJECT IDENTIFIER.

ASN1_OBJECT_new() allocates and initializes a ASN1_OBJECT structure.

ASN1_OBJECT_free() frees up the **ASN1_OBJECT** structure **a**.

NOTES

Although ASN1_OBJECT_new() allocates a new ASN1_OBJECT structure it is almost never used in applications. The ASN1 object utility functions such as OBJ_nid2obj() are used instead.

RETURN VALUES

If the allocation fails, ASN1_OBJECT_new() returns **NULL** and sets an error code that can be obtained by ERR_get_error(3). Otherwise it returns a pointer to the newly allocated structure.

ASN1_OBJECT_free() returns no value.

SEE ALSO

ERR_get_error(3), d2i_ASN1_OBJECT(3)

HISTORY

ASN1_OBJECT_new() and ASN1_OBJECT_free() are available in all versions of SSLeay and OpenSSL.

Name

ASN1_STRING_dup, ASN1_STRING_cmp, ASN1_STRING_set, ASN1_STRING_length, ASN1_STRING_length_set, ASN1_STRING_type and ASN1_STRING_data — ASN1_STRING utility functions

Synopsis

```
#include  <openssl/asn1.h>

int ASN1_STRING_length(ASN1_STRING *x);
unsigned char * ASN1_STRING_data(ASN1_STRING *x);

ASN1_STRING * ASN1_STRING_dup(ASN1_STRING *a);

int ASN1_STRING_cmp(ASN1_STRING *a, ASN1_STRING *b);

int ASN1_STRING_set(ASN1_STRING *str, const void *data, int len);

int ASN1_STRING_type(ASN1_STRING *x);

int ASN1_STRING_to_UTF8(unsigned char **out, ASN1_STRING *in);
```

DESCRIPTION

These functions allow an **ASN1_STRING** structure to be manipulated.

ASN1_STRING_length() returns the length of the content of **x**.

ASN1_STRING_data() returns an internal pointer to the data of **x**. Since this is an internal pointer it should **not** be freed or modified in any way.

ASN1_STRING_dup() returns a copy of the structure **a**.

ASN1_STRING_cmp() compares **a** and **b** returning 0 if the two are identical. The string types and content are compared.

ASN1_STRING_set() sets the data of string **str** to the buffer **data** or length **len**. The supplied data is copied. If **len** is -1 then the length is determined by strlen(data).

ASN1_STRING_type() returns the type of **x**, using standard constants such as **V_ASN1_OCTET_STRING**.

ASN1_STRING_to_UTF8() converts the string **in** to UTF8 format, the converted data is allocated in a buffer in ***out**. The length of **out** is returned or a negative error code. The buffer ***out** should be free using OPENSSL_free().

NOTES

Almost all ASN1 types in OpenSSL are represented as an **ASN1_STRING** structure. Other types such as **ASN1_OCTET_STRING** are simply typedefed to **ASN1_STRING** and the functions call the **ASN1_STRING** equivalents. **ASN1_STRING** is also used for some **CHOICE** types which consist entirely of primitive string types such as **DirectoryString** and **Time**.

These functions should **not** be used to examine or modify **ASN1_INTEGER** or **ASN1_ENUMERATED** types: the relevant **INTEGER** or **ENUMERATED** utility functions should be used instead.

In general it cannot be assumed that the data returned by ASN1_STRING_data() is null terminated or does not contain embedded nulls. The actual format of the data will depend on the actual string type itself: for example for and IA5String the data will be ASCII, for a BMPString two bytes per character in big endian format, UTF8String will be in UTF8 format.

Similar care should be take to ensure the data is in the correct format when calling ASN1_STRING_set().

RETURN VALUES

SEE ALSO

ERR_get_error(3)

HISTORY

Name

ASN1_STRING_new, ASN1_STRING_type_new and ASN1_STRING_free — ASN1_STRING allocation functions

Synopsis

```
#include  <openssl/asn1.h>
```

```
ASN1_STRING * ASN1_STRING_new(void);
ASN1_STRING * ASN1_STRING_type_new(int type);
void ASN1_STRING_free(ASN1_STRING *a);
```

DESCRIPTION

ASN1_STRING_new() returns an allocated **ASN1_STRING** structure. Its type is undefined.

ASN1_STRING_type_new() returns an allocated **ASN1_STRING** structure of type **type**.

ASN1_STRING_free() frees up **a**.

NOTES

Other string types call the **ASN1_STRING** functions. For example ASN1_OCTET_STRING_new() calls ASN1_STRING_type(V_ASN1_OCTET_STRING).

RETURN VALUES

ASN1_STRING_new() and ASN1_STRING_type_new() return a valid ASN1_STRING structure or **NULL** if an error occurred.

ASN1_STRING_free() does not return a value.

SEE ALSO

ERR_get_error(3)

HISTORY

TBA

Name

ASN1_STRING_print_ex and ASN1_STRING_print_ex_fp — ASN1_STRING output routines.

Synopsis

```
#include  <openssl/asn1.h>
```

```
int ASN1_STRING_print_ex(BIO *out, ASN1_STRING *str, unsigned long flags);
int ASN1_STRING_print_ex_fp(FILE *fp, ASN1_STRING *str, unsigned long flags);
int ASN1_STRING_print(BIO *out, ASN1_STRING *str);
```

DESCRIPTION

These functions output an **ASN1_STRING** structure. **ASN1_STRING** is used to represent all the ASN1 string types.

ASN1_STRING_print_ex() outputs **str** to **out**, the format is determined by the options **flags**. ASN1_STRING_print_ex_fp() is identical except it outputs to **fp** instead.

ASN1_STRING_print() prints **str** to **out** but using a different format to ASN1_STRING_print_ex(). It replaces unprintable characters (other than CR, LF) with '.'.

NOTES

ASN1_STRING_print() is a legacy function which should be avoided in new applications.

Although there are a large number of options frequently **ASN1_STRFLGS_RFC2253** is suitable, or on UTF8 terminals **ASN1_STRFLGS_RFC2253 & ~ASN1_STRFLGS_ESC_MSB**.

The complete set of supported options for **flags** is listed below.

Various characters can be escaped. If **ASN1_STRFLGS_ESC_2253** is set the characters determined by RFC2253 are escaped. If **ASN1_STRFLGS_ESC_CTRL** is set control characters are escaped. If **ASN1_STRFLGS_ESC_MSB** is set characters with the MSB set are escaped: this option should **not** be used if the terminal correctly interprets UTF8 sequences.

Escaping takes several forms.

If the character being escaped is a 16 bit character then the form "\UXXXX" is used using exactly four characters for the hex representation. If it is 32 bits then "\WXXXXXXXX" is used using eight characters of its hex representation. These forms will only be used if UTF8 conversion is not set (see below).

Printable characters are normally escaped using the backslash '\' character. If **ASN1_STRFLGS_ESC_QUOTE** is set then the whole string is instead surrounded by double quote characters: this is arguably more readable than the backslash notation. Other characters use the "\XX" using exactly two characters of the hex representation.

If **ASN1_STRFLGS_UTF8_CONVERT** is set then characters are converted to UTF8 format first. If the terminal supports the display of UTF8 sequences then this option will correctly display multi byte characters.

If **ASN1_STRFLGS_IGNORE_TYPE** is set then the string type is not interpreted at all: everything is assumed to be one byte per character. This is primarily for debugging purposes and can result in confusing output in multi character strings.

If **ASN1_STRFLGS_SHOW_TYPE** is set then the string type itself is printed out before its value (for example "BMPSTRING"), this actually uses ASN1_tag2str().

The content of a string instead of being interpreted can be "dumped": this just outputs the value of the string using the form #XXXX using hex format for each octet.

If **ASN1_STRFLGS_DUMP_ALL** is set then any type is dumped.

Normally non character string types (such as OCTET STRING) are assumed to be one byte per character, if **ASN1_STRFLGS_DUMP_UNKNOWN** is set then they will be dumped instead.

When a type is dumped normally just the content octets are printed, if **ASN1_STRFLGS_DUMP_DER** is set then the complete encoding is dumped instead (including tag and length octets).

ASN1_STRFLGS_RFC2253 includes all the flags required by RFC2253. It is equivalent to: ASN1_STRFLGS_ESC_2253 | ASN1_STRFLGS_ESC_CTRL | ASN1_STRFLGS_ESC_MSB | ASN1_STRFLGS_UTF8_CONVERT | ASN1_STRFLGS_DUMP_UNKNOWN ASN1_STRFLGS_DUMP_DER

HISTORY

TBA

Name

bio — I/O abstraction

Synopsis

```
#include <openssl/bio.h>
```

```
TBA
```

DESCRIPTION

A BIO is an I/O abstraction, it hides many of the underlying I/O details from an application. If an application uses a BIO for its I/O it can transparently handle SSL connections, unencrypted network connections and file I/O.

There are two type of BIO, a source/sink BIO and a filter BIO.

As its name implies a source/sink BIO is a source and/or sink of data, examples include a socket BIO and a file BIO.

A filter BIO takes data from one BIO and passes it through to another, or the application. The data may be left unmodified (for example a message digest BIO) or translated (for example an encryption BIO). The effect of a filter BIO may change according to the I/O operation it is performing: for example an encryption BIO will encrypt data if it is being written to and decrypt data if it is being read from.

BIOs can be joined together to form a chain (a single BIO is a chain with one component). A chain normally consist of one source/sink BIO and one or more filter BIOs. Data read from or written to the first BIO then traverses the chain to the end (normally a source/sink BIO).

```

DESCRIPTION

BIO_ctrl(), BIO_callback_ctrl(), BIO_ptr_ctrl() and BIO_int_ctrl() are BIO "control" operations taking arguments of various types. These functions are not normally called directly, various macros are used instead. The standard macros are described below, macros specific to a particular type of BIO are described in the specific BIOs manual page as well as any special features of the standard calls.

BIO_reset() typically resets a BIO to some initial state, in the case of file related BIOs for example it rewinds the file pointer to the start of the file.

BIO_seek() resets a file related BIO's (that is file descriptor and FILE BIOs) file position pointer to **ofs** bytes from start of file.

BIO_tell() returns the current file position of a file related BIO.

BIO_flush() normally writes out any internally buffered data, in some cases it is used to signal EOF and that no more data will be written.

BIO_eof() returns 1 if the BIO has read EOF, the precise meaning of "EOF" varies according to the BIO type.

BIO_set_close() sets the BIO **b** close flag to **flag**. **flag** can take the value BIO_CLOSE or BIO_NOCLOSE. Typically BIO_CLOSE is used in a source/sink BIO to indicate that the underlying I/O stream should be closed when the BIO is freed.

BIO_get_close() returns the BIOs close flag.

BIO_pending(), BIO_ctrl_pending(), BIO_wpending() and BIO_ctrl_wpending() return the number of pending characters in the BIOs read and write buffers. Not all BIOs support these calls. BIO_ctrl_pending() and BIO_ctrl_wpending() return a size_t type and are functions, BIO_pending() and BIO_wpending() are macros which call BIO_ctrl().

RETURN VALUES

BIO_reset() normally returns 1 for success and 0 or -1 for failure. File BIOs are an exception, they return 0 for success and -1 for failure.

BIO_seek() and BIO_tell() both return the current file position on success and -1 for failure, except file BIOs which for BIO_seek() always return 0 for success and -1 for failure.

BIO_flush() returns 1 for success and 0 or -1 for failure.

BIO_eof() returns 1 if EOF has been reached 0 otherwise.

BIO_set_close() always returns 1.

BIO_get_close() returns the close flag value: BIO_CLOSE or BIO_NOCLOSE.

BIO_pending(), BIO_ctrl_pending(), BIO_wpending() and BIO_ctrl_wpending() return the amount of pending data.

NOTES

BIO_flush(), because it can write data may return 0 or -1 indicating that the call should be retried later in a similar manner to BIO_write(). The BIO_should_retry() call should be used and appropriate action taken is the call fails.

The return values of BIO_pending() and BIO_wpending() may not reliably determine the amount of pending data in all cases. For example in the case of a file BIO some data may be available in the FILE structures internal buffers but it is not possible to determine this in a portably way. For other types of BIO they may not be supported.

Filter BIOs if they do not internally handle a particular BIO_ctrl() operation usually pass the operation to the next BIO in the chain. This often means there is no need to locate the required BIO for a particular operation, it can be called on a chain and it will be automatically passed to the relevant BIO. However this can cause unexpected results: for example no current filter BIOs implement BIO_seek(), but this may still succeed if the chain ends in a FILE or file descriptor BIO.

Source/sink BIOs return an 0 if they do not recognize the BIO_ctrl() operation.

BUGS

Some of the return values are ambiguous and care should be taken. In particular a return value of 0 can be returned if an operation is not supported, if an error occurred, if EOF has not been reached and in the case of BIO_seek() on a file BIO for a successful operation.

SEE ALSO

TBA

Name

BIO_f_base64 — base64 BIO filter

Synopsis

```
#include  <openssl/bio.h>
#include  <openssl/evp.h>
```

```
BIO_METHOD *   BIO_f_base64(void);
```

DESCRIPTION

BIO_f_base64() returns the base64 BIO method. This is a filter BIO that base64 encodes any data written through it and decodes any data read through it.

Base64 BIOs do not support BIO_gets() or BIO_puts().

BIO_flush() on a base64 BIO that is being written through is used to signal that no more data is to be encoded: this is used to flush the final block through the BIO.

The flag BIO_FLAGS_BASE64_NO_NL can be set with BIO_set_flags() to encode the data all on one line or expect the data to be all on one line.

NOTES

Because of the format of base64 encoding the end of the encoded block cannot always be reliably determined.

RETURN VALUES

BIO_f_base64() returns the base64 BIO method.

EXAMPLES

Base64 encode the string "Hello World\n" and write the result to standard output:

```
BIO *bio, *b64;
char message[] = "Hello World \n";

b64 = BIO_new(BIO_f_base64());
bio = BIO_new_fp(stdout, BIO_NOCLOSE);
BIO_push(b64, bio);
BIO_write(b64, message, strlen(message));
BIO_flush(b64);

BIO_free_all(b64);
```

Read Base64 encoded data from standard input and write the decoded data to standard output:

```
BIO *bio, *b64, *bio_out;
char inbuf[512];
int inlen;

b64 = BIO_new(BIO_f_base64());
bio = BIO_new_fp(stdin, BIO_NOCLOSE);
bio_out = BIO_new_fp(stdout, BIO_NOCLOSE);
BIO_push(b64, bio);
while((inlen = BIO_read(b64, inbuf, 512)) > 0)
       BIO_write(bio_out, inbuf, inlen);
```

```
BIO_flush(bio_out);
BIO_free_all(b64);
```

BUGS

The ambiguity of EOF in base64 encoded data can cause additional data following the base64 encoded block to be misinterpreted.

There should be some way of specifying a test that the BIO can perform to reliably determine EOF (for example a MIME boundary).

Name

BIO_f_buffer — buffering BIO

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO_METHOD * BIO_f_buffer(void);
```

```
#define BIO_get_buffer_num_lines(b)          BIO_ctrl(b,BIO_C_GET_BUFF_NUM_LINES,0,NULL)
#define BIO_set_read_buffer_size(b,size)     BIO_int_ctrl(b,BIO_C_SET_BUFF_SIZE,size,0)
#define BIO_set_write_buffer_size(b,size)    BIO_int_ctrl(b,BIO_C_SET_BUFF_SIZE,size,1)
#define BIO_set_buffer_size(b,size)          BIO_ctrl(b,BIO_C_SET_BUFF_SIZE,size,NULL)
#define BIO_set_buffer_read_data(b,buf,num)  BIO_ctrl(b,BIO_C_SET_BUFF_READ_DATA,num,buf)
```

DESCRIPTION

BIO_f_buffer() returns the buffering BIO method.

Data written to a buffering BIO is buffered and periodically written to the next BIO in the chain. Data read from a buffering BIO comes from an internal buffer which is filled from the next BIO in the chain. Both BIO_gets() and BIO_puts() are supported.

Calling BIO_reset() on a buffering BIO clears any buffered data.

BIO_get_buffer_num_lines() returns the number of lines currently buffered.

BIO_set_read_buffer_size(), BIO_set_write_buffer_size() and BIO_set_buffer_size() set the read, write or both read and write buffer sizes to **size**. The initial buffer size is DEFAULT_BUFFER_SIZE, currently 4096. Any attempt to reduce the buffer size below DEFAULT_BUFFER_SIZE is ignored. Any buffered data is cleared when the buffer is resized.

BIO_set_buffer_read_data() clears the read buffer and fills it with **num** bytes of **buf**. If **num** is larger than the current buffer size the buffer is expanded.

NOTES

Buffering BIOs implement BIO_gets() by using BIO_read() operations on the next BIO in the chain. By prepending a buffering BIO to a chain it is therefore possible to provide BIO_gets() functionality if the following BIOs do not support it (for example SSL BIOs).

Data is only written to the next BIO in the chain when the write buffer fills or when BIO_flush() is called. It is therefore important to call BIO_flush() whenever any pending data should be written such as when removing a buffering BIO using BIO_pop(). BIO_flush() may need to be retried if the ultimate source/sink BIO is non blocking.

RETURN VALUES

BIO_f_buffer() returns the buffering BIO method.

BIO_get_buffer_num_lines() returns the number of lines buffered (may be 0).

BIO_set_read_buffer_size(), BIO_set_write_buffer_size() and BIO_set_buffer_size() return 1 if the buffer was successfully resized or 0 for failure.

BIO_set_buffer_read_data() returns 1 if the data was set correctly or 0 if there was an error.

Name

BIO_f_cipher, BIO_set_cipher, BIO_get_cipher_status and BIO_get_cipher_ctx — cipher BIO filter

Synopsis

```
#include  <openssl/bio.h>
#include  <openssl/evp.h>
```

```
BIO_METHOD *   BIO_f_cipher(void);
void BIO_set_cipher(BIO *b,const EVP_CIPHER *cipher,
               unsigned char *key, unsigned char *iv, int enc);
int BIO_get_cipher_status(BIO *b)
int BIO_get_cipher_ctx(BIO *b, EVP_CIPHER_CTX **pctx)
```

DESCRIPTION

BIO_f_cipher() returns the cipher BIO method. This is a filter BIO that encrypts any data written through it, and decrypts any data read from it. It is a BIO wrapper for the cipher routines EVP_CipherInit(), EVP_CipherUpdate() and EVP_CipherFinal().

Cipher BIOs do not support BIO_gets() or BIO_puts().

BIO_flush() on an encryption BIO that is being written through is used to signal that no more data is to be encrypted: this is used to flush and possibly pad the final block through the BIO.

BIO_set_cipher() sets the cipher of BIO **b** to **cipher** using key **key** and IV **iv**. **enc** should be set to 1 for encryption and zero for decryption.

When reading from an encryption BIO the final block is automatically decrypted and checked when EOF is detected. BIO_get_cipher_status() is a BIO_ctrl() macro which can be called to determine whether the decryption operation was successful.

BIO_get_cipher_ctx() is a BIO_ctrl() macro which retrieves the internal BIO cipher context. The retrieved context can be used in conjunction with the standard cipher routines to set it up. This is useful when BIO_set_cipher() is not flexible enough for the applications needs.

NOTES

When encrypting BIO_flush() **must** be called to flush the final block through the BIO. If it is not then the final block will fail a subsequent decrypt.

When decrypting an error on the final block is signalled by a zero return value from the read operation. A successful decrypt followed by EOF will also return zero for the final read. BIO_get_cipher_status() should be called to determine if the decrypt was successful.

As always, if BIO_gets() or BIO_puts() support is needed then it can be achieved by preceding the cipher BIO with a buffering BIO.

RETURN VALUES

BIO_f_cipher() returns the cipher BIO method.

BIO_set_cipher() does not return a value.

BIO_get_cipher_status() returns 1 for a successful decrypt and 0 for failure.

BIO_get_cipher_ctx() currently always returns 1.

#define BIO_TYPE_FILTER        0x0200
#define BIO_TYPE_SOURCE_SINK   0x0400
```

DESCRIPTION

The BIO_find_type() searches for a BIO of a given type in a chain, starting at BIO **b**. If **type** is a specific type (such as BIO_TYPE_MEM) then a search is made for a BIO of that type. If **type** is a general type (such as **BIO_TYPE_SOURCE_SINK**) then the next matching BIO of the given general type is searched for. BIO_find_type() returns the next matching BIO or NULL if none is found.

Note: not all the **BIO_TYPE_*** types above have corresponding BIO implementations.

BIO_next() returns the next BIO in a chain. It can be used to traverse all BIOs in a chain or used in conjunction with BIO_find_type() to find all BIOs of a certain type.

BIO_method_type() returns the type of a BIO.

RETURN VALUES

BIO_find_type() returns a matching BIO or NULL for no match.

BIO_next() returns the next BIO in a chain.

BIO_method_type() returns the type of the BIO **b**.

NOTES

BIO_next() was added to OpenSSL 0.9.6 to provide a 'clean' way to traverse a BIO chain or find multiple matches using BIO_find_type(). Previous versions had to use:

```
next = bio->next_bio;
```

BUGS

BIO_find_type() in OpenSSL 0.9.5a and earlier could not be safely passed a NULL pointer for the **b** argument.

EXAMPLE

Traverse a chain looking for digest BIOs:

```
BIO *btmp;
btmp = in_bio; /* in_bio is chain to search through */

do {
       btmp = BIO_find_type(btmp, BIO_TYPE_MD);
       if(btmp == NULL) break; /* Not found */
       /* btmp is a digest BIO, do something with it …*/
       …

       btmp = BIO_next(btmp);
} while(btmp);
```

SEE ALSO

TBA

Name

BIO_f_md, BIO_set_md, BIO_get_md and BIO_get_md_ctx — message digest BIO filter

Synopsis

```
#include  <openssl/bio.h>
#include  <openssl/evp.h>
```

```
BIO_METHOD *   BIO_f_md(void);
int BIO_set_md(BIO *b,EVP_MD *md);
int BIO_get_md(BIO *b,EVP_MD **mdp);
int BIO_get_md_ctx(BIO *b,EVP_MD_CTX **mdcp);
```

DESCRIPTION

BIO_f_md() returns the message digest BIO method. This is a filter BIO that digests any data passed through it, it is a BIO wrapper for the digest routines EVP_DigestInit(), EVP_DigestUpdate() and EVP_DigestFinal().

Any data written or read through a digest BIO using BIO_read() and BIO_write() is digested.

BIO_gets(), if its **size** parameter is large enough finishes the digest calculation and returns the digest value. BIO_puts() is not supported.

BIO_reset() reinitialises a digest BIO.

BIO_set_md() sets the message digest of BIO **b** to **md**: this must be called to initialize a digest BIO before any data is passed through it. It is a BIO_ctrl() macro.

BIO_get_md() places the a pointer to the digest BIOs digest method in **mdp**, it is a BIO_ctrl() macro.

BIO_get_md_ctx() returns the digest BIOs context into **mdcp**.

NOTES

The context returned by BIO_get_md_ctx() can be used in calls to EVP_DigestFinal() and also the signature routines EVP_SignFinal() and EVP_VerifyFinal().

The context returned by BIO_get_md_ctx() is an internal context structure. Changes made to this context will affect the digest BIO itself and the context pointer will become invalid when the digest BIO is freed.

After the digest has been retrieved from a digest BIO it must be reinitialized by calling BIO_reset(), or BIO_set_md() before any more data is passed through it.

If an application needs to call BIO_gets() or BIO_puts() through a chain containing digest BIOs then this can be done by prepending a buffering BIO.

Before OpenSSL 1.0.0 the call to BIO_get_md_ctx() would only work if the BIO had been initialized for example by calling BIO_set_md()). In OpenSSL 1.0.0 and later the context is always returned and the BIO is state is set to initialized. This allows applications to initialize the context externally if the standard calls such as BIO_set_md() are not sufficiently flexible.

RETURN VALUES

BIO_f_md() returns the digest BIO method.

BIO_set_md(), BIO_get_md() and BIO_md_ctx() return 1 for success and 0 for failure.

EXAMPLES

The following example creates a BIO chain containing an SHA1 and MD5 digest BIO and passes the string "Hello World" through it. Error checking has been omitted for clarity.

```
BIO *bio, *mdtmp;
char message[] = "Hello World";
bio = BIO_new(BIO_s_null());
mdtmp = BIO_new(BIO_f_md());
BIO_set_md(mdtmp, EVP_sha1());
/* For BIO_push() we want to append the sink BIO and keep a note of
 * the start of the chain.
 */
bio = BIO_push(mdtmp, bio);
mdtmp = BIO_new(BIO_f_md());
BIO_set_md(mdtmp, EVP_md5());
bio = BIO_push(mdtmp, bio);
/* Note: mdtmp can now be discarded */
BIO_write(bio, message, strlen(message));
```

The next example digests data by reading through a chain instead:

```
BIO *bio, *mdtmp;
char buf[1024];
int rdlen;
bio = BIO_new_file(file, "rb");
mdtmp = BIO_new(BIO_f_md());
BIO_set_md(mdtmp, EVP_sha1());
bio = BIO_push(mdtmp, bio);
mdtmp = BIO_new(BIO_f_md());
BIO_set_md(mdtmp, EVP_md5());
bio = BIO_push(mdtmp, bio);
do {
       rdlen = BIO_read(bio, buf, sizeof(buf));
       /* Might want to do something with the data here */
} while(rdlen > 0);
```

This next example retrieves the message digests from a BIO chain and outputs them. This could be used with the examples above.

```
BIO *mdtmp;
unsigned char mdbuf[EVP_MAX_MD_SIZE];
int mdlen;
int i;
mdtmp = bio;   /* Assume bio has previously been set up */
do {
       EVP_MD *md;
       mdtmp = BIO_find_type(mdtmp, BIO_TYPE_MD);
       if(!mdtmp) break;
       BIO_get_md(mdtmp, &md);
       printf("%s digest", OBJ_nid2sn(EVP_MD_type(md)));
       mdlen = BIO_gets(mdtmp, mdbuf, EVP_MAX_MD_SIZE);
       for(i = 0; i < mdlen; i++) printf(":%02X", mdbuf[i]);
       printf("\n");
       mdtmp = BIO_next(mdtmp);
} while(mdtmp);

BIO_free_all(bio);
```

BUGS

The lack of support for BIO_puts() and the non standard behaviour of BIO_gets() could be regarded as anomalous. It could be argued that BIO_gets() and BIO_puts() should be passed to the next BIO in the chain and digest the data passed through and that digests should be retrieved using a separate BIO_ctrl() call.

SEE ALSO

TBA

Name

BIO_f_null — null filter

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO_METHOD *   BIO_f_null(void);
```

DESCRIPTION

BIO_f_null() returns the null filter BIO method. This is a filter BIO that does nothing.

All requests to a null filter BIO are passed through to the next BIO in the chain: this means that a BIO chain containing a null filter BIO behaves just as though the BIO was not there.

NOTES

As may be apparent a null filter BIO is not particularly useful.

RETURN VALUES

BIO_f_null() returns the null filter BIO method.

```

DESCRIPTION

BIO_f_ssl() returns the SSL BIO method. This is a filter BIO which is a wrapper round the OpenSSL SSL routines adding a BIO "flavour" to SSL I/O.

I/O performed on an SSL BIO communicates using the SSL protocol with the SSLs read and write BIOs. If an SSL connection is not established then an attempt is made to establish one on the first I/O call.

If a BIO is appended to an SSL BIO using BIO_push() it is automatically used as the SSL BIOs read and write BIOs.

Calling BIO_reset() on an SSL BIO closes down any current SSL connection by calling SSL_shutdown(). BIO_reset() is then sent to the next BIO in the chain: this will typically disconnect the underlying transport. The SSL BIO is then reset to the initial accept or connect state.

If the close flag is set when an SSL BIO is freed then the internal SSL structure is also freed using SSL_free().

BIO_set_ssl() sets the internal SSL pointer of BIO **b** to **ssl** using the close flag **c**.

BIO_get_ssl() retrieves the SSL pointer of BIO **b**, it can then be manipulated using the standard SSL library functions.

BIO_set_ssl_mode() sets the SSL BIO mode to **client**. If **client** is 1 client mode is set. If **client** is 0 server mode is set.

BIO_set_ssl_renegotiate_bytes() sets the renegotiate byte count to **num**. When set after every **num** bytes of I/O (read and write) the SSL session is automatically renegotiated. **num** must be at least 512 bytes.

BIO_set_ssl_renegotiate_timeout() sets the renegotiate timeout to **seconds**. When the renegotiate timeout elapses the session is automatically renegotiated.

BIO_get_num_renegotiates() returns the total number of session renegotiations due to I/O or timeout.

BIO_new_ssl() allocates an SSL BIO using SSL_CTX **ctx** and using client mode if **client** is non zero.

BIO_new_ssl_connect() creates a new BIO chain consisting of an SSL BIO (using **ctx**) followed by a connect BIO.

BIO_new_buffer_ssl_connect() creates a new BIO chain consisting of a buffering BIO, an SSL BIO (using **ctx**) and a connect BIO.

BIO_ssl_copy_session_id() copies an SSL session id between BIO chains **from** and **to**. It does this by locating the SSL BIOs in each chain and calling SSL_copy_session_id() on the internal SSL pointer.

BIO_ssl_shutdown() closes down an SSL connection on BIO chain **bio**. It does this by locating the SSL BIO in the chain and calling SSL_shutdown() on its internal SSL pointer.

BIO_do_handshake() attempts to complete an SSL handshake on the supplied BIO and establish the SSL connection. It returns 1 if the connection was established successfully. A zero or negative value is returned if the connection could not be established, the call BIO_should_retry() should be used for non blocking connect BIOs to determine if the call should be retried. If an SSL connection has already been established this call has no effect.

NOTES

SSL BIOs are exceptional in that if the underlying transport is non blocking they can still request a retry in exceptional circumstances. Specifically this will happen if a session renegotiation takes place during a BIO_read() operation, one case where this happens is when SGC or step up occurs.

In OpenSSL 0.9.6 and later the SSL flag SSL_AUTO_RETRY can be set to disable this behaviour. That is when this flag is set an SSL BIO using a blocking transport will never request a retry.

Since unknown BIO_ctrl() operations are sent through filter BIOs the servers name and port can be set using BIO_set_host() on the BIO returned by BIO_new_ssl_connect() without having to locate the connect BIO first.

Applications do not have to call BIO_do_handshake() but may wish to do so to separate the handshake process from other I/O processing.

RETURN VALUES

TBA

EXAMPLE

This SSL/TLS client example, attempts to retrieve a page from an SSL/TLS web server. The I/O routines are identical to those of the unencrypted example in BIO_s_connect(3).

```
BIO *sbio, *out;
int len;
char tmpbuf[1024];
SSL_CTX *ctx;
SSL *ssl;

ERR_load_crypto_strings();
ERR_load_SSL_strings();
OpenSSL_add_all_algorithms();

/* We would seed the PRNG here if the platform didn't
 * do it automatically
 */

ctx = SSL_CTX_new(SSLv23_client_method());

/* We'd normally set some stuff like the verify paths and
 * mode here because as things stand this will connect to
 * any server whose certificate is signed by any CA.
 */

sbio = BIO_new_ssl_connect(ctx);
```

```
BIO_get_ssl(sbio, &ssl);

if(!ssl) {
  fprintf(stderr, "Can't locate SSL pointer\n");
  /* whatever … */
}

/* Don't want any retries */
SSL_set_mode(ssl, SSL_MODE_AUTO_RETRY);

/* We might want to do other things with ssl here */

BIO_set_conn_hostname(sbio, "localhost:https");

out = BIO_new_fp(stdout, BIO_NOCLOSE);
if(BIO_do_connect(sbio) <= 0) {
       fprintf(stderr, "Error connecting to server\n");
       ERR_print_errors_fp(stderr);
       /* whatever … */
}

if(BIO_do_handshake(sbio) <= 0) {
       fprintf(stderr, "Error establishing SSL connection\n");
       ERR_print_errors_fp(stderr);
       /* whatever … */
}

/* Could examine ssl here to get connection info */

BIO_puts(sbio, "GET / HTTP/1.0\n\n");
for(;;) {
       len = BIO_read(sbio, tmpbuf, 1024);
       if(len <= 0) break;
       BIO_write(out, tmpbuf, len);
}
BIO_free_all(sbio);
BIO_free(out);
```

Here is a simple server example. It makes use of a buffering BIO to allow lines to be read from the SSL BIO using BIO_gets. It creates a pseudo web page containing the actual request from a client and also echoes the request to standard output.

```
BIO *sbio, *bbio, *acpt, *out;
int len;
char tmpbuf[1024];
SSL_CTX *ctx;
SSL *ssl;

ERR_load_crypto_strings();
ERR_load_SSL_strings();
OpenSSL_add_all_algorithms();

/* Might seed PRNG here */

ctx = SSL_CTX_new(SSLv23_server_method());

if (!SSL_CTX_use_certificate_file(ctx,"server.pem",SSL_FILETYPE_PEM)
       || !SSL_CTX_use_PrivateKey_file(ctx,"server.pem",SSL_FILETYPE_PEM)
       || !SSL_CTX_check_private_key(ctx)) {

       fprintf(stderr, "Error setting up SSL_CTX\n");
       ERR_print_errors_fp(stderr);
       return 0;
}

/* Might do other things here like setting verify locations and
 * DH and/or RSA temporary key callbacks
 */
```

```
/* New SSL BIO setup as server */
sbio=BIO_new_ssl(ctx,0);

BIO_get_ssl(sbio, &ssl);

if(!ssl) {
  fprintf(stderr, "Can't locate SSL pointer\n");
  /* whatever … */
}

/* Don't want any retries */
SSL_set_mode(ssl, SSL_MODE_AUTO_RETRY);

/* Create the buffering BIO */

bbio = BIO_new(BIO_f_buffer());

/* Add to chain */
sbio = BIO_push(bbio, sbio);

acpt=BIO_new_accept("4433");

/* By doing this when a new connection is established
 * we automatically have sbio inserted into it. The
 * BIO chain is now 'swallowed' by the accept BIO and
 * will be freed when the accept BIO is freed.
 */

BIO_set_accept_bios(acpt,sbio);

out = BIO_new_fp(stdout, BIO_NOCLOSE);

/* Setup accept BIO */
if(BIO_do_accept(acpt) <= 0) {
       fprintf(stderr, "Error setting up accept BIO\n");
       ERR_print_errors_fp(stderr);
       return 0;
}

/* Now wait for incoming connection */
if(BIO_do_accept(acpt) <= 0) {
       fprintf(stderr, "Error in connection\n");
       ERR_print_errors_fp(stderr);
       return 0;
}

/* We only want one connection so remove and free
 * accept BIO
 */

sbio = BIO_pop(acpt);

BIO_free_all(acpt);

if(BIO_do_handshake(sbio) <= 0) {
       fprintf(stderr, "Error in SSL handshake\n");
       ERR_print_errors_fp(stderr);
       return 0;
}

BIO_puts(sbio, "HTTP/1.0 200 OK\r\nContent-type: text/plain\r\n\r\n");
BIO_puts(sbio, "\r\nConnection Established\r\nRequest headers:\r\n");
BIO_puts(sbio, "--------------------------------------------------\r\n");

for(;;) {
       len = BIO_gets(sbio, tmpbuf, 1024);
       if(len <= 0) break;
       BIO_write(sbio, tmpbuf, len);
       BIO_write(out, tmpbuf, len);
       /* Look for blank line signifying end of headers*/
       if((tmpbuf[0] == '\r') || (tmpbuf[0] == '\n')) break;
}

BIO_puts(sbio, "--------------------------------------------------\r\n");
BIO_puts(sbio, "\r\n");

/* Since there is a buffering BIO present we had better flush it */
BIO_flush(sbio);

BIO_free_all(sbio);
```

BUGS

In OpenSSL versions before 1.0.0 the BIO_pop() call was handled incorrectly, the I/O BIO reference count was incorrectly incremented (instead of decremented) and dissociated with the SSL BIO even if the SSL BIO was not explicitly being popped (e.g. a pop higher up the chain). Applications which included workarounds for this bug (e.g. freeing BIOs more than once) should be modified to handle this fix or they may free up an already freed BIO.

Name

BIO_new_CMS — CMS streaming filter BIO

Synopsis

```
#include  <openssl/cms.h>
```

```
BIO *BIO_new_CMS(BIO *out, CMS_ContentInfo *cms);
```

DESCRIPTION

BIO_new_CMS() returns a streaming filter BIO chain based on **cms**. The output of the filter is written to **out**. Any data written to the chain is automatically translated to a BER format CMS structure of the appropriate type.

NOTES

The chain returned by this function behaves like a standard filter BIO. It supports non blocking I/O. Content is processed and streamed on the fly and not all held in memory at once: so it is possible to encode very large structures. After all content has been written through the chain BIO_flush() must be called to finalise the structure.

The **CMS_STREAM** flag must be included in the corresponding **flags** parameter of the **cms** creation function.

If an application wishes to write additional data to **out** BIOs should be removed from the chain using BIO_pop() and freed with BIO_free() until **out** is reached. If no additional data needs to be written BIO_free_all() can be called to free up the whole chain.

Any content written through the filter is used verbatim: no canonical translation is performed.

It is possible to chain multiple BIOs to, for example, create a triple wrapped signed, enveloped, signed structure. In this case it is the applications responsibility to set the inner content type of any outer CMS_ContentInfo structures.

Large numbers of small writes through the chain should be avoided as this will produce an output consisting of lots of OCTET STRING structures. Prepending a BIO_f_buffer() buffering BIO will prevent this.

BUGS

There is currently no corresponding inverse BIO: i.e. one which can decode a CMS structure on the fly.

RETURN VALUES

BIO_new_CMS() returns a BIO chain when successful or NULL if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), CMS_sign(3), CMS_encrypt(3)

HISTORY

BIO_new_CMS() was added to OpenSSL 1.0.0

Name

BIO_new, BIO_set, BIO_free, BIO_vfree and BIO_free_all — BIO allocation and freeing functions

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO *  BIO_new(BIO_METHOD *type);
int    BIO_set(BIO *a,BIO_METHOD *type);
int    BIO_free(BIO *a);
void   BIO_vfree(BIO *a);
void   BIO_free_all(BIO *a);
```

DESCRIPTION

BIO_set() sets the method of an already existing BIO.

BIO_free() frees up a single BIO, BIO_vfree() also frees up a single BIO but it does not return a value. Calling BIO_free() may also have some effect on the underlying I/O structure, for example it may close the file being referred to under certain circumstances. For more details see the individual BIO_METHOD descriptions.

BIO_free_all() frees up an entire BIO chain, it does not halt if an error occurs freeing up an individual BIO in the chain.

RETURN VALUES

BIO_new() returns a newly created BIO or NULL if the call fails.

BIO_set(), BIO_free() return 1 for success and 0 for failure.

BIO_free_all() and BIO_vfree() do not return values.

NOTES

Some BIOs (such as memory BIOs) can be used immediately after calling BIO_new(). Others (such as file BIOs) need some additional initialization, and frequently a utility function exists to create and initialize such BIOs.

If BIO_free() is called on a BIO chain it will only free one BIO resulting in a memory leak.

Calling BIO_free_all() a single BIO has the same effect as calling BIO_free() on it other than the discarded return value.

Normally the **type** argument is supplied by a function which returns a pointer to a BIO_METHOD. There is a naming convention for such functions: a source/sink BIO is normally called BIO_s_*() and a filter BIO BIO_f_*();

EXAMPLE

Create a memory BIO:

```
BIO *mem = BIO_new(BIO_s_mem());
```

SEE ALSO

TBA

Name

BIO_push and BIO_pop — add and remove BIOs from a chain.

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO *  BIO_push(BIO *b,BIO *append);
BIO *  BIO_pop(BIO *b);
```

DESCRIPTION

The BIO_push() function appends the BIO **append** to **b**, it returns **b**.

BIO_pop() removes the BIO **b** from a chain and returns the next BIO in the chain, or NULL if there is no next BIO. The removed BIO then becomes a single BIO with no association with the original chain, it can thus be freed or attached to a different chain.

NOTES

The names of these functions are perhaps a little misleading. BIO_push() joins two BIO chains whereas BIO_pop() deletes a single BIO from a chain, the deleted BIO does not need to be at the end of a chain.

The process of calling BIO_push() and BIO_pop() on a BIO may have additional consequences (a control call is made to the affected BIOs) any effects will be noted in the descriptions of individual BIOs.

EXAMPLES

For these examples suppose **md1** and **md2** are digest BIOs, **b64** is a base64 BIO and **f** is a file BIO.

If the call:

```
BIO_push(b64, f);
```

is made then the new chain will be **b64-f**. After making the calls

```
BIO_push(md2, b64);
BIO_push(md1, md2);
```

the new chain is **md1-md2-b64-f**. Data written to **md1** will be digested by **md1** and **md2**, **base64** encoded and written to **f**.

It should be noted that reading causes data to pass in the reverse direction, that is data is read from **f**, base64 **decoded** and digested by **md1** and **md2**. If the call:

```
BIO_pop(md2);
```

The call will return **b64** and the new chain will be **md1-b64-f** data can be written to **md1** as before.

RETURN VALUES

BIO_push() returns the end of the chain, **b**.

BIO_pop() returns the next BIO in the chain, or NULL if there is no next BIO.

SEE ALSO

TBA

Name

BIO_read, BIO_write, BIO_gets and BIO_puts — BIO I/O functions

Synopsis

```
#include  <openssl/bio.h>
```

```
int    BIO_read(BIO *b, void *buf, int len);
int    BIO_gets(BIO *b, char *buf, int size);
int    BIO_write(BIO *b, const void *buf, int len);
int    BIO_puts(BIO *b, const char *buf);
```

DESCRIPTION

BIO_read() attempts to read **len** bytes from BIO **b** and places the data in **buf**.

BIO_gets() performs the BIOs "gets" operation and places the data in **buf**. Usually this operation will attempt to read a line of data from the BIO of maximum length **len**. There are exceptions to this however, for example BIO_gets() on a digest BIO will calculate and return the digest and other BIOs may not support BIO_gets() at all.

BIO_write() attempts to write **len** bytes from **buf** to BIO **b**.

BIO_puts() attempts to write a null terminated string **buf** to BIO **b**.

RETURN VALUES

All these functions return either the amount of data successfully read or written (if the return value is positive) or that no data was successfully read or written if the result is 0 or -1. If the return value is -2 then the operation is not implemented in the specific BIO type.

NOTES

A 0 or -1 return is not necessarily an indication of an error. In particular when the source/sink is non-blocking or of a certain type it may merely be an indication that no data is currently available and that the application should retry the operation later.

One technique sometimes used with blocking sockets is to use a system call (such as select(), poll() or equivalent) to determine when data is available and then call read() to read the data. The equivalent with BIOs (that is call select() on the underlying I/O structure and then call BIO_read() to read the data) should **not** be used because a single call to BIO_read() can cause several reads (and writes in the case of SSL BIOs) on the underlying I/O structure and may block as a result. Instead select() (or equivalent) should be combined with non blocking I/O so successive reads will request a retry instead of blocking.

See BIO_should_retry(3) for details of how to determine the cause of a retry and other I/O issues.

If the BIO_gets() function is not supported by a BIO then it possible to work around this by adding a buffering BIO BIO_f_buffer(3) to the chain.

#define BIO_BIND_REUSEADDR              2
```

```
int BIO_do_accept(BIO *b);
```

DESCRIPTION

BIO_s_accept() returns the accept BIO method. This is a wrapper round the platform's TCP/IP socket accept routines.

Using accept BIOs, TCP/IP connections can be accepted and data transferred using only BIO routines. In this way any platform specific operations are hidden by the BIO abstraction.

Read and write operations on an accept BIO will perform I/O on the underlying connection. If no connection is established and the port (see below) is set up properly then the BIO waits for an incoming connection.

Accept BIOs support BIO_puts() but not BIO_gets().

If the close flag is set on an accept BIO then any active connection on that chain is shutdown and the socket closed when the BIO is freed.

Calling BIO_reset() on a accept BIO will close any active connection and reset the BIO into a state where it awaits another incoming connection.

BIO_get_fd() and BIO_set_fd() can be called to retrieve or set the accept socket. See BIO_s_fd(3)

BIO_set_accept_port() uses the string **name** to set the accept port. The port is represented as a string of the form "host:port", where "host" is the interface to use and "port" is the port. The host can be can be "*" which is interpreted as meaning any interface; "port" has the same syntax as the port specified in BIO_set_conn_port() for connect BIOs, that is it can be a numerical port string or a string to lookup using getservbyname() and a string table.

BIO_new_accept() combines BIO_new() and BIO_set_accept_port() into a single call: that is it creates a new accept BIO with port **host_port**.

BIO_set_nbio_accept() sets the accept socket to blocking mode (the default) if **n** is 0 or non blocking mode if **n** is 1.

BIO_set_accept_bios() can be used to set a chain of BIOs which will be duplicated and prepended to the chain when an incoming connection is received. This is useful if, for example, a buffering or SSL BIO is required for each connection. The chain of BIOs must not be freed after this call, they will be automatically freed when the accept BIO is freed.

BIO_set_bind_mode() and BIO_get_bind_mode() set and retrieve the current bind mode. If BIO_BIND_NORMAL (the default) is set then another socket cannot be bound to the same port. If BIO_BIND_REUSEADDR is set then other sockets can bind to the same port. If BIO_BIND_REUSEADDR_IF_UNUSED is set then and attempt is first made to use BIO_BIN_NORMAL, if this fails and the port is not in use then a second attempt is made using BIO_BIND_REUSEADDR.

BIO_do_accept() serves two functions. When it is first called, after the accept BIO has been setup, it will attempt to create the accept socket and bind an address to it. Second and subsequent calls to BIO_do_accept() will await an incoming connection, or request a retry in non blocking mode.

NOTES

When an accept BIO is at the end of a chain it will await an incoming connection before processing I/O calls. When an accept BIO is not at then end of a chain it passes I/O calls to the next BIO in the chain.

When a connection is established a new socket BIO is created for the connection and appended to the chain. That is the chain is now accept->socket. This effectively means that attempting I/O on an initial accept socket will await an incoming connection then perform I/O on it.

If any additional BIOs have been set using BIO_set_accept_bios() then they are placed between the socket and the accept BIO, that is the chain will be accept->otherbios->socket.

If a server wishes to process multiple connections (as is normally the case) then the accept BIO must be made available for further incoming connections. This can be done by waiting for a connection and then calling:

```
connection = BIO_pop(accept);
```

After this call **connection** will contain a BIO for the recently established connection and **accept** will now be a single BIO again which can be used to await further incoming connections. If no further connections will be accepted the **accept** can be freed using BIO_free().

If only a single connection will be processed it is possible to perform I/O using the accept BIO itself. This is often undesirable however because the accept BIO will still accept additional incoming connections. This can be resolved by using BIO_pop() (see above) and freeing up the accept BIO after the initial connection.

If the underlying accept socket is non-blocking and BIO_do_accept() is called to await an incoming connection it is possible for BIO_should_io_special() with the reason BIO_RR_ACCEPT. If this happens then it is an indication that an accept attempt would block: the application should take appropriate action to wait until the underlying socket has accepted a connection and retry the call.

BIO_set_accept_port(), BIO_get_accept_port(), BIO_set_nbio_accept(), BIO_set_accept_bios(), BIO_set_bind_mode(), BIO_get_bind_mode() and BIO_do_accept() are macros.

RETURN VALUES

TBA

EXAMPLE

This example accepts two connections on port 4444, sends messages down each and finally closes both down.

```
BIO *abio, *cbio, *cbio2;
ERR_load_crypto_strings();
abio = BIO_new_accept("4444");

/* First call to BIO_accept() sets up accept BIO */
if(BIO_do_accept(abio) <= 0) {
       fprintf(stderr, "Error setting up accept\n");
       ERR_print_errors_fp(stderr);
       exit(0);
}

/* Wait for incoming connection */
if(BIO_do_accept(abio) <= 0) {
       fprintf(stderr, "Error accepting connection\n");
       ERR_print_errors_fp(stderr);
       exit(0);
}
fprintf(stderr, "Connection 1 established\n");
/* Retrieve BIO for connection */
cbio = BIO_pop(abio);
BIO_puts(cbio, "Connection 1: Sending out Data on initial connection\n");
fprintf(stderr, "Sent out data on connection 1\n");
/* Wait for another connection */
if(BIO_do_accept(abio) <= 0) {
       fprintf(stderr, "Error accepting connection\n");
       ERR_print_errors_fp(stderr);
       exit(0);
}
fprintf(stderr, "Connection 2 established\n");
/* Close accept BIO to refuse further connections */
cbio2 = BIO_pop(abio);
BIO_free(abio);
BIO_puts(cbio2, "Connection 2: Sending out Data on second\n");
fprintf(stderr, "Sent out data on connection 2\n");

BIO_puts(cbio, "Connection 1: Second connection established\n");
/* Close the two established connections */
BIO_free(cbio);
BIO_free(cbio2);
```

int BIO_ctrl_reset_read_request(BIO *b);
```

DESCRIPTION

BIO_s_bio() returns the method for a BIO pair. A BIO pair is a pair of source/sink BIOs where data written to either half of the pair is buffered and can be read from the other half. Both halves must usually by handled by the same application thread since no locking is done on the internal data structures.

Since BIO chains typically end in a source/sink BIO it is possible to make this one half of a BIO pair and have all the data processed by the chain under application control.

One typical use of BIO pairs is to place TLS/SSL I/O under application control, this can be used when the application wishes to use a non standard transport for TLS/SSL or the normal socket routines are inappropriate.

Calls to BIO_read() will read data from the buffer or request a retry if no data is available.

Calls to BIO_write() will place data in the buffer or request a retry if the buffer is full.

The standard calls BIO_ctrl_pending() and BIO_ctrl_wpending() can be used to determine the amount of pending data in the read or write buffer.

BIO_reset() clears any data in the write buffer.

BIO_make_bio_pair() joins two separate BIOs into a connected pair.

BIO_destroy_pair() destroys the association between two connected BIOs. Freeing up any half of the pair will automatically destroy the association.

BIO_shutdown_wr() is used to close down a BIO **b**. After this call no further writes on BIO **b** are allowed (they will return an error). Reads on the other half of the pair will return any pending data or EOF when all pending data has been read.

BIO_set_write_buf_size() sets the write buffer size of BIO **b** to **size**. If the size is not initialized a default value is used. This is currently 17K, sufficient for a maximum size TLS record.

BIO_get_write_buf_size() returns the size of the write buffer.

BIO_new_bio_pair() combines the calls to BIO_new(), BIO_make_bio_pair() and BIO_set_write_buf_size() to create a connected pair of BIOs **bio1**, **bio2** with write buffer sizes **writebuf1** and **writebuf2**. If either size is zero then the default size is used. BIO_new_bio_pair() does not check whether **bio1** or **bio2** do point to some other BIO, the values are overwritten, BIO_free() is not called.

BIO_get_write_guarantee() and BIO_ctrl_get_write_guarantee() return the maximum length of data that can be currently written to the BIO. Writes larger than this value will return a value from BIO_write() less than the amount requested or if the buffer is full request a retry. BIO_ctrl_get_write_guarantee() is a function whereas BIO_get_write_guarantee() is a macro.

BIO_get_read_request() and BIO_ctrl_get_read_request() return the amount of data requested, or the buffer size if it is less, if the last read attempt at the other half of the BIO pair failed due to an empty buffer. This can be used to determine how much data should be written to the BIO so the next read will succeed: this is most useful in TLS/SSL applications where the amount of data read is usually meaningful rather than just a buffer size. After a successful read this call will return zero. It also will return zero once new data has been written satisfying the read request or part of it. Note that BIO_get_read_request() never returns an amount larger than that returned by BIO_get_write_guarantee().

BIO_ctrl_reset_read_request() can also be used to reset the value returned by BIO_get_read_request() to zero.

NOTES

Both halves of a BIO pair should be freed. That is even if one half is implicit freed due to a BIO_free_all() or SSL_free() call the other half needs to be freed.

When used in bidirectional applications (such as TLS/SSL) care should be taken to flush any data in the write buffer. This can be done by calling BIO_pending() on the other half of the pair and, if any data is pending, reading it and sending it to the underlying transport. This must be done before any normal processing (such as calling select()) due to a request and BIO_should_read() being true.

To see why this is important consider a case where a request is sent using BIO_write() and a response read with BIO_read(), this can occur during an TLS/SSL handshake for example. BIO_write() will succeed and place data in the write buffer. BIO_read() will initially fail and BIO_should_read() will be true. If the application then waits for data to be available on the underlying transport before flushing the write buffer it will never succeed because the request was never sent!

RETURN VALUES

BIO_new_bio_pair() returns 1 on success, with the new BIOs available in **bio1** and **bio2**, or 0 on failure, with NULL pointers stored into the locations for **bio1** and **bio2**. Check the error stack for more information.

[XXXXX: More return values need to be added here]

EXAMPLE

The BIO pair can be used to have full control over the network access of an application. The application can call select() on the socket as required without having to go through the SSL-interface.

```
BIO *internal_bio, *network_bio;
…
BIO_new_bio_pair(internal_bio, 0, network_bio, 0);
SSL_set_bio(ssl, internal_bio, internal_bio);
SSL_operations();
…

application |   TLS-engine
   |        |
   +----------> SSL_operations()
```

```
            |     /\    ||
            |     ||    \/
            |   BIO-pair (internal_bio)
   +----------< BIO-pair (network_bio)
   |        |
 socket     |

…
SSL_free(ssl);                /* implicitly frees internal_bio */
BIO_free(network_bio);
…
```

As the BIO pair will only buffer the data and never directly access the connection, it behaves non-blocking and will return as soon as the write buffer is full or the read buffer is drained. Then the application has to flush the write buffer and/or fill the read buffer.

Use the BIO_ctrl_pending(), to find out whether data is buffered in the BIO and must be transfered to the network. Use BIO_ctrl_get_read_request() to find out, how many bytes must be written into the buffer before the SSL_operation() can successfully be continued.

WARNING

As the data is buffered, SSL_operation() may return with a ERROR_SSL_WANT_READ condition, but there is still data in the write buffer. An application must not rely on the error value of SSL_operation() but must assure that the write buffer is always flushed first. Otherwise a deadlock may occur as the peer might be waiting for the data before being able to continue.

```

DESCRIPTION

BIO_s_connect() returns the connect BIO method. This is a wrapper round the platform's TCP/IP socket connection routines.

Using connect BIOs, TCP/IP connections can be made and data transferred using only BIO routines. In this way any platform specific operations are hidden by the BIO abstraction.

Read and write operations on a connect BIO will perform I/O on the underlying connection. If no connection is established and the port and hostname (see below) is set up properly then a connection is established first.

Connect BIOs support BIO_puts() but not BIO_gets().

If the close flag is set on a connect BIO then any active connection is shutdown and the socket closed when the BIO is freed.

Calling BIO_reset() on a connect BIO will close any active connection and reset the BIO into a state where it can connect to the same host again.

BIO_get_fd() places the underlying socket in **c** if it is not NULL, it also returns the socket . If **c** is not NULL it should be of type (int *).

BIO_set_conn_hostname() uses the string **name** to set the hostname. The hostname can be an IP address. The hostname can also include the port in the form hostname:port . It is also acceptable to use the form "hostname/any/other/path" or "hostname:port/any/other/path".

BIO_set_conn_port() sets the port to **port**. **port** can be the numerical form or a string such as "http". A string will be looked up first using getservbyname() on the host platform but if that fails a standard table of port names will be used. Currently the list is http, telnet, socks, https, ssl, ftp, gopher and wais.

BIO_set_conn_ip() sets the IP address to **ip** using binary form, that is four bytes specifying the IP address in big-endian form.

BIO_set_conn_int_port() sets the port using **port**. **port** should be of type (int *).

BIO_get_conn_hostname() returns the hostname of the connect BIO or NULL if the BIO is initialized but no hostname is set. This return value is an internal pointer which should not be modified.

BIO_get_conn_port() returns the port as a string.

BIO_get_conn_ip() returns the IP address in binary form.

BIO_get_conn_int_port() returns the port as an int.

BIO_set_nbio() sets the non blocking I/O flag to **n**. If **n** is zero then blocking I/O is set. If **n** is 1 then non blocking I/O is set. Blocking I/O is the default. The call to BIO_set_nbio() should be made before the connection is established because non blocking I/O is set during the connect process.

BIO_new_connect() combines BIO_new() and BIO_set_conn_hostname() into a single call: that is it creates a new connect BIO with **name**.

BIO_do_connect() attempts to connect the supplied BIO. It returns 1 if the connection was established successfully. A zero or negative value is returned if the connection could not be established, the call BIO_should_retry() should be used for non blocking connect BIOs to determine if the call should be retried.

NOTES

If blocking I/O is set then a non positive return value from any I/O call is caused by an error condition, although a zero return will normally mean that the connection was closed.

If the port name is supplied as part of the host name then this will override any value set with BIO_set_conn_port(). This may be undesirable if the application does not wish to allow connection to arbitrary ports. This can be avoided by checking for the presence of the ':' character in the passed hostname and either indicating an error or truncating the string at that point.

The values returned by BIO_get_conn_hostname(), BIO_get_conn_port(), BIO_get_conn_ip() and BIO_get_conn_int_port() are updated when a connection attempt is made. Before any connection attempt the values returned are those set by the application itself.

Applications do not have to call BIO_do_connect() but may wish to do so to separate the connection process from other I/O processing.

If non blocking I/O is set then retries will be requested as appropriate.

It addition to BIO_should_read() and BIO_should_write() it is also possible for BIO_should_io_special() to be true during the initial connection process with the reason BIO_RR_CONNECT. If this is returned then this is an indication that a connection attempt would block, the application should then take appropriate action to wait until the underlying socket has connected and retry the call.

BIO_set_conn_hostname(), BIO_set_conn_port(), BIO_set_conn_ip(), BIO_set_conn_int_port(), BIO_get_conn_hostname(), BIO_get_conn_port(), BIO_get_conn_ip(), BIO_get_conn_int_port(), BIO_set_nbio() and BIO_do_connect() are macros.

RETURN VALUES

BIO_s_connect() returns the connect BIO method.

BIO_get_fd() returns the socket or -1 if the BIO has not been initialized.

BIO_set_conn_hostname(), BIO_set_conn_port(), BIO_set_conn_ip() and BIO_set_conn_int_port() always return 1.

BIO_get_conn_hostname() returns the connected hostname or NULL is none was set.

BIO_get_conn_port() returns a string representing the connected port or NULL if not set.

BIO_get_conn_ip() returns a pointer to the connected IP address in binary form or all zeros if not set.

BIO_get_conn_int_port() returns the connected port or 0 if none was set.

BIO_set_nbio() always returns 1.

BIO_do_connect() returns 1 if the connection was successfully established and 0 or -1 if the connection failed.

EXAMPLE

This is example connects to a webserver on the local host and attempts to retrieve a page and copy the result to standard output.

```
BIO *cbio, *out;
int len;
char tmpbuf[1024];
ERR_load_crypto_strings();
cbio = BIO_new_connect("localhost:http");
out = BIO_new_fp(stdout, BIO_NOCLOSE);
if(BIO_do_connect(cbio) <= 0) {
       fprintf(stderr, "Error connecting to server\n");
       ERR_print_errors_fp(stderr);
       /* whatever … */
       }
BIO_puts(cbio, "GET / HTTP/1.0\n\n");
for(;;) {
       len = BIO_read(cbio, tmpbuf, 1024);
       if(len <= 0) break;
       BIO_write(out, tmpbuf, len);
}
BIO_free(cbio);
BIO_free(out);
```

BIO_set_callback, BIO_get_callback, BIO_set_callback_arg, BIO_get_callback_arg and BIO_debug_callback — BIO callback functions

Synopsis

```
#include  <openssl/bio.h>
```

```
#define BIO_set_callback(b,cb)          ((b)->callback=(cb))
#define BIO_get_callback(b)             ((b)->callback)
#define BIO_set_callback_arg(b,arg)     ((b)->cb_arg=(char *)(arg))
#define BIO_get_callback_arg(b)                 ((b)->cb_arg)
```

```
long BIO_debug_callback(BIO *bio,int cmd,const char *argp,int argi,
       long argl,long ret);
```

```
typedef long (*callback)(BIO *b, int oper, const char *argp,
                       int argi, long argl, long retvalue);
```

DESCRIPTION

BIO_set_callback() and BIO_get_callback() set and retrieve the BIO callback, they are both macros. The callback is called during most high level BIO operations. It can be used for debugging purposes to trace operations on a BIO or to modify its operation.

BIO_set_callback_arg() and BIO_get_callback_arg() are macros which can be used to set and retrieve an argument for use in the callback.

BIO_debug_callback() is a standard debugging callback which prints out information relating to each BIO operation. If the callback argument is set if is interpreted as a BIO to send the information to, otherwise stderr is used.

callback() is the callback function itself. The meaning of each argument is described below.

The BIO the callback is attached to is passed in **b**.

oper is set to the operation being performed. For some operations the callback is called twice, once before and once after the actual operation, the latter case has **oper** or'ed with BIO_CB_RETURN.

The meaning of the arguments **argp**, **argi** and **argl** depends on the value of **oper**, that is the operation being performed.

retvalue is the return value that would be returned to the application if no callback were present. The actual value returned is the return value of the callback itself. In the case of callbacks called before the actual BIO operation 1 is placed in retvalue, if the return value is not positive it will be immediately returned to the application and the BIO operation will not be performed.

The callback should normally simply return **retvalue** when it has finished processing, unless if specifically wishes to modify the value returned to the application.

CALLBACK OPERATIONS

BIO_free(b)

callback(b,BIO_CB_FREE,NULL,0L,0L,1L) is called before the free operation.

BIO_read(b, out, outl)

callback(b,BIO_CB_READ,out,outl,0L,1L) is called before the read.

callback(b,BIO_CB_READ|BIO_CB_RETURN,out outl,0L,retvalue) after the read.

BIO_write(b, in, inl)

callback(b,BIO_CB_WRITE,in,inl,0L,1L) is called before the write.

callback(b,BIO_CB_WRITE|BIO_CB_RETURN,in,inl,0L,retvalue) after the write.

BIO_gets(b, out, outl)

callback(b,BIO_CB_GETS,out,outl,0L,1L) is called before the operation.

callback(b,BIO_CB_GETS|BIO_CB_RETURN,out,outl,0L,retvalue) is called after the operation.

BIO_puts(b, in)

callback(b,BIO_CB_WRITE,in,0,0L 1L) is called before the operation.

callback(b, BIO_CB_WRITE|BIO_CB_RETURN, in, 0, 0L, retvalue) is called after the operation.

BIO_ctrl(BIO *b, int cmd, long larg, void *parg)

callback(b,BIO_CB_CTRL,parg,cmd,larg,1L) is called before the call.

callback(b,BIO_CB_CTRL|BIO_CB_RETURN,parg,cmd,larg,ret) is called after the call.

EXAMPLE

The BIO_debug_callback() function is a good example, its source is in crypto/bio/bio_cb.c

Name

BIO_s_fd, BIO_set_fd, BIO_get_fd and BIO_new_fd — file descriptor BIO

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO_METHOD *   BIO_s_fd(void);
```

```
#define BIO_set_fd(b,fd,c)     BIO_int_ctrl(b,BIO_C_SET_FD,c,fd)
#define BIO_get_fd(b,c)        BIO_ctrl(b,BIO_C_GET_FD,0,(char *)c)
```

```
BIO *BIO_new_fd(int fd, int close_flag);
```

DESCRIPTION

BIO_s_fd() returns the file descriptor BIO method. This is a wrapper round the platforms file descriptor routines such as read() and write().

BIO_read() and BIO_write() read or write the underlying descriptor. BIO_puts() is supported but BIO_gets() is not.

If the close flag is set then then close() is called on the underlying file descriptor when the BIO is freed.

BIO_reset() attempts to change the file pointer to the start of file using lseek(fd, 0, 0).

BIO_seek() sets the file pointer to position **ofs** from start of file using lseek(fd, ofs, 0).

BIO_tell() returns the current file position by calling lseek(fd, 0, 1).

BIO_set_fd() sets the file descriptor of BIO **b** to **fd** and the close flag to **c**.

BIO_get_fd() places the file descriptor in **c** if it is not NULL, it also returns the file descriptor. If **c** is not NULL it should be of type (int *).

BIO_new_fd() returns a file descriptor BIO using **fd** and **close_flag**.

NOTES

The behaviour of BIO_read() and BIO_write() depends on the behavior of the platforms read() and write() calls on the descriptor. If the underlying file descriptor is in a non blocking mode then the BIO will behave in the manner described in the BIO_read(3) and BIO_should_retry(3) manual pages.

File descriptor BIOs should not be used for socket I/O. Use socket BIOs instead.

RETURN VALUES

BIO_s_fd() returns the file descriptor BIO method.

BIO_reset() returns zero for success and -1 if an error occurred. BIO_seek() and BIO_tell() return the current file position or -1 is an error occurred. These values reflect the underlying lseek() behaviour.

BIO_set_fd() always returns 1.

BIO_get_fd() returns the file descriptor or -1 if the BIO has not been initialized.

BIO_new_fd() returns the newly allocated BIO or NULL is an error occurred.

EXAMPLE

This is a file descriptor BIO version of "Hello World":

```
BIO *out;
out = BIO_new_fd(fileno(stdout), BIO_NOCLOSE);
BIO_printf(out, "Hello World\n");
BIO_free(out);
```

SEE ALSO

Name

BIO_s_file, BIO_new_file, BIO_new_fp, BIO_set_fp, BIO_get_fp, BIO_read_filename, BIO_write_filename, BIO_append_filename and BIO_rw_filename — FILE bio

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO_METHOD *   BIO_s_file(void);
BIO *BIO_new_file(const char *filename, const char *mode);
BIO *BIO_new_fp(FILE *stream, int flags);
```

```
BIO_set_fp(BIO *b,FILE *fp, int flags);
BIO_get_fp(BIO *b,FILE **fpp);
```

```
int BIO_read_filename(BIO *b, char *name)
int BIO_write_filename(BIO *b, char *name)
int BIO_append_filename(BIO *b, char *name)
int BIO_rw_filename(BIO *b, char *name)
```

DESCRIPTION

BIO_s_file() returns the BIO file method. As its name implies it is a wrapper round the stdio FILE structure and it is a source/sink BIO.

Calls to BIO_read() and BIO_write() read and write data to the underlying stream. BIO_gets() and BIO_puts() are supported on file BIOs.

BIO_flush() on a file BIO calls the fflush() function on the wrapped stream.

BIO_reset() attempts to change the file pointer to the start of file using fseek(stream, 0, 0).

BIO_seek() sets the file pointer to position **ofs** from start of file using fseek(stream, ofs, 0).

BIO_eof() calls feof().

Setting the BIO_CLOSE flag calls fclose() on the stream when the BIO is freed.

BIO_new_file() creates a new file BIO with mode **mode** the meaning of **mode** is the same as the stdio function fopen(). The BIO_CLOSE flag is set on the returned BIO.

BIO_new_fp() creates a file BIO wrapping **stream**. Flags can be: BIO_CLOSE, BIO_NOCLOSE (the close flag) BIO_FP_TEXT (sets the underlying stream to text mode, default is binary: this only has any effect under Win32).

BIO_set_fp() set the fp of a file BIO to **fp**. **flags** has the same meaning as in BIO_new_fp(), it is a macro.

BIO_get_fp() retrieves the fp of a file BIO, it is a macro.

BIO_seek() is a macro that sets the position pointer to **offset** bytes from the start of file.

BIO_tell() returns the value of the position pointer.

BIO_read_filename(), BIO_write_filename(), BIO_append_filename() and BIO_rw_filename() set the file BIO **b** to use file **name** for reading, writing, append or read write respectively.

NOTES

When wrapping stdout, stdin or stderr the underlying stream should not normally be closed so the BIO_NOCLOSE flag should be set.

Because the file BIO calls the underlying stdio functions any quirks in stdio behaviour will be mirrored by the corresponding BIO.

On Windows BIO_new_files reserves for the filename argument to be UTF-8 encoded. In other words if you have to make it work in multi- lingual environment, encode file names in UTF-8.

EXAMPLES

File BIO "hello world":

```
BIO *bio_out;
bio_out = BIO_new_fp(stdout, BIO_NOCLOSE);
BIO_printf(bio_out, "Hello World\n");
```

Alternative technique:

```
BIO *bio_out;
bio_out = BIO_new(BIO_s_file());
if(bio_out == NULL) /* Error … */
if(!BIO_set_fp(bio_out, stdout, BIO_NOCLOSE)) /* Error … */
BIO_printf(bio_out, "Hello World\n");
```

Write to a file:

```
BIO *out;
out = BIO_new_file("filename.txt", "w");
if(!out) /* Error occurred */
BIO_printf(out, "Hello World\n");
BIO_free(out);
```

Alternative technique:

```
BIO *out;
out = BIO_new(BIO_s_file());
if(out == NULL) /* Error … */
if(!BIO_write_filename(out, "filename.txt")) /* Error … */
BIO_printf(out, "Hello World\n");
BIO_free(out);
```

RETURN VALUES

BIO_s_file() returns the file BIO method.

BIO_new_file() and BIO_new_fp() return a file BIO or NULL if an error occurred.

BIO_set_fp() and BIO_get_fp() return 1 for success or 0 for failure (although the current implementation never return 0).

BIO_seek() returns the same value as the underlying fseek() function: 0 for success or -1 for failure.

BIO_tell() returns the current file position.

BIO_read_filename(), BIO_write_filename(), BIO_append_filename() and BIO_rw_filename() return 1 for success or 0 for failure.

BUGS

BIO_reset() and BIO_seek() are implemented using fseek() on the underlying stream. The return value for fseek() is 0 for success or -1 if an error occurred this differs from other types of BIO which will typically return 1 for success and a non positive value if an error occurred.

#define BIO_FLAGS_SHOULD_RETRY 0x08
```

```
BIO *  BIO_get_retry_BIO(BIO *bio, int *reason);
int    BIO_get_retry_reason(BIO *bio);
```

DESCRIPTION

These functions determine why a BIO is not able to read or write data. They will typically be called after a failed BIO_read() or BIO_write() call.

BIO_should_retry() is true if the call that produced this condition should then be retried at a later time.

If BIO_should_retry() is false then the cause is an error condition.

BIO_should_read() is true if the cause of the condition is that a BIO needs to read data.

BIO_should_write() is true if the cause of the condition is that a BIO needs to read data.

BIO_should_io_special() is true if some "special" condition, that is a reason other than reading or writing is the cause of the condition.

BIO_retry_type() returns a mask of the cause of a retry condition consisting of the values **BIO_FLAGS_READ**, **BIO_FLAGS_WRITE**, **BIO_FLAGS_IO_SPECIAL** though current BIO types will only set one of these.

BIO_get_retry_BIO() determines the precise reason for the special condition, it returns the BIO that caused this condition and if **reason** is not NULL it contains the reason code. The meaning of the reason code and the action that should be taken depends on the type of BIO that resulted in this condition.

BIO_get_retry_reason() returns the reason for a special condition if passed the relevant BIO, for example as returned by BIO_get_retry_BIO().

NOTES

If BIO_should_retry() returns false then the precise "error condition" depends on the BIO type that caused it and the return code of the BIO operation. For example if a call to BIO_read() on a socket BIO returns 0 and BIO_should_retry() is false then the cause will be that the connection closed. A similar condition on a file BIO will mean that it has reached EOF. Some BIO types may place additional information on the error queue. For more details see the individual BIO type manual pages.

If the underlying I/O structure is in a blocking mode almost all current BIO types will not request a retry, because the underlying I/O calls will not. If the application knows that the BIO type will never signal a retry then it need not call BIO_should_retry() after a failed BIO I/O call. This is typically done with file BIOs.

SSL BIOs are the only current exception to this rule: they can request a retry even if the underlying I/O structure is blocking, if a handshake occurs during a call to BIO_read(). An application can retry the failed call immediately or avoid this situation by setting SSL_MODE_AUTO_RETRY on the underlying SSL structure.

While an application may retry a failed non blocking call immediately this is likely to be very inefficient because the call will fail repeatedly until data can be processed or is available. An application will normally wait until the necessary condition is satisfied. How this is done depends on the underlying I/O structure.

For example if the cause is ultimately a socket and BIO_should_read() is true then a call to select() may be made to wait until data is available and then retry the BIO operation. By combining the retry conditions of several non blocking BIOs in a single select() call it is possible to service several BIOs in a single thread, though the performance may be poor if SSL BIOs are present because long delays can occur during the initial handshake process.

It is possible for a BIO to block indefinitely if the underlying I/O structure cannot process or return any data. This depends on the behaviour of the platforms I/O functions. This is often not desirable: one solution is to use non blocking I/O and use a timeout on the select() (or equivalent) call.

BUGS

The OpenSSL ASN1 functions cannot gracefully deal with non blocking I/O: that is they cannot retry after a partial read or write. This is usually worked around by only passing the relevant data to ASN1 functions when the entire structure can be read or written.

SEE ALSO

Name

BIO_s_mem, BIO_set_mem_eof_return, BIO_get_mem_data, BIO_set_mem_buf, BIO_get_mem_ptr and BIO_new_mem_buf — memory BIO

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO_METHOD *   BIO_s_mem(void);
```

```
BIO_set_mem_eof_return(BIO *b,int v)
long BIO_get_mem_data(BIO *b, char **pp)
BIO_set_mem_buf(BIO *b,BUF_MEM *bm,int c)
BIO_get_mem_ptr(BIO *b,BUF_MEM **pp)
```

```
BIO *BIO_new_mem_buf(void *buf, int len);
```

DESCRIPTION

BIO_s_mem() return the memory BIO method function.

A memory BIO is a source/sink BIO which uses memory for its I/O. Data written to a memory BIO is stored in a BUF_MEM structure which is extended as appropriate to accommodate the stored data.

Any data written to a memory BIO can be recalled by reading from it. Unless the memory BIO is read only any data read from it is deleted from the BIO.

Memory BIOs support BIO_gets() and BIO_puts().

If the BIO_CLOSE flag is set when a memory BIO is freed then the underlying BUF_MEM structure is also freed.

Calling BIO_reset() on a read write memory BIO clears any data in it. On a read only BIO it restores the BIO to its original state and the read only data can be read again.

BIO_eof() is true if no data is in the BIO.

BIO_ctrl_pending() returns the number of bytes currently stored.

BIO_set_mem_eof_return() sets the behaviour of memory BIO **b** when it is empty. If the **v** is zero then an empty memory BIO will return EOF (that is it will return zero and BIO_should_retry(b) will be false. If **v** is non zero then it will return **v** when it is empty and it will set the read retry flag (that is BIO_read_retry(b) is true). To avoid ambiguity with a normal positive return value **v** should be set to a negative value, typically -1.

BIO_get_mem_data() sets **pp** to a pointer to the start of the memory BIOs data and returns the total amount of data available. It is implemented as a macro.

BIO_set_mem_buf() sets the internal BUF_MEM structure to **bm** and sets the close flag to **c**, that is **c** should be either BIO_CLOSE or BIO_NOCLOSE. It is a macro.

BIO_get_mem_ptr() places the underlying BUF_MEM structure in **pp**. It is a macro.

BIO_new_mem_buf() creates a memory BIO using **len** bytes of data at **buf**, if **len** is -1 then the **buf** is assumed to be null terminated and its length is determined by **strlen**. The BIO is set to a read only state and as a result cannot be written to. This is useful when some data needs to be made available from a static area of memory in the form of a BIO. The supplied data is read directly from the supplied buffer: it is **not** copied first, so the supplied area of memory must be unchanged until the BIO is freed.

NOTES

Writes to memory BIOs will always succeed if memory is available: that is their size can grow indefinitely.

Every read from a read write memory BIO will remove the data just read with an internal copy operation, if a BIO contains a lot of data and it is read in small chunks the operation can be very slow. The use of a read only memory BIO avoids this problem. If the BIO must be read write then adding a buffering BIO to the chain will speed up the process.

BUGS

There should be an option to set the maximum size of a memory BIO.

There should be a way to "rewind" a read write BIO without destroying its contents.

The copying operation should not occur after every small read of a large BIO to improve efficiency.

EXAMPLE

Create a memory BIO and write some data to it:

```
BIO *mem = BIO_new(BIO_s_mem());
BIO_puts(mem, "Hello World\n");
```

Create a read only memory BIO:

```
char data[] = "Hello World";
BIO *mem;
mem = BIO_new_mem_buf(data, -1);
```

Extract the BUF_MEM structure from a memory BIO and then free up the BIO:

```
BUF_MEM *bptr;
BIO_get_mem_ptr(mem, &bptr);
BIO_set_close(mem, BIO_NOCLOSE); /* So BIO_free() leaves BUF_MEM alone */
BIO_free(mem);
```

SEE ALSO

TBA

Name

BIO_s_null — null data sink

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO_METHOD *   BIO_s_null(void);
```

DESCRIPTION

BIO_s_null() returns the null sink BIO method. Data written to the null sink is discarded, reads return EOF.

NOTES

A null sink BIO behaves in a similar manner to the Unix /dev/null device.

A null bio can be placed on the end of a chain to discard any data passed through it.

A null sink is useful if, for example, an application wishes to digest some data by writing through a digest bio but not send the digested data anywhere. Since a BIO chain must normally include a source/sink BIO this can be achieved by adding a null sink BIO to the end of the chain

RETURN VALUES

BIO_s_null() returns the null sink BIO method.

SEE ALSO

Name

BIO_s_socket and BIO_new_socket — socket BIO

Synopsis

```
#include  <openssl/bio.h>
```

```
BIO_METHOD *BIO_s_socket(void);
```

```
long BIO_set_fd(BIO *b, int fd, long close_flag);
long BIO_get_fd(BIO *b, int *c);
```

```
BIO *BIO_new_socket(int sock, int close_flag);
```

DESCRIPTION

BIO_s_socket() returns the socket BIO method. This is a wrapper round the platform's socket routines.

BIO_read() and BIO_write() read or write the underlying socket. BIO_puts() is supported but BIO_gets() is not.

If the close flag is set then the socket is shut down and closed when the BIO is freed.

BIO_set_fd() sets the socket of BIO **b** to **fd** and the close flag to **close_flag**.

BIO_get_fd() places the socket in **c** if it is not NULL, it also returns the socket. If **c** is not NULL it should be of type (int *).

BIO_new_socket() returns a socket BIO using **sock** and **close_flag**.

NOTES

Socket BIOs also support any relevant functionality of file descriptor BIOs.

The reason for having separate file descriptor and socket BIOs is that on some platforms sockets are not file descriptors and use distinct I/O routines, Windows is one such platform. Any code mixing the two will not work on all platforms.

BIO_set_fd() and BIO_get_fd() are macros.

RETURN VALUES

BIO_s_socket() returns the socket BIO method.

BIO_set_fd() always returns 1.

BIO_get_fd() returns the socket or -1 if the BIO has not been initialized.

BIO_new_socket() returns the newly allocated BIO or NULL is an error occurred.

DESCRIPTION

This library implements the Blowfish cipher, which was invented and described by Counterpane (see http://www.counterpane.com/blowfish.html).

Blowfish is a block cipher that operates on 64 bit (8 byte) blocks of data. It uses a variable size key, but typically, 128 bit (16 byte) keys are considered good for strong encryption. Blowfish can be used in the same modes as DES (see des_modes(7)). Blowfish is currently one of the faster block ciphers. It is quite a bit faster than DES, and much faster than IDEA or RC2.

Blowfish consists of a key setup phase and the actual encryption or decryption phase.

BF_set_key() sets up the **BF_KEY key** using the **len** bytes long key at **data**.

BF_ecb_encrypt() is the basic Blowfish encryption and decryption function. It encrypts or decrypts the first 64 bits of **in** using the key **key**, putting the result in **out**. **enc** decides if encryption (**BF_ENCRYPT**) or decryption (**BF_DECRYPT**) shall be performed. The vector pointed at by **in** and **out** must be 64 bits in length, no less. If they are larger, everything after the first 64 bits is ignored.

The mode functions BF_cbc_encrypt(), BF_cfb64_encrypt() and BF_ofb64_encrypt() all operate on variable length data. They all take an initialization vector **ivec** which needs to be passed along into the next call of the same function for the same message. **ivec** may be initialized with anything, but the recipient needs to know what it was initialized with, or it won't be able to decrypt. Some programs and protocols simplify this, like SSH, where **ivec** is simply initialized to zero. BF_cbc_encrypt() operates on data that is a multiple of 8 bytes long, while BF_cfb64_encrypt() and BF_ofb64_encrypt() are used to encrypt an variable number of bytes (the amount does not have to be an exact multiple of 8). The purpose of the latter two is to simulate stream ciphers, and therefore, they need the parameter **num**, which is a pointer to an integer where the current offset in **ivec** is stored between calls. This integer must be initialized to zero when **ivec** is initialized.

BF_cbc_encrypt() is the Cipher Block Chaining function for Blowfish. It encrypts or decrypts the 64 bits chunks of **in** using the key **schedule**, putting the result in **out**. **enc** decides if encryption (BF_ENCRYPT) or decryption (BF_DECRYPT) shall be performed. **ivec** must point at an 8 byte long initialization vector.

BF_cfb64_encrypt() is the CFB mode for Blowfish with 64 bit feedback. It encrypts or decrypts the bytes in **in** using the key **schedule**, putting the result in **out**. **enc** decides if encryption (**BF_ENCRYPT**) or decryption (**BF_DECRYPT**) shall be performed. **ivec** must point at an 8 byte long initialization vector. **num** must point at an integer which must be initially zero.

BF_ofb64_encrypt() is the OFB mode for Blowfish with 64 bit feedback. It uses the same parameters as BF_cfb64_encrypt(), which must be initialized the same way.

BF_encrypt() and BF_decrypt() are the lowest level functions for Blowfish encryption. They encrypt/decrypt the first 64 bits of the vector pointed by **data**, using the key **key**. These functions should not be used unless you implement 'modes' of Blowfish. The alternative is to use BF_ecb_encrypt(). If you still want to use these functions, you should be aware that they take each 32-bit chunk in host-byte order, which is little-endian on little-endian platforms and big-endian on big-endian ones.

RETURN VALUES

None of the functions presented here return any value.

NOTE

Applications should use the higher level functions EVP_EncryptInit(3) etc. instead of calling the blowfish functions directly.

DESCRIPTION

This library performs arithmetic operations on integers of arbitrary size. It was written for use in public key cryptography, such as RSA and Diffie-Hellman.

It uses dynamic memory allocation for storing its data structures. That means that there is no limit on the size of the numbers manipulated by these functions, but return values must always be checked in case a memory allocation error has occurred.

The basic object in this library is a **BIGNUM**. It is used to hold a single large integer. This type should be considered opaque and fields should not be modified or accessed directly.

The creation of **BIGNUM** objects is described in BN_new(3); BN_add(3) describes most of the arithmetic operations. Comparison is described in BN_cmp(3); BN_zero(3) describes certain assignments, BN_rand(3) the generation of random numbers, BN_generate_prime(3) deals with prime numbers and BN_set_bit(3) with bit operations. The conversion of **BIGNUM**s to external formats is described in BN_bn2bin(3).

DESCRIPTION

This page documents the internal functions used by the OpenSSL **BIGNUM** implementation. They are described here to facilitate debugging and extending the library. They are *not* to be used by applications.

The BIGNUM structure

```
typedef struct bignum_st BIGNUM;

struct bignum_st
       {
       BN_ULONG *d;    /* Pointer to an array of 'BN_BITS2' bit chunks. */
       int top;        /* Index of last used d +1. */
       /* The next are internal book keeping for bn_expand. */
       int dmax;       /* Size of the d array. */
       int neg;        /* one if the number is negative */
       int flags;
       };
```

The integer value is stored in **d**, a malloc()ed array of words (**BN_ULONG**), least significant word first. A **BN_ULONG** can be either 16, 32 or 64 bits in size, depending on the 'number of bits' (**BITS2**) specified in `openssl/bn.h`.

dmax is the size of the **d** array that has been allocated. **top** is the number of words being used, so for a value of 4, bn.d[0]=4 and bn.top=1. **neg** is 1 if the number is negative. When a **BIGNUM** is **0**, the **d** field can be **NULL** and **top** == **0**.

flags is a bit field of flags which are defined in `openssl/bn.h`. The flags begin with **BN_FLG_**. The macros BN_set_flags(b,n) and BN_get_flags(b,n) exist to enable or fetch flag(s) **n** from **BIGNUM** structure **b**.

Various routines in this library require the use of temporary **BIGNUM** variables during their execution. Since dynamic memory allocation to create **BIGNUM**s is rather expensive when used in conjunction with repeated subroutine calls, the **BN_CTX** structure is used. This structure contains **BN_CTX_NUM** **BIGNUM**s, see BN_CTX_start(3).

Low-level arithmetic operations

These functions are implemented in C and for several platforms in assembly language:

bn_mul_words(**rp**, **ap**, **num**, **w**) operates on the **num** word arrays **rp** and **ap**. It computes **ap** * **w**, places the result in **rp**, and returns the high word (carry).

bn_mul_add_words(**rp**, **ap**, **num**, **w**) operates on the **num** word arrays **rp** and **ap**. It computes **ap** * **w** + **rp**, places the result in **rp**, and returns the high word (carry).

bn_sqr_words(**rp**, **ap**, **n**) operates on the **num** word array **ap** and the 2***num** word array **ap**. It computes **ap** * **ap** word-wise, and places the low and high bytes of the result in **rp**.

bn_div_words(**h**, **l**, **d**) divides the two word number (**h**,**l**) by **d** and returns the result.

bn_add_words(**rp**, **ap**, **bp**, **num**) operates on the **num** word arrays **ap**, **bp** and **rp**. It computes **ap** + **bp**, places the result in **rp**, and returns the high word (carry).

bn_sub_words(**rp**, **ap**, **bp**, **num**) operates on the **num** word arrays **ap**, **bp** and **rp**. It computes **ap** - **bp**, places the result in **rp**, and returns the carry (1 if **bp** > **ap**, 0 otherwise).

bn_mul_comba4(**r**, **a**, **b**) operates on the 4 word arrays **a** and **b** and the 8 word array **r**. It computes **a***__b__ and places the result in **r**.

bn_mul_comba8(**r**, **a**, **b**) operates on the 8 word arrays **a** and **b** and the 16 word array **r**. It computes **a***__b__ and places the result in **r**.

bn_sqr_comba4(**r**, **a**, **b**) operates on the 4 word arrays **a** and **b** and the 8 word array **r**.

bn_sqr_comba8(**r**, **a**, **b**) operates on the 8 word arrays **a** and **b** and the 16 word array **r**.

The following functions are implemented in C:

bn_cmp_words(**a**, **b**, **n**) operates on the **n** word arrays **a** and **b**. It returns 1, 0 and -1 if **a** is greater than, equal and less than **b**.

bn_mul_normal(**r**, **a**, **na**, **b**, **nb**) operates on the **na** word array **a**, the **nb** word array **b** and the **na**+**nb** word array **r**. It computes **a*****b** and places the result in **r**.

bn_mul_low_normal(**r**, **a**, **b**, **n**) operates on the **n** word arrays **r**, **a** and **b**. It computes the **n** low words of **a*****b** and places the result in **r**.

bn_mul_recursive(**r**, **a**, **b**, **n2**, **dna**, **dnb**, **t**) operates on the word arrays **a** and **b** of length **n2**+**dna** and **n2**+**dnb** (**dna** and **dnb** are currently allowed to be 0 or negative) and the 2***n2** word arrays **r** and **t**. **n2** must be a power of 2. It computes **a*****b** and places the result in **r**.

bn_mul_part_recursive(**r**, **a**, **b**, **n**, **tna**, **tnb**, **tmp**) operates on the word arrays **a** and **b** of length **n**+**tna** and **n**+**tnb** and the 4***n** word arrays **r** and **tmp**.

bn_mul_low_recursive(**r**, **a**, **b**, **n2**, **tmp**) operates on the **n2** word arrays **r** and **tmp** and the **n2**/2 word arrays **a** and **b**.

bn_mul_high(**r**, **a**, **b**, **l**, **n2**, **tmp**) operates on the **n2** word arrays **r**, **a**, **b** and **l** (?) and the 3***n2** word array **tmp**.

BN_mul() calls bn_mul_normal(), or an optimized implementation if the factors have the same size: bn_mul_comba8() is used if they are 8 words long, bn_mul_recursive() if they are larger than **BN_MULL_SIZE_NORMAL** and the size is an exact multiple of the word size, and bn_mul_part_recursive() for others that are larger than **BN_MULL_SIZE_NORMAL**.

bn_sqr_normal(**r**, **a**, **n**, **tmp**) operates on the **n** word array **a** and the 2***n** word arrays **tmp** and **r**.

The implementations use the following macros which, depending on the architecture, may use "long long" C operations or inline assembler. They are defined in `bn_lcl.h`.

mul(**r**, **a**, **w**, **c**) computes **w*****a**+**c** and places the low word of the result in **r** and the high word in **c**.

mul_add(**r**, **a**, **w**, **c**) computes **w*****a**+**r**+**c** and places the low word of the result in **r** and the high word in **c**.

sqr(**r0**, **r1**, **a**) computes **a*****a** and places the low word of the result in **r0** and the high word in **r1**.

Size changes

bn_expand() ensures that **b** has enough space for a **bits** bit number. bn_wexpand() ensures that **b** has enough space for an **n** word number. If the number has to be expanded, both macros call bn_expand2(), which allocates a new **d** array and copies the data. They return **NULL** on error, **b** otherwise.

The bn_fix_top() macro reduces **a->top** to point to the most significant non-zero word plus one when **a** has shrunk.

Debugging

bn_check_top() verifies that `((a)-&gt;top &gt;= 0 && (a)-&gt;top &lt;= (a)-&gt;dmax)`. A violation will cause the program to abort.

bn_print() prints **a** to stderr. bn_dump() prints **n** words at **d** (in reverse order, i.e. most significant word first) to stderr.

bn_set_max() makes **a** a static number with a **dmax** of its current size. This is used by bn_set_low() and bn_set_high() to make **r** a read-only **BIGNUM** that contains the **n** low or high words of **a**.

If **BN_DEBUG** is not defined, bn_check_top(), bn_print(), bn_dump() and bn_set_max() are defined as empty macros.

        const BIGNUM *m, BN_CTX *ctx);
```

```
int BN_gcd(BIGNUM *r, BIGNUM *a, BIGNUM *b, BN_CTX *ctx);
```

DESCRIPTION

BN_add() adds *a* and *b* and places the result in *r* (`r=a+b`). *r* may be the same **BIGNUM** as *a* or *b*.

BN_sub() subtracts *b* from *a* and places the result in *r* (`r=a-b`).

BN_mul() multiplies *a* and *b* and places the result in *r* (`r=a*b`). *r* may be the same **BIGNUM** as *a* or *b*. For multiplication by powers of 2, use BN_lshift(3).

BN_sqr() takes the square of *a* and places the result in *r* (`r=a^2`). *r* and *a* may be the same **BIGNUM**. This function is faster than BN_mul(r,a,a).

BN_div() divides *a* by *d* and places the result in *dv* and the remainder in *rem* (`dv=a/d, rem=a%d`). Either of *dv* and *rem* may be **NULL**, in which case the respective value is not returned. The result is rounded towards zero; thus if *a* is negative, the remainder will be zero or negative. For division by powers of 2, use BN_rshift(3).

BN_mod() corresponds to BN_div() with *dv* set to **NULL**.

BN_nnmod() reduces *a* modulo *m* and places the non-negative remainder in *r*.

BN_mod_add() adds *a* to *b* modulo *m* and places the non-negative result in *r*.

BN_mod_sub() subtracts *b* from *a* modulo *m* and places the non-negative result in *r*.

BN_mod_mul() multiplies *a* by *b* and finds the non-negative remainder respective to modulus *m* (`r=(a*b) mod m`). *r* may be the same **BIGNUM** as *a* or *b*. For more efficient algorithms for repeated computations using the same modulus, see BN_mod_mul_montgomery(3) and BN_mod_mul_reciprocal(3).

BN_mod_sqr() takes the square of *a* modulo **m** and places the result in *r*.

BN_exp() raises *a* to the *p*-th power and places the result in *r* (`r=a^p`). This function is faster than repeated applications of BN_mul().

BN_mod_exp() computes *a* to the *p*-th power modulo *m* (`r=a^p % m`). This function uses less time and space than BN_exp().

BN_gcd() computes the greatest common divisor of *a* and *b* and places the result in *r*. *r* may be the same **BIGNUM** as *a* or *b*.

For all functions, *ctx* is a previously allocated **BN_CTX** used for temporary variables; see BN_CTX_new(3).

Unless noted otherwise, the result **BIGNUM** must be different from the arguments.

RETURN VALUES

For all functions, 1 is returned for success, 0 on error. The return value should always be checked (e.g., `if (!BN_add(r,a,b)) goto err;`). The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), ERR_get_error(3), BN_CTX_new(3), BN_add_word(3), BN_set_bit(3)

HISTORY

BN_add(), BN_sub(), BN_sqr(), BN_div(), BN_mod(), BN_mod_mul(), BN_mod_exp() and BN_gcd() are available in all versions of SSLeay and OpenSSL. The *ctx* argument to BN_mul() was added in SSLeay 0.9.1b. BN_exp() appeared in SSLeay 0.9.0. BN_nnmod(), BN_mod_add(), BN_mod_sub(), and BN_mod_sqr() were added in OpenSSL 0.9.7.

Name

BN_add_word, BN_sub_word, BN_mul_word, BN_div_word and BN_mod_word — arithmetic functions on BIGNUMs with integers

Synopsis

```
#include  <openssl/bn.h>
```

```
int BN_add_word(BIGNUM *a, BN_ULONG w);
```

```
int BN_sub_word(BIGNUM *a, BN_ULONG w);
```

```
int BN_mul_word(BIGNUM *a, BN_ULONG w);
```

```
BN_ULONG BN_div_word(BIGNUM *a, BN_ULONG w);
```

```
BN_ULONG BN_mod_word(const BIGNUM *a, BN_ULONG w);
```

DESCRIPTION

These functions perform arithmetic operations on BIGNUMs with unsigned integers. They are much more efficient than the normal BIGNUM arithmetic operations.

BN_add_word() adds **w** to **a** (`a+=w`).

BN_sub_word() subtracts **w** from **a** (`a-=w`).

BN_mul_word() multiplies **a** and **w** (`a*=w`).

BN_div_word() divides **a** by **w** (`a/=w`) and returns the remainder.

BN_mod_word() returns the remainder of **a** divided by **w** (`a%w`).

For BN_div_word() and BN_mod_word(), **w** must not be 0.

RETURN VALUES

BN_add_word(), BN_sub_word() and BN_mul_word() return 1 for success, 0 on error. The error codes can be obtained by ERR_get_error(3).

BN_mod_word() and BN_div_word() return **a**%**w** on success and **(BN_ULONG)-1** if an error occurred.

SEE ALSO

bn(3), ERR_get_error(3), BN_add(3)

HISTORY

BN_add_word() and BN_mod_word() are available in all versions of SSLeay and OpenSSL. BN_div_word() was added in SSLeay 0.8, and BN_sub_word() and BN_mul_word() in SSLeay 0.9.0.

Before 0.9.8a the return value for BN_div_word() and BN_mod_word() in case of an error was 0.

       int (*bn_mod_exp)(BIGNUM *r, const BIGNUM *a, const BIGNUM *p,
                         const BIGNUM *m, BN_CTX *ctx, BN_MONT_CTX *m_ctx),
       BN_MONT_CTX *m_ctx);
```

DESCRIPTION

BN_BLINDING_new() allocates a new **BN_BLINDING** structure and copies the **A** and **Ai** values into the newly created **BN_BLINDING** object.

BN_BLINDING_free() frees the **BN_BLINDING** structure.

BN_BLINDING_update() updates the **BN_BLINDING** parameters by squaring the **A** and **Ai** or, after specific number of uses and if the necessary parameters are set, by re-creating the blinding parameters.

BN_BLINDING_convert_ex() multiplies **n** with the blinding factor **A**. If **r** is not NULL a copy the inverse blinding factor **Ai** will be returned in **r** (this is useful if a **RSA** object is shared among several threads). BN_BLINDING_invert_ex() multiplies **n** with the inverse blinding factor **Ai**. If **r** is not NULL it will be used as the inverse blinding.

BN_BLINDING_convert() and BN_BLINDING_invert() are wrapper functions for BN_BLINDING_convert_ex() and BN_BLINDING_invert_ex() with **r** set to NULL.

BN_BLINDING_thread_id() provides access to the **CRYPTO_THREADID** object within the **BN_BLINDING** structure. This is to help users provide proper locking if needed for multi-threaded use. The "thread id" object of a newly allocated **BN_BLINDING** structure is initialised to the thread id in which BN_BLINDING_new() was called.

BN_BLINDING_get_flags() returns the BN_BLINDING flags. Currently there are two supported flags: **BN_BLINDING_NO_UPDATE** and **BN_BLINDING_NO_RECREATE**. **BN_BLINDING_NO_UPDATE** inhibits the automatic update of the **BN_BLINDING** parameters after each use and **BN_BLINDING_NO_RECREATE** inhibits the automatic re-creation of the **BN_BLINDING** parameters after a fixed number of uses (currently 32). In newly allocated **BN_BLINDING** objects no flags are set. BN_BLINDING_set_flags() sets the **BN_BLINDING** parameters flags.

BN_BLINDING_create_param() creates new **BN_BLINDING** parameters using the exponent **e** and the modulus **m**. **bn_mod_exp** and **m_ctx** can be used to pass special functions for exponentiation (normally BN_mod_exp_mont() and **BN_MONT_CTX**).

RETURN VALUES

BN_BLINDING_new() returns the newly allocated **BN_BLINDING** structure or NULL in case of an error.

BN_BLINDING_update(), BN_BLINDING_convert(), BN_BLINDING_invert(), BN_BLINDING_convert_ex() and BN_BLINDING_invert_ex() return 1 on success and 0 if an error occured.

BN_BLINDING_thread_id() returns a pointer to the thread id object within a **BN_BLINDING** object.

BN_BLINDING_get_flags() returns the currently set **BN_BLINDING** flags (a **unsigned long** value).

BN_BLINDING_create_param() returns the newly created **BN_BLINDING** parameters or NULL on error.

Name

BN_bn2bin, BN_bin2bn, BN_bn2hex, BN_bn2dec, BN_hex2bn, BN_dec2bn, BN_print, BN_print_fp, BN_bn2mpi and BN_mpi2bn — format conversions

Synopsis

```
#include  <openssl/bn.h>
```

```
int BN_bn2bin(const BIGNUM *a, unsigned char *to);
BIGNUM *BN_bin2bn(const unsigned char *s, int len, BIGNUM *ret);
```

```
char *BN_bn2hex(const BIGNUM *a);
char *BN_bn2dec(const BIGNUM *a);
int BN_hex2bn(BIGNUM **a, const char *str);
int BN_dec2bn(BIGNUM **a, const char *str);
```

```
int BN_print(BIO *fp, const BIGNUM *a);
int BN_print_fp(FILE *fp, const BIGNUM *a);
```

```
int BN_bn2mpi(const BIGNUM *a, unsigned char *to);
BIGNUM *BN_mpi2bn(unsigned char *s, int len, BIGNUM *ret);
```

DESCRIPTION

BN_bn2bin() converts the absolute value of **a** into big-endian form and stores it at **to**. **to** must point to BN_num_bytes(**a**) bytes of memory.

BN_bin2bn() converts the positive integer in big-endian form of length **len** at **s** into a **BIGNUM** and places it in **ret**. If **ret** is NULL, a new **BIGNUM** is created.

BN_bn2hex() and BN_bn2dec() return printable strings containing the hexadecimal and decimal encoding of **a** respectively. For negative numbers, the string is prefaced with a leading '-'. The string must be freed later using OPENSSL_free().

BN_hex2bn() converts the string **str** containing a hexadecimal number to a **BIGNUM** and stores it in ****bn**. If ***bn** is NULL, a new **BIGNUM** is created. If **bn** is NULL, it only computes the number's length in hexadecimal digits. If the string starts with '-', the number is negative. BN_dec2bn() is the same using the decimal system.

BN_print() and BN_print_fp() write the hexadecimal encoding of **a**, with a leading '-' for negative numbers, to the **BIO** or **FILE fp**.

BN_bn2mpi() and BN_mpi2bn() convert **BIGNUM**s from and to a format that consists of the number's length in bytes represented as a 4-byte big-endian number, and the number itself in big-endian format, where the most significant bit signals a negative number (the representation of numbers with the MSB set is prefixed with null byte).

BN_bn2mpi() stores the representation of **a** at **to**, where **to** must be large enough to hold the result. The size can be determined by calling BN_bn2mpi(**a**, NULL).

BN_mpi2bn() converts the **len** bytes long representation at **s** to a **BIGNUM** and stores it at **ret**, or in a newly allocated **BIGNUM** if **ret** is NULL.

RETURN VALUES

BN_bn2bin() returns the length of the big-endian number placed at **to**. BN_bin2bn() returns the **BIGNUM**, NULL on error.

BN_bn2hex() and BN_bn2dec() return a null-terminated string, or NULL on error. BN_hex2bn() and BN_dec2bn() return the number's length in hexadecimal or decimal digits, and 0 on error.

BN_print_fp() and BN_print() return 1 on success, 0 on write errors.

BN_bn2mpi() returns the length of the representation. BN_mpi2bn() returns the **BIGNUM**, and NULL on error.

The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), ERR_get_error(3), BN_zero(3), ASN1_INTEGER_to_BN(3), BN_num_bytes(3)

HISTORY

BN_bn2bin(), BN_bin2bn(), BN_print_fp() and BN_print() are available in all versions of SSLeay and OpenSSL.

BN_bn2hex(), BN_bn2dec(), BN_hex2bn(), BN_dec2bn(), BN_bn2mpi() and BN_mpi2bn() were added in SSLeay 0.9.0.

Name

BN_cmp, BN_ucmp, BN_is_zero, BN_is_one, BN_is_word and BN_is_odd — BIGNUM comparison and test functions

Synopsis

```
#include  <openssl/bn.h>
```

```
int BN_cmp(BIGNUM *a, BIGNUM *b);
int BN_ucmp(BIGNUM *a, BIGNUM *b);
```

```
int BN_is_zero(BIGNUM *a);
int BN_is_one(BIGNUM *a);
int BN_is_word(BIGNUM *a, BN_ULONG w);
int BN_is_odd(BIGNUM *a);
```

DESCRIPTION

BN_cmp() compares the numbers **a** and **b**. BN_ucmp() compares their absolute values.

BN_is_zero(), BN_is_one() and BN_is_word() test if **a** equals 0, 1, or **w** respectively. BN_is_odd() tests if a is odd.

BN_is_zero(), BN_is_one(), BN_is_word() and BN_is_odd() are macros.

RETURN VALUES

BN_cmp() returns -1 if **a** < **b**, 0 if **a** == **b** and 1 if **a** > **b**. BN_ucmp() is the same using the absolute values of **a** and **b**.

BN_is_zero(), BN_is_one() BN_is_word() and BN_is_odd() return 1 if the condition is true, 0 otherwise.

SEE ALSO

bn(3)

HISTORY

BN_cmp(), BN_ucmp(), BN_is_zero(), BN_is_one() and BN_is_word() are available in all versions of SSLeay and OpenSSL. BN_is_odd() was added in SSLeay 0.8.

Name

BN_copy and BN_dup — copy BIGNUMs

Synopsis

```
#include  <openssl/bn.h>
```

```
BIGNUM *BN_copy(BIGNUM *to, const BIGNUM *from);
```

```
BIGNUM *BN_dup(const BIGNUM *from);
```

DESCRIPTION

BN_copy() copies **from** to **to**. BN_dup() creates a new **BIGNUM** containing the value **from**.

RETURN VALUES

BN_copy() returns **to** on success, NULL on error. BN_dup() returns the new **BIGNUM**, and NULL on error. The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), ERR_get_error(3)

HISTORY

BN_copy() and BN_dup() are available in all versions of SSLeay and OpenSSL.

Name

BN_CTX_new, BN_CTX_init and BN_CTX_free — allocate and free BN_CTX structures

Synopsis

```
#include  <openssl/bn.h>
```

```
BN_CTX *BN_CTX_new(void);
```

```
void BN_CTX_init(BN_CTX *c);
```

```
void BN_CTX_free(BN_CTX *c);
```

DESCRIPTION

A **BN_CTX** is a structure that holds **BIGNUM** temporary variables used by library functions. Since dynamic memory allocation to create **BIGNUM**s is rather expensive when used in conjunction with repeated subroutine calls, the **BN_CTX** structure is used.

BN_CTX_new() allocates and initializes a **BN_CTX** structure. BN_CTX_init() initializes an existing uninitialized **BN_CTX**.

BN_CTX_free() frees the components of the **BN_CTX**, and if it was created by BN_CTX_new(), also the structure itself. If BN_CTX_start(3) has been used on the **BN_CTX**, BN_CTX_end(3) must be called before the **BN_CTX** may be freed by BN_CTX_free().

RETURN VALUES

BN_CTX_new() returns a pointer to the **BN_CTX**. If the allocation fails, it returns **NULL** and sets an error code that can be obtained by ERR_get_error(3).

BN_CTX_init() and BN_CTX_free() have no return values.

SEE ALSO

bn(3), ERR_get_error(3), BN_add(3), BN_CTX_start(3)

HISTORY

BN_CTX_new() and BN_CTX_free() are available in all versions on SSLeay and OpenSSL. BN_CTX_init() was added in SSLeay 0.9.1b.

Name

BN_CTX_start, BN_CTX_get and BN_CTX_end — use temporary BIGNUM variables

Synopsis

```
#include  <openssl/bn.h>
```

```
void BN_CTX_start(BN_CTX *ctx);
```

```
BIGNUM *BN_CTX_get(BN_CTX *ctx);
```

```
void BN_CTX_end(BN_CTX *ctx);
```

DESCRIPTION

These functions are used to obtain temporary **BIGNUM** variables from a **BN_CTX** (which can been created by using BN_CTX_new(3)) in order to save the overhead of repeatedly creating and freeing **BIGNUM**s in functions that are called from inside a loop.

A function must call BN_CTX_start() first. Then, BN_CTX_get() may be called repeatedly to obtain temporary **BIGNUM**s. All BN_CTX_get() calls must be made before calling any other functions that use the **ctx** as an argument.

Finally, BN_CTX_end() must be called before returning from the function. When BN_CTX_end() is called, the **BIGNUM** pointers obtained from BN_CTX_get() become invalid.

RETURN VALUES

BN_CTX_start() and BN_CTX_end() return no values.

BN_CTX_get() returns a pointer to the **BIGNUM**, or **NULL** on error. Once BN_CTX_get() has failed, the subsequent calls will return **NULL** as well, so it is sufficient to check the return value of the last BN_CTX_get() call. In case of an error, an error code is set, which can be obtained by ERR_get_error(3).

SEE ALSO

BN_CTX_new(3)

HISTORY

BN_CTX_start(), BN_CTX_get() and BN_CTX_end() were added in OpenSSL 0.9.5.

Name

BN_generate_prime, BN_is_prime and BN_is_prime_fasttest — generate primes and test for primality

Synopsis

```
#include  <openssl/bn.h>
```

```
BIGNUM *BN_generate_prime(BIGNUM *ret, int num, int safe, BIGNUM *add,
    BIGNUM *rem, void (*callback)(int, int, void *), void *cb_arg);
```

```
int BN_is_prime(const BIGNUM *a, int checks, void (*callback)(int, int,
    void *), BN_CTX *ctx, void *cb_arg);
```

```
int BN_is_prime_fasttest(const BIGNUM *a, int checks,
    void (*callback)(int, int, void *), BN_CTX *ctx, void *cb_arg,
    int do_trial_division);
```

DESCRIPTION

BN_generate_prime() generates a pseudo-random prime number of **num** bits. If **ret** is not **NULL**, it will be used to store the number.

If **callback** is not **NULL**, it is called as follows:

- **callback(0, i, cb_arg)** is called after generating the i-th potential prime number.

- While the number is being tested for primality, **callback(1, j, cb_arg)** is called as described below.

- When a prime has been found, **callback(2, i, cb_arg)** is called.

The prime may have to fulfill additional requirements for use in Diffie-Hellman key exchange:

If **add** is not **NULL**, the prime will fulfill the condition p % **add** == **rem** (p % **add** == 1 if **rem** == **NULL**) in order to suit a given generator.

If **safe** is true, it will be a safe prime (i.e. a prime p so that (p-1)/2 is also prime).

The PRNG must be seeded prior to calling BN_generate_prime(). The prime number generation has a negligible error probability.

BN_is_prime() and BN_is_prime_fasttest() test if the number **a** is prime. The following tests are performed until one of them shows that **a** is composite; if **a** passes all these tests, it is considered prime.

BN_is_prime_fasttest(), when called with **do_trial_division == 1**, first attempts trial division by a number of small primes; if no divisors are found by this test and **callback** is not **NULL**, **callback(1, -1, cb_arg)** is called. If **do_trial_division == 0**, this test is skipped.

Both BN_is_prime() and BN_is_prime_fasttest() perform a Miller-Rabin probabilistic primality test with **checks** iterations. If **checks == BN_prime_checks**, a number of iterations is used that yields a false positive rate of at most 2^-80 for random input.

If **callback** is not **NULL**, **callback(1, j, cb_arg)** is called after the j-th iteration (j = 0, 1, …). **ctx** is a pre-allocated **BN_CTX** (to save the overhead of allocating and freeing the structure in a loop), or **NULL**.

RETURN VALUES

BN_generate_prime() returns the prime number on success, **NULL** otherwise.

BN_is_prime() returns 0 if the number is composite, 1 if it is prime with an error probability of less than 0.25^**checks**, and -1 on error.

The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), ERR_get_error(3), rand(3)

HISTORY

The **cb_arg** arguments to BN_generate_prime() and to BN_is_prime() were added in SSLeay 0.9.0. The **ret** argument to BN_generate_prime() was added in SSLeay 0.9.1. BN_is_prime_fasttest() was added in OpenSSL 0.9.5.

Name

BN_mod_inverse — compute inverse modulo n

Synopsis

```
#include  <openssl/bn.h>
```

```
BIGNUM *BN_mod_inverse(BIGNUM *r, BIGNUM *a, const BIGNUM *n,
          BN_CTX *ctx);
```

DESCRIPTION

BN_mod_inverse() computes the inverse of **a** modulo **n** places the result in **r** (`(a*r)%n==1`). If **r** is NULL, a new **BIGNUM** is created.

ctx is a previously allocated **BN_CTX** used for temporary variables. **r** may be the same **BIGNUM** as **a** or **n**.

RETURN VALUES

BN_mod_inverse() returns the **BIGNUM** containing the inverse, and NULL on error. The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), ERR_get_error(3), BN_add(3)

HISTORY

BN_mod_inverse() is available in all versions of SSLeay and OpenSSL.

Name

BN_mod_mul_montgomery, BN_MONT_CTX_new, BN_MONT_CTX_init, BN_MONT_CTX_free, BN_MONT_CTX_set, BN_MONT_CTX_copy, BN_from_montgomery and BN_to_montgomery — Montgomery multiplication

Synopsis

```
#include  <openssl/bn.h>
```

```
BN_MONT_CTX *BN_MONT_CTX_new(void);
void BN_MONT_CTX_init(BN_MONT_CTX *ctx);
void BN_MONT_CTX_free(BN_MONT_CTX *mont);
```

```
int BN_MONT_CTX_set(BN_MONT_CTX *mont, const BIGNUM *m, BN_CTX *ctx);
BN_MONT_CTX *BN_MONT_CTX_copy(BN_MONT_CTX *to, BN_MONT_CTX *from);
```

```
int BN_mod_mul_montgomery(BIGNUM *r, BIGNUM *a, BIGNUM *b,
        BN_MONT_CTX *mont, BN_CTX *ctx);
```

```
int BN_from_montgomery(BIGNUM *r, BIGNUM *a, BN_MONT_CTX *mont,
        BN_CTX *ctx);
```

```
int BN_to_montgomery(BIGNUM *r, BIGNUM *a, BN_MONT_CTX *mont,
        BN_CTX *ctx);
```

DESCRIPTION

These functions implement Montgomery multiplication. They are used automatically when BN_mod_exp(3) is called with suitable input, but they may be useful when several operations are to be performed using the same modulus.

BN_MONT_CTX_new() allocates and initializes a **BN_MONT_CTX** structure. BN_MONT_CTX_init() initializes an existing uninitialized **BN_MONT_CTX**.

BN_MONT_CTX_set() sets up the *mont* structure from the modulus *m* by precomputing its inverse and a value R.

BN_MONT_CTX_copy() copies the **BN_MONT_CTX** *from* to *to*.

BN_MONT_CTX_free() frees the components of the **BN_MONT_CTX**, and, if it was created by BN_MONT_CTX_new(), also the structure itself.

BN_mod_mul_montgomery() computes Mont(*a*,*b*):=*a***b**R^-1 and places the result in *r*.

BN_from_montgomery() performs the Montgomery reduction *r* = *a**R^-1.

BN_to_montgomery() computes Mont(*a*,R^2), i.e. *a**R. Note that *a* must be non-negative and smaller than the modulus.

For all functions, *ctx* is a previously allocated **BN_CTX** used for temporary variables.

The **BN_MONT_CTX** structure is defined as follows:

```
typedef struct bn_mont_ctx_st
       {
       int ri;         /* number of bits in R */
       BIGNUM RR;      /* R^2 (used to convert to Montgomery form) */
       BIGNUM N;       /* The modulus */
       BIGNUM Ni;      /* R*(1/R mod N) - N*Ni = 1
                        * (Ni is only stored for bignum algorithm) */
       BN_ULONG n0;    /* least significant word of Ni */
       int flags;
       } BN_MONT_CTX;
```

BN_to_montgomery() is a macro.

RETURN VALUES

BN_MONT_CTX_new() returns the newly allocated **BN_MONT_CTX**, and NULL on error.

BN_MONT_CTX_init() and BN_MONT_CTX_free() have no return values.

For the other functions, 1 is returned for success, 0 on error. The error codes can be obtained by ERR_get_error(3).

WARNING

The inputs must be reduced modulo **m**, otherwise the result will be outside the expected range.

SEE ALSO

bn(3), ERR_get_error(3), BN_add(3), BN_CTX_new(3)

HISTORY

BN_MONT_CTX_new(), BN_MONT_CTX_free(), BN_MONT_CTX_set(), BN_mod_mul_montgomery(), BN_from_montgomery() and BN_to_montgomery() are available in all versions of SSLeay and OpenSSL.

BN_MONT_CTX_init() and BN_MONT_CTX_copy() were added in SSLeay 0.9.1b.

Name

BN_mod_mul_reciprocal, BN_div_recp, BN_RECP_CTX_new, BN_RECP_CTX_init, BN_RECP_CTX_free and BN_RECP_CTX_set — modular multiplication using reciprocal

Synopsis

```
#include  <openssl/bn.h>
```

```
BN_RECP_CTX *BN_RECP_CTX_new(void);
void BN_RECP_CTX_init(BN_RECP_CTX *recp);
void BN_RECP_CTX_free(BN_RECP_CTX *recp);
```

```
int BN_RECP_CTX_set(BN_RECP_CTX *recp, const BIGNUM *m, BN_CTX *ctx);
```

```
int BN_div_recp(BIGNUM *dv, BIGNUM *rem, BIGNUM *a, BN_RECP_CTX *recp,
       BN_CTX *ctx);
```

```
int BN_mod_mul_reciprocal(BIGNUM *r, BIGNUM *a, BIGNUM *b,
       BN_RECP_CTX *recp, BN_CTX *ctx);
```

DESCRIPTION

BN_mod_mul_reciprocal() can be used to perform an efficient BN_mod_mul(3) operation when the operation will be performed repeatedly with the same modulus. It computes **r**=(**a*****b**)%**m** using **recp**=1/**m**, which is set as described below. **ctx** is a previously allocated **BN_CTX** used for temporary variables.

BN_RECP_CTX_new() allocates and initializes a **BN_RECP** structure. BN_RECP_CTX_init() initializes an existing uninitialized **BN_RECP**.

BN_RECP_CTX_free() frees the components of the **BN_RECP**, and, if it was created by BN_RECP_CTX_new(), also the structure itself.

BN_RECP_CTX_set() stores **m** in **recp** and sets it up for computing 1/**m** and shifting it left by BN_num_bits(**m**)+1 to make it an integer. The result and the number of bits it was shifted left will later be stored in **recp**.

BN_div_recp() divides **a** by **m** using **recp**. It places the quotient in **dv** and the remainder in **rem**.

The **BN_RECP_CTX** structure is defined as follows:

```
typedef struct bn_recp_ctx_st
       {
       BIGNUM N;       /* the divisor */
       BIGNUM Nr;      /* the reciprocal */
       int num_bits;
       int shift;
       int flags;
       } BN_RECP_CTX;
```

It cannot be shared between threads.

RETURN VALUES

BN_RECP_CTX_new() returns the newly allocated **BN_RECP_CTX**, and NULL on error.

BN_RECP_CTX_init() and BN_RECP_CTX_free() have no return values.

For the other functions, 1 is returned for success, 0 on error. The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), ERR_get_error(3), BN_add(3), BN_CTX_new(3)

HISTORY

BN_RECP_CTX was added in SSLeay 0.9.0. Before that, the function BN_reciprocal() was used instead, and the BN_mod_mul_reciprocal() arguments were different.

Name

BN_new, BN_init, BN_clear, BN_free and BN_clear_free — allocate and free BIGNUMs

Synopsis

```
#include  <openssl/bn.h>
```

```
BIGNUM *BN_new(void);
```

```
void BN_init(BIGNUM *);
```

```
void BN_clear(BIGNUM *a);
```

```
void BN_free(BIGNUM *a);
```

```
void BN_clear_free(BIGNUM *a);
```

DESCRIPTION

BN_new() allocates and initializes a **BIGNUM** structure. BN_init() initializes an existing uninitialized **BIGNUM**.

BN_clear() is used to destroy sensitive data such as keys when they are no longer needed. It erases the memory used by **a** and sets it to the value 0.

BN_free() frees the components of the **BIGNUM**, and if it was created by BN_new(), also the structure itself. BN_clear_free() additionally overwrites the data before the memory is returned to the system.

RETURN VALUES

BN_new() returns a pointer to the **BIGNUM**. If the allocation fails, it returns **NULL** and sets an error code that can be obtained by ERR_get_error(3).

BN_init(), BN_clear(), BN_free() and BN_clear_free() have no return values.

SEE ALSO

bn(3), ERR_get_error(3)

HISTORY

BN_new(), BN_clear(), BN_free() and BN_clear_free() are available in all versions on SSLeay and OpenSSL. BN_init() was added in SSLeay 0.9.1b.

Name

BN_num_bits, BN_num_bytes and BN_num_bits_word — get BIGNUM size

Synopsis

```
#include  <openssl/bn.h>
```

```
int BN_num_bytes(const BIGNUM *a);
```

```
int BN_num_bits(const BIGNUM *a);
```

```
int BN_num_bits_word(BN_ULONG w);
```

DESCRIPTION

BN_num_bytes() returns the size of a **BIGNUM** in bytes.

BN_num_bits_word() returns the number of significant bits in a word. If we take 0x00000432 as an example, it returns 11, not 16, not 32. Basically, except for a zero, it returns *floor(log2(w))+1*.

BN_num_bits() returns the number of significant bits in a **BIGNUM**, following the same principle as BN_num_bits_word().

BN_num_bytes() is a macro.

RETURN VALUES

The size.

NOTES

Some have tried using BN_num_bits() on individual numbers in RSA keys, DH keys and DSA keys, and found that they don't always come up with the number of bits they expected (something like 512, 1024, 2048, …). This is because generating a number with some specific number of bits doesn't always set the highest bits, thereby making the number of *significant* bits a little lower. If you want to know the "key size" of such a key, either use functions like RSA_size(), DH_size() and DSA_size(), or use BN_num_bytes() and multiply with 8 (although there's no real guarantee that will match the "key size", just a lot more probability).

SEE ALSO

bn(3), DH_size(3), DSA_size(3), RSA_size(3)

HISTORY

BN_num_bytes(), BN_num_bits() and BN_num_bits_word() are available in all versions of SSLeay and OpenSSL.

Name

BN_rand and BN_pseudo_rand — generate pseudo-random number

Synopsis

```
#include  <openssl/bn.h>
```

```
int BN_rand(BIGNUM *rnd, int bits, int top, int bottom);
```

```
int BN_pseudo_rand(BIGNUM *rnd, int bits, int top, int bottom);
```

```
int BN_rand_range(BIGNUM *rnd, BIGNUM *range);
```

```
int BN_pseudo_rand_range(BIGNUM *rnd, BIGNUM *range);
```

DESCRIPTION

BN_rand() generates a cryptographically strong pseudo-random number of **bits** in length and stores it in **rnd**. If **top** is -1, the most significant bit of the random number can be zero. If **top** is 0, it is set to 1, and if **top** is 1, the two most significant bits of the number will be set to 1, so that the product of two such random numbers will always have 2***bits** length. If **bottom** is true, the number will be odd. The value of **bits** must be zero or greater. If **bits** is 1 then **top** cannot also be 1.

BN_pseudo_rand() does the same, but pseudo-random numbers generated by this function are not necessarily unpredictable. They can be used for non-cryptographic purposes and for certain purposes in cryptographic protocols, but usually not for key generation etc.

BN_rand_range() generates a cryptographically strong pseudo-random number **rnd** in the range 0 <= **rnd** < **range**. BN_pseudo_rand_range() does the same, but is based on BN_pseudo_rand(), and hence numbers generated by it are not necessarily unpredictable.

The PRNG must be seeded prior to calling BN_rand() or BN_rand_range().

RETURN VALUES

The functions return 1 on success, 0 on error. The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), ERR_get_error(3), rand(3), RAND_add(3), RAND_bytes(3)

HISTORY

BN_rand() is available in all versions of SSLeay and OpenSSL. BN_pseudo_rand() was added in OpenSSL 0.9.5. The **top** == -1 case and the function BN_rand_range() were added in OpenSSL 0.9.6a. BN_pseudo_rand_range() was added in OpenSSL 0.9.6c.

Name

BN_set_bit, BN_clear_bit, BN_is_bit_set, BN_mask_bits, BN_lshift, BN_lshift1, BN_rshift and BN_rshift1 — bit operations on BIGNUMs

Synopsis

```
#include  <openssl/bn.h>
```

```
int BN_set_bit(BIGNUM *a, int n);
int BN_clear_bit(BIGNUM *a, int n);
```

```
int BN_is_bit_set(const BIGNUM *a, int n);
```

```
int BN_mask_bits(BIGNUM *a, int n);
```

```
int BN_lshift(BIGNUM *r, const BIGNUM *a, int n);
int BN_lshift1(BIGNUM *r, BIGNUM *a);
```

```
int BN_rshift(BIGNUM *r, BIGNUM *a, int n);
int BN_rshift1(BIGNUM *r, BIGNUM *a);
```

DESCRIPTION

BN_set_bit() sets bit **n** in **a** to 1 (`a|=(1&lt;&lt;n)`). The number is expanded if necessary.

BN_clear_bit() sets bit **n** in **a** to 0 (`a&=~(1&lt;&lt;n)`). An error occurs if **a** is shorter than **n** bits.

BN_is_bit_set() tests if bit **n** in **a** is set.

BN_mask_bits() truncates **a** to an **n** bit number (`a&=~((~0)&gt;&gt;n)`). An error occurs if **a** already is shorter than **n** bits.

BN_lshift() shifts **a** left by **n** bits and places the result in **r** (`r=a*2^n`). Note that **n** must be non-negative. BN_lshift1() shifts **a** left by one and places the result in **r** (`r=2*a`).

BN_rshift() shifts **a** right by **n** bits and places the result in **r** (`r=a/2^n`). Note that **n** must be non-negative. BN_rshift1() shifts **a** right by one and places the result in **r** (`r=a/2`).

For the shift functions, **r** and **a** may be the same variable.

RETURN VALUES

BN_is_bit_set() returns 1 if the bit is set, 0 otherwise.

All other functions return 1 for success, 0 on error. The error codes can be obtained by ERR_get_error(3).

SEE ALSO

bn(3), BN_num_bytes(3), BN_add(3)

HISTORY

BN_set_bit(), BN_clear_bit(), BN_is_bit_set(), BN_mask_bits(), BN_lshift(), BN_lshift1(), BN_rshift(), and BN_rshift1() are available in all versions of SSLeay and OpenSSL.

Name

BN_swap — exchange BIGNUMs

Synopsis

```
#include  <openssl/bn.h>
```

```
void BN_swap(BIGNUM *a, BIGNUM *b);
```

DESCRIPTION

BN_swap() exchanges the values of *a* and *b*.

bn(3)

HISTORY

BN_swap was added in OpenSSL 0.9.7.

Name

BN_zero, BN_one, BN_value_one, BN_set_word and BN_get_word — BIGNUM assignment operations

Synopsis

```
#include  <openssl/bn.h>
```

```
int BN_zero(BIGNUM *a);
int BN_one(BIGNUM *a);
```

```
const BIGNUM *BN_value_one(void);
```

```
int BN_set_word(BIGNUM *a, unsigned long w);
unsigned long BN_get_word(BIGNUM *a);
```

DESCRIPTION

BN_zero(), BN_one() and BN_set_word() set **a** to the values 0, 1 and **w** respectively. BN_zero() and BN_one() are macros.

BN_value_one() returns a **BIGNUM** constant of value 1. This constant is useful for use in comparisons and assignment.

BN_get_word() returns **a**, if it can be represented as an unsigned long.

RETURN VALUES

BN_get_word() returns the value **a**, and 0xffffffffL if **a** cannot be represented as an unsigned long.

BN_zero(), BN_one() and BN_set_word() return 1 on success, 0 otherwise. BN_value_one() returns the constant.

BUGS

Someone might change the constant.

If a **BIGNUM** is equal to 0xffffffffL it can be represented as an unsigned long but this value is also returned on error.

SEE ALSO

bn(3), BN_bn2bin(3)

HISTORY

BN_zero(), BN_one() and BN_set_word() are available in all versions of SSLeay and OpenSSL. BN_value_one() and BN_get_word() were added in SSLeay 0.8.

BN_value_one() was changed to return a true const BIGNUM * in OpenSSL 0.9.7.

Name

BUF_MEM_new, BUF_MEM_new_ex, BUF_MEM_free, BUF_MEM_grow, BUF_strdup, BUF_strndup, BUF_memdup, BUF_strlcpy and BUF_strlcat — simple character array structure, with some standard C library equivalents

Synopsis

```
#include  <openssl/buffer.h>
```

```
BUF_MEM *BUF_MEM_new(void);
```

```
void   BUF_MEM_free(BUF_MEM *a);
```

```
int    BUF_MEM_grow(BUF_MEM *str, int len);
```

```
char *BUF_strdup(const char *str);
```

```
char *BUF_strndup(const char *str, size_t siz);
```

```
void *BUF_memdup(const void *data, size_t siz);
```

```
size_t BUF_strlcpy(char *dst, const char *src, size_t size);
```

```
size_t BUF_strlcat(char *dst, const char *src, size_t size);
```

DESCRIPTION

The buffer library handles simple character arrays. Buffers are used for various purposes in the library, most notably memory BIOs.

BUF_MEM_new() allocates a new buffer of zero size.

BUF_MEM_free() frees up an already existing buffer. The data is zeroed before freeing up in case the buffer contains sensitive data.

BUF_MEM_grow() changes the size of an already existing buffer to **len**. Any data already in the buffer is preserved if it increases in size.

BUF_strdup(), BUF_strndup(), BUF_memdup(), BUF_strlcpy() and BUF_strlcat() are equivalents of the standard C library functions. The dup() functions use OPENSSL_malloc() underneath and so should be used in preference to the standard library for memory leak checking or replacing the malloc() function.

Memory allocated from these functions should be freed up using the OPENSSL_free() function.

BUF_strndup makes the explicit guarantee that it will never read past the first **siz** bytes of **str**.

RETURN VALUES

BUF_MEM_new() returns the buffer or NULL on error.

BUF_MEM_free() has no return value.

BUF_MEM_grow() returns zero on error or the new size (i.e. **len**).

SEE ALSO

bio(3)

HISTORY

BUF_MEM_new(), BUF_MEM_free() and BUF_MEM_grow() are available in all versions of SSLeay and OpenSSL. BUF_strdup() was added in SSLeay 0.8.

Name

CMS_add0_cert, CMS_add1_cert, CMS_get1_certs, CMS_add0_crl and CMS_get1_crls — CMS certificate and CRL utility functions

Synopsis

```
#include  <openssl/cms.h>
```

```
int CMS_add0_cert(CMS_ContentInfo *cms, X509 *cert);
int CMS_add1_cert(CMS_ContentInfo *cms, X509 *cert);
STACK_OF(X509) *CMS_get1_certs(CMS_ContentInfo *cms);
```

```
int CMS_add0_crl(CMS_ContentInfo *cms, X509_CRL *crl);
int CMS_add1_crl(CMS_ContentInfo *cms, X509_CRL *crl);
STACK_OF(X509_CRL) *CMS_get1_crls(CMS_ContentInfo *cms);
```

DESCRIPTION

CMS_add0_cert() and CMS_add1_cert() add certificate **cert** to **cms**. must be of type signed data or enveloped data.

CMS_get1_certs() returns all certificates in **cms**.

CMS_add0_crl() and CMS_add1_crl() add CRL **crl** to **cms**. CMS_get1_crls() returns any CRLs in **cms**.

NOTES

The CMS_ContentInfo structure **cms** must be of type signed data or enveloped data or an error will be returned.

For signed data certificates and CRLs are added to the **certificates** and **crls** fields of SignedData structure. For enveloped data they are added to **OriginatorInfo**.

As the **0** implies CMS_add0_cert() adds **cert** internally to **cms** and it must not be freed up after the call as opposed to CMS_add1_cert() where **cert** must be freed up.

The same certificate or CRL must not be added to the same cms structure more than once.

RETURN VALUES

CMS_add0_cert(), CMS_add1_cert() and CMS_add0_crl() and CMS_add1_crl() return 1 for success and 0 for failure.

CMS_get1_certs() and CMS_get1_crls() return the STACK of certificates or CRLs or NULL if there are none or an error occurs. The only error which will occur in practice is if the **cms** type is invalid.

SEE ALSO

ERR_get_error(3), CMS_sign(3), CMS_encrypt(3)

HISTORY

CMS_add0_cert(), CMS_add1_cert(), CMS_get1_certs(), CMS_add0_crl() and CMS_get1_crls() were all first added to OpenSSL 0.9.8

Name

CMS_add1_recipient_cert and CMS_add0_recipient_key — add recipients to a CMS enveloped data structure

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_RecipientInfo *CMS_add1_recipient_cert(CMS_ContentInfo *cms, X509 *recip, unsigned int flags);
```

```
CMS_RecipientInfo *CMS_add0_recipient_key(CMS_ContentInfo *cms, int nid, unsigned char *key,
    size_t keylen, unsigned char *id, size_t idlen, ASN1_GENERALIZEDTIME *date,
    WASN1_OBJECT *otherTypeId, ASN1_TYPE *otherType);
```

DESCRIPTION

CMS_add1_recipient_cert() adds recipient **recip** to CMS_ContentInfo enveloped data structure **cms** as a KeyTransRecipientInfo structure.

CMS_add0_recipient_key() adds symmetric key **key** of length **keylen** using wrapping algorithm **nid**, identifier **id** of length **idlen** and optional values **date**, **otherTypeId** and **otherType** to CMS_ContentInfo enveloped data structure **cms** as a KEKRecipientInfo structure.

The CMS_ContentInfo structure should be obtained from an initial call to CMS_encrypt() with the flag **CMS_PARTIAL** set.

NOTES

The main purpose of this function is to provide finer control over a CMS enveloped data structure where the simpler CMS_encrypt() function defaults are not appropriate. For example if one or more KEKRecipientInfo structures need to be added. New attributes can also be added using the returned CMS_RecipientInfo structure and the CMS attribute utility functions.

OpenSSL will by default identify recipient certificates using issuer name and serial number. If **CMS_USE_KEYID** is set it will use the subject key identifier value instead. An error occurs if all recipient certificates do not have a subject key identifier extension.

Currently only AES based key wrapping algorithms are supported for **nid**, specifically: NID_id_aes128_wrap, NID_id_aes192_wrap and NID_id_aes256_wrap. If **nid** is set to **NID_undef** then an AES wrap algorithm will be used consistent with **keylen**.

RETURN VALUES

CMS_add1_recipient_cert() and CMS_add0_recipient_key() return an internal pointer to the CMS_RecipientInfo structure just added or NULL if an error occurs.

SEE ALSO

ERR_get_error(3), CMS_decrypt(3), CMS_final(3)

HISTORY

CMS_add1_recipient_cert() and CMS_add0_recipient_key() were added to OpenSSL 0.9.8

Name

CMS_compress — create a CMS CompressedData structure

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_ContentInfo *CMS_compress(BIO *in, int comp_nid, unsigned int flags);
```

DESCRIPTION

CMS_compress() creates and returns a CMS CompressedData structure. **comp_nid** is the compression algorithm to use or **NID_undef** to use the default algorithm (zlib compression). **in** is the content to be compressed. **flags** is an optional set of flags.

NOTES

The only currently supported compression algorithm is zlib using the NID NID_zlib_compression.

If zlib support is not compiled into OpenSSL then CMS_compress() will return an error.

If the **CMS_TEXT** flag is set MIME headers for type **text/plain** are prepended to the data.

Normally the supplied content is translated into MIME canonical format (as required by the S/MIME specifications) if **CMS_BINARY** is set no translation occurs. This option should be used if the supplied data is in binary format otherwise the translation will corrupt it. If **CMS_BINARY** is set then **CMS_TEXT** is ignored.

If the **CMS_STREAM** flag is set a partial **CMS_ContentInfo** structure is returned suitable for streaming I/O: no data is read from the BIO **in**.

The compressed data is included in the CMS_ContentInfo structure, unless **CMS_DETACHED** is set in which case it is omitted. This is rarely used in practice and is not supported by SMIME_write_CMS().

NOTES

If the flag **CMS_STREAM** is set the returned **CMS_ContentInfo** structure is **not** complete and outputting its contents via a function that does not properly finalize the **CMS_ContentInfo** structure will give unpredictable results.

Several functions including SMIME_write_CMS(), i2d_CMS_bio_stream(), PEM_write_bio_CMS_stream() finalize the structure. Alternatively finalization can be performed by obtaining the streaming ASN1 **BIO** directly using BIO_new_CMS().

Additional compression parameters such as the zlib compression level cannot currently be set.

RETURN VALUES

CMS_compress() returns either a CMS_ContentInfo structure or NULL if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), CMS_uncompress(3)

HISTORY

CMS_compress() was added to OpenSSL 0.9.8 The **CMS_STREAM** flag was first supported in OpenSSL 1.0.0.

Name

CMS_decrypt — decrypt content from a CMS envelopedData structure

Synopsis

```
#include  <openssl/cms.h>
```

```
int CMS_decrypt(CMS_ContentInfo *cms, EVP_PKEY *pkey, X509 *cert, BIO *dcont, BIO *out,
    unsigned int flags);
```

DESCRIPTION

CMS_decrypt() extracts and decrypts the content from a CMS EnvelopedData structure. **pkey** is the private key of the recipient, **cert** is the recipient's certificate, **out** is a BIO to write the content to and **flags** is an optional set of flags.

The **dcont** parameter is used in the rare case where the encrypted content is detached. It will normally be set to NULL.

NOTES

OpenSSL_add_all_algorithms() (or equivalent) should be called before using this function or errors about unknown algorithms will occur.

Although the recipients certificate is not needed to decrypt the data it is needed to locate the appropriate (of possible several) recipients in the CMS structure.

If **cert** is set to NULL all possible recipients are tried. This case however is problematic. To thwart the MMA attack (Bleichenbacher's attack on PKCS #1 v1.5 RSA padding) all recipients are tried whether they succeed or not. If no recipient succeeds then a random symmetric key is used to decrypt the content: this will typically output garbage and may (but is not guaranteed to) ultimately return a padding error only. If CMS_decrypt() just returned an error when all recipient encrypted keys failed to decrypt an attacker could use this in a timing attack. If the special flag **CMS_DEBUG_DECRYPT** is set then the above behaviour is modified and an error **is** returned if no recipient encrypted key can be decrypted **without** generating a random content encryption key. Applications should use this flag with **extreme caution** especially in automated gateways as it can leave them open to attack.

It is possible to determine the correct recipient key by other means (for example looking them up in a database) and setting them in the CMS structure in advance using the CMS utility functions such as CMS_set1_pkey(). In this case both **cert** and **pkey** should be set to NULL.

To process KEKRecipientInfo types CMS_set1_key() or CMS_RecipientInfo_set0_key() and CMS_ReceipientInfo_decrypt() should be called before CMS_decrypt() and **cert** and **pkey** set to NULL.

The following flags can be passed in the **flags** parameter.

If the **CMS_TEXT** flag is set MIME headers for type **text/plain** are deleted from the content. If the content is not of type **text/plain** then an error is returned.

RETURN VALUES

CMS_decrypt() returns either 1 for success or 0 for failure. The error can be obtained from ERR_get_error(3)

BUGS

The lack of single pass processing and the need to hold all data in memory as mentioned in CMS_verify() also applies to CMS_decrypt().

SEE ALSO

ERR_get_error(3), CMS_encrypt(3)

HISTORY

CMS_decrypt() was added to OpenSSL 0.9.8

Name

CMS_encrypt — create a CMS envelopedData structure

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_ContentInfo *CMS_encrypt(STACK_OF(X509) *certs, BIO *in, const EVP_CIPHER *cipher,
      unsigned int flags);
```

DESCRIPTION

CMS_encrypt() creates and returns a CMS EnvelopedData structure. **certs** is a list of recipient certificates. **in** is the content to be encrypted. **cipher** is the symmetric cipher to use. **flags** is an optional set of flags.

NOTES

Only certificates carrying RSA keys are supported so the recipient certificates supplied to this function must all contain RSA public keys, though they do not have to be signed using the RSA algorithm.

EVP_des_ede3_cbc() (triple DES) is the algorithm of choice for S/MIME use because most clients will support it.

The algorithm passed in the **cipher** parameter must support ASN1 encoding of its parameters.

Many browsers implement a "sign and encrypt" option which is simply an S/MIME envelopedData containing an S/MIME signed message. This can be readily produced by storing the S/MIME signed message in a memory BIO and passing it to CMS_encrypt().

The following flags can be passed in the **flags** parameter.

If the **CMS_TEXT** flag is set MIME headers for type **text/plain** are prepended to the data.

Normally the supplied content is translated into MIME canonical format (as required by the S/MIME specifications) if **CMS_BINARY** is set no translation occurs. This option should be used if the supplied data is in binary format otherwise the translation will corrupt it. If **CMS_BINARY** is set then **CMS_TEXT** is ignored.

OpenSSL will by default identify recipient certificates using issuer name and serial number. If **CMS_USE_KEYID** is set it will use the subject key identifier value instead. An error occurs if all recipient certificates do not have a subject key identifier extension.

If the **CMS_STREAM** flag is set a partial **CMS_ContentInfo** structure is returned suitable for streaming I/O: no data is read from the BIO **in**.

If the **CMS_PARTIAL** flag is set a partial **CMS_ContentInfo** structure is returned to which additional recipients and attributes can be added before finalization.

The data being encrypted is included in the CMS_ContentInfo structure, unless **CMS_DETACHED** is set in which case it is omitted. This is rarely used in practice and is not supported by SMIME_write_CMS().

NOTES

If the flag **CMS_STREAM** is set the returned **CMS_ContentInfo** structure is **not** complete and outputting its contents via a function that does not properly finalize the **CMS_ContentInfo** structure will give unpredictable results.

Several functions including SMIME_write_CMS(), i2d_CMS_bio_stream(), PEM_write_bio_CMS_stream() finalize the structure. Alternatively finalization can be performed by obtaining the streaming ASN1 **BIO** directly using BIO_new_CMS().

The recipients specified in **certs** use a CMS KeyTransRecipientInfo info structure. KEKRecipientInfo is also supported using the flag **CMS_PARTIAL** and CMS_add0_recipient_key().

The parameter **certs** may be NULL if **CMS_PARTIAL** is set and recipients added later using CMS_add1_recipient_cert() or CMS_add0_recipient_key().

RETURN VALUES

CMS_encrypt() returns either a CMS_ContentInfo structure or NULL if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), CMS_decrypt(3)

HISTORY

CMS_decrypt() was added to OpenSSL 0.9.8 The **CMS_STREAM** flag was first supported in OpenSSL 1.0.0.

Name

CMS_final — finalise a CMS_ContentInfo structure

Synopsis

```
#include  <openssl/cms.h>
```

```
int CMS_final(CMS_ContentInfo *cms, BIO *data, BIO *dcont, unsigned int flags);
```

DESCRIPTION

CMS_final() finalises the structure **cms**. It's purpose is to perform any operations necessary on **cms** (digest computation for example) and set the appropriate fields. The parameter **data** contains the content to be processed. The **dcont** parameter contains a BIO to write content to after processing: this is only used with detached data and will usually be set to NULL.

NOTES

This function will normally be called when the **CMS_PARTIAL** flag is used. It should only be used when streaming is not performed because the streaming I/O functions perform finalisation operations internally.

RETURN VALUES

CMS_final() returns 1 for success or 0 for failure.

SEE ALSO

int CMS_RecipientInfo_kekri_id_cmp(CMS_RecipientInfo *ri, const unsigned char *id, size_t idlen);
int CMS_RecipientInfo_set0_key(CMS_RecipientInfo *ri, unsigned char *key, size_t keylen);
```

```
int CMS_RecipientInfo_decrypt(CMS_ContentInfo *cms, CMS_RecipientInfo *ri);
```

DESCRIPTION

The function CMS_get0_RecipientInfos() returns all the CMS_RecipientInfo structures associated with a CMS EnvelopedData structure.

CMS_RecipientInfo_type() returns the type of CMS_RecipientInfo structure **ri**. It will currently return CMS_RECIPINFO_TRANS, CMS_RECIPINFO_AGREE, CMS_RECIPINFO_KEK, CMS_RECIPINFO_PASS, or CMS_RECIPINFO_OTHER.

CMS_RecipientInfo_ktri_get0_signer_id() retrieves the certificate recipient identifier associated with a specific CMS_RecipientInfo structure **ri**, which must be of type CMS_RECIPINFO_TRANS. Either the keyidentifier will be set in **keyid** or **both** issuer name and serial number in **issuer** and **sno**.

CMS_RecipientInfo_ktri_cert_cmp() compares the certificate **cert** against the CMS_RecipientInfo structure **ri**, which must be of type CMS_RECIPINFO_TRANS. It returns zero if the comparison is successful and non zero if not.

CMS_RecipientInfo_set0_pkey() associates the private key **pkey** with the CMS_RecipientInfo structure **ri**, which must be of type CMS_RECIPINFO_TRANS.

CMS_RecipientInfo_kekri_get0_id() retrieves the key information from the CMS_RecipientInfo structure **ri** which must be of type CMS_RECIPINFO_KEK. Any of the remaining parameters can be NULL if the application is not interested in the value of a field. Where a field is optional and absent NULL will be written to the corresponding parameter. The keyEncryptionAlgorithm field is written to **palg**, the **keyIdentifier** field is written to **pid**, the **date** field if present is written to **pdate**, if the **other** field is present the components **keyAttrId** and **keyAttr** are written to parameters **potherid** and **pothertype**.

CMS_RecipientInfo_kekri_id_cmp() compares the ID in the **id** and **idlen** parameters against the **keyIdentifier** CMS_RecipientInfo structure **ri**, which must be of type CMS_RECIPINFO_KEK. It returns zero if the comparison is successful and non zero if not.

CMS_RecipientInfo_set0_key() associates the symmetric key **key** of length **keylen** with the CMS_RecipientInfo structure **ri**, which must be of type CMS_RECIPINFO_KEK.

CMS_RecipientInfo_decrypt() attempts to decrypt CMS_RecipientInfo structure **ri** in structure **cms**. A key must have been associated with the structure first.

NOTES

The main purpose of these functions is to enable an application to lookup recipient keys using any appropriate technique when the simpler method of CMS_decrypt() is not appropriate.

In typical usage and application will retrieve all CMS_RecipientInfo structures using CMS_get0_RecipientInfos() and check the type of each using CMS_RecpientInfo_type(). Depending on the type the CMS_RecipientInfo structure can be ignored or its key identifier data retrieved using an appropriate function. Then if the corresponding secret or private key can be obtained by any appropriate means it can then associated with the structure and CMS_RecpientInfo_decrypt() called. If successful CMS_decrypt() can be called with a NULL key to decrypt the enveloped content.

RETURN VALUES

CMS_get0_RecipientInfos() returns all CMS_RecipientInfo structures, or NULL if an error occurs.

CMS_RecipientInfo_ktri_get0_signer_id(), CMS_RecipientInfo_set0_pkey(), CMS_RecipientInfo_kekri_get0_id(), CMS_RecipientInfo_set0_key() and CMS_RecipientInfo_decrypt() return 1 for success or 0 if an error occurs.

CMS_RecipientInfo_ktri_cert_cmp() and CMS_RecipientInfo_kekri_cmp() return 0 for a successful comparison and non zero otherwise.

Any error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), CMS_decrypt(3)

HISTORY

These functions were first was added to OpenSSL 0.9.8

Name

CMS_get0_SignerInfos, CMS_SignerInfo_get0_signer_id, CMS_SignerInfo_cert_cmp and CMS_set1_signer_certs — CMS signedData signer functions.

Synopsis

```
#include  <openssl/cms.h>
```

```
STACK_OF(CMS_SignerInfo) *CMS_get0_SignerInfos(CMS_ContentInfo *cms);
```

```
int CMS_SignerInfo_get0_signer_id(CMS_SignerInfo *si, ASN1_OCTET_STRING **keyid, X509_NAME **issuer,
    ASN1_INTEGER **sno);
int CMS_SignerInfo_cert_cmp(CMS_SignerInfo *si, X509 *cert);
void CMS_SignerInfo_set1_signer_cert(CMS_SignerInfo *si, X509 *signer);
```

DESCRIPTION

The function CMS_get0_SignerInfos() returns all the CMS_SignerInfo structures associated with a CMS signedData structure.

CMS_SignerInfo_get0_signer_id() retrieves the certificate signer identifier associated with a specific CMS_SignerInfo structure **si**. Either the keyidentifier will be set in **keyid** or **both** issuer name and serial number in **issuer** and **sno**.

CMS_SignerInfo_cert_cmp() compares the certificate **cert** against the signer identifier **si**. It returns zero if the comparison is successful and non zero if not.

CMS_SignerInfo_set1_signer_cert() sets the signers certificate of **si** to **signer**.

NOTES

The main purpose of these functions is to enable an application to lookup signers certificates using any appropriate technique when the simpler method of CMS_verify() is not appropriate.

In typical usage and application will retrieve all CMS_SignerInfo structures using CMS_get0_SignerInfo() and retrieve the identifier information using CMS. It will then obtain the signer certificate by some unspecified means (or return and error if it cannot be found) and set it using CMS_SignerInfo_set1_signer_cert().

Once all signer certificates have been set CMS_verify() can be used.

Although CMS_get0_SignerInfos() can return NULL is an error occur **or** if there are no signers this is not a problem in practice because the only error which can occur is if the **cms** structure is not of type signedData due to application error.

RETURN VALUES

CMS_get0_SignerInfos() returns all CMS_SignerInfo structures, or NULL there are no signers or an error occurs.

CMS_SignerInfo_get0_signer_id() returns 1 for success and 0 for failure.

CMS_SignerInfo_cert_cmp() returns 0 for a successful comparison and non zero otherwise.

CMS_SignerInfo_set1_signer_cert() does not return a value.

Any error can be obtained from ERR_get_error(3)

SEE ALSO

ERR_get_error(3), CMS_verify(3)

HISTORY

These functions were first was added to OpenSSL 0.9.8

Name

CMS_get0_type, CMS_set1_eContentType, CMS_get0_eContentType and CMS_get0_content — get and set CMS content types and content

Synopsis

```
#include  <openssl/cms.h>
```

```
const ASN1_OBJECT *CMS_get0_type(CMS_ContentInfo *cms);
int CMS_set1_eContentType(CMS_ContentInfo *cms, const ASN1_OBJECT *oid);
const ASN1_OBJECT *CMS_get0_eContentType(CMS_ContentInfo *cms);
ASN1_OCTET_STRING **CMS_get0_content(CMS_ContentInfo *cms);
```

DESCRIPTION

CMS_get0_type() returns the content type of a CMS_ContentInfo structure as and ASN1_OBJECT pointer. An application can then decide how to process the CMS_ContentInfo structure based on this value.

CMS_set1_eContentType() sets the embedded content type of a CMS_ContentInfo structure. It should be called with CMS functions with the **CMS_PARTIAL** flag and **before** the structure is finalised, otherwise the results are undefined.

ASN1_OBJECT *CMS_get0_eContentType() returns a pointer to the embedded content type.

CMS_get0_content() returns a pointer to the **ASN1_OCTET_STRING** pointer containing the embedded content.

NOTES

As the **0** implies CMS_get0_type(), CMS_get0_eContentType() and CMS_get0_content() return internal pointers which should **not** be freed up. CMS_set1_eContentType() copies the supplied OID and it **should** be freed up after use.

The **ASN1_OBJECT** values returned can be converted to an integer **NID** value using OBJ_obj2nid(). For the currently supported content types the following values are returned:

```
NID_pkcs7_data
NID_pkcs7_signed
NID_pkcs7_digest
NID_id_smime_ct_compressedData:
NID_pkcs7_encrypted
NID_pkcs7_enveloped
```

The return value of CMS_get0_content() is a pointer to the **ASN1_OCTET_STRING** content pointer. That means that for example:

```
ASN1_OCTET_STRING **pconf = CMS_get0_content(cms);
```

***pconf** could be NULL if there is no embedded content. Applications can access, modify or create the embedded content in a **CMS_ContentInfo** structure using this function. Applications usually will not need to modify the embedded content as it is normally set by higher level functions.

RETURN VALUES

CMS_get0_type() and CMS_get0_eContentType() return and ASN1_OBJECT structure.

CMS_set1_eContentType() returns 1 for success or 0 if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3)

HISTORY

CMS_get0_type(), CMS_set1_eContentType() and CMS_get0_eContentType() were all first added to OpenSSL 0.9.8

Name

CMS_ReceiptRequest_create0, CMS_add1_ReceiptRequest, CMS_get1_ReceiptRequest and CMS_ReceiptRequest_get0_values — CMS signed receipt request functions.

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_ReceiptRequest *CMS_ReceiptRequest_create0(unsigned char *id, int idlen, int allorfirst,
    STACK_OF(GENERAL_NAMES) *receiptList, STACK_OF(GENERAL_NAMES) *receiptsTo);
int CMS_add1_ReceiptRequest(CMS_SignerInfo *si, CMS_ReceiptRequest *rr);
int CMS_get1_ReceiptRequest(CMS_SignerInfo *si, CMS_ReceiptRequest **prr);
void CMS_ReceiptRequest_get0_values(CMS_ReceiptRequest *rr, ASN1_STRING **pcid, int *pallorfirst,
    STACK_OF(GENERAL_NAMES) **plist, STACK_OF(GENERAL_NAMES) **prto);
```

DESCRIPTION

CMS_ReceiptRequest_create0() creates a signed receipt request structure. The **signedContentIdentifier** field is set using **id** and **idlen**, or it is set to 32 bytes of pseudo random data if **id** is NULL. If **receiptList** is NULL the allOrFirstTier option in **receiptsFrom** is used and set to the value of the **allorfirst** parameter. If **receiptList** is not NULL the **receiptList** option in **receiptsFrom** is used. The **receiptsTo** parameter specifies the **receiptsTo** field value.

The CMS_add1_ReceiptRequest() function adds a signed receipt request **rr** to SignerInfo structure **si**.

int CMS_get1_ReceiptRequest() looks for a signed receipt request in **si**, if any is found it is decoded and written to **prr**.

CMS_ReceiptRequest_get0_values() retrieves the values of a receipt request. The signedContentIdentifier is copied to **pcid**. If the **allOrFirstTier** option of **receiptsFrom** is used its value is copied to **pallorfirst** otherwise the **receiptList** field is copied to **plist**. The **receiptsTo** parameter is copied to **prto**.

NOTES

For more details of the meaning of the fields see RFC2634.

The contents of a signed receipt should only be considered meaningful if the corresponding CMS_ContentInfo structure can be successfully verified using CMS_verify().

RETURN VALUES

CMS_ReceiptRequest_create0() returns a signed receipt request structure or NULL if an error occurred.

CMS_add1_ReceiptRequest() returns 1 for success or 0 is an error occurred.

CMS_get1_ReceiptRequest() returns 1 is a signed receipt request is found and decoded. It returns 0 if a signed receipt request is not present and -1 if it is present but malformed.

HISTORY

CMS_ReceiptRequest_create0(), CMS_add1_ReceiptRequest(), CMS_get1_ReceiptRequest() and CMS_ReceiptRequest_get0_values() were added to OpenSSL 0.9.8

Name

CMS_add1_signer and CMS_SignerInfo_sign — add a signer to a CMS_ContentInfo signed data structure.

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_SignerInfo *CMS_add1_signer(CMS_ContentInfo *cms, X509 *signcert, EVP_PKEY *pkey, const EVP_MD *md,
    unsigned int flags);
```

```
int CMS_SignerInfo_sign(CMS_SignerInfo *si);
```

DESCRIPTION

CMS_add1_signer() adds a signer with certificate **signcert** and private key **pkey** using message digest **md** to CMS_ContentInfo SignedData structure **cms**.

The CMS_ContentInfo structure should be obtained from an initial call to CMS_sign() with the flag **CMS_PARTIAL** set or in the case or re-signing a valid CMS_ContentInfo SignedData structure.

If the **md** parameter is **NULL** then the default digest for the public key algorithm will be used.

Unless the **CMS_REUSE_DIGEST** flag is set the returned CMS_ContentInfo structure is not complete and must be finalized either by streaming (if applicable) or a call to CMS_final().

The CMS_SignerInfo_sign() function will explicitly sign a CMS_SignerInfo structure, its main use is when **CMS_REUSE_DIGEST** and **CMS_PARTIAL** flags are both set.

NOTES

The main purpose of CMS_add1_signer() is to provide finer control over a CMS signed data structure where the simpler CMS_sign() function defaults are not appropriate. For example if multiple signers or non default digest algorithms are needed. New attributes can also be added using the returned CMS_SignerInfo structure and the CMS attribute utility functions or the CMS signed receipt request functions.

Any of the following flags (ored together) can be passed in the **flags** parameter.

If **CMS_REUSE_DIGEST** is set then an attempt is made to copy the content digest value from the CMS_ContentInfo structure: to add a signer to an existing structure. An error occurs if a matching digest value cannot be found to copy. The returned CMS_ContentInfo structure will be valid and finalized when this flag is set.

If **CMS_PARTIAL** is set in addition to **CMS_REUSE_DIGEST** then the CMS_SignerInfo structure will not be finalized so additional attributes can be added. In this case an explicit call to CMS_SignerInfo_sign() is needed to finalize it.

If **CMS_NOCERTS** is set the signer's certificate will not be included in the CMS_ContentInfo structure, the signer's certificate must still be supplied in the **signcert** parameter though. This can reduce the size of the signature if the signers certificate can be obtained by other means: for example a previously signed message.

The SignedData structure includes several CMS signedAttributes including the signing time, the CMS content type and the supported list of ciphers in an SMIMECapabilities attribute. If **CMS_NOATTR** is set then no signedAttributes will be used. If **CMS_NOSMIMECAP** is set then just the SMIMECapabilities are omitted.

OpenSSL will by default identify signing certificates using issuer name and serial number. If **CMS_USE_KEYID** is set it will use the subject key identifier value instead. An error occurs if the signing certificate does not have a subject key identifier extension.

If present the SMIMECapabilities attribute indicates support for the following algorithms in preference order: 256 bit AES, Gost R3411-94, Gost 28147-89, 192 bit AES, 128 bit AES, triple DES, 128 bit RC2, 64 bit RC2, DES and 40 bit RC2. If any of these algorithms is not available then it will not be included: for example the GOST algorithms will not be included if the GOST ENGINE is not loaded.

CMS_add1_signer() returns an internal pointer to the CMS_SignerInfo structure just added, this can be used to set additional attributes before it is finalized.

RETURN VALUES

CMS_add1_signer() returns an internal pointer to the CMS_SignerInfo structure just added or NULL if an error occurs.

SEE ALSO

ERR_get_error(3), CMS_sign(3), CMS_final(3)

HISTORY

CMS_add1_signer() was added to OpenSSL 0.9.8

Name

CMS_sign — create a CMS SignedData structure

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_ContentInfo *CMS_sign(X509 *signcert, EVP_PKEY *pkey, STACK_OF(X509) *certs, BIO *data,
    unsigned int flags);
```

DESCRIPTION

CMS_sign() creates and returns a CMS SignedData structure. **signcert** is the certificate to sign with, **pkey** is the corresponding private key. **certs** is an optional additional set of certificates to include in the CMS structure (for example any intermediate CAs in the chain). Any or all of these parameters can be **NULL**, see **NOTES** below.

The data to be signed is read from BIO **data**.

flags is an optional set of flags.

NOTES

Any of the following flags (ored together) can be passed in the **flags** parameter.

Many S/MIME clients expect the signed content to include valid MIME headers. If the **CMS_TEXT** flag is set MIME headers for type **text/plain** are prepended to the data.

If **CMS_NOCERTS** is set the signer's certificate will not be included in the CMS_ContentInfo structure, the signer's certificate must still be supplied in the **signcert** parameter though. This can reduce the size of the signature if the signers certificate can be obtained by other means: for example a previously signed message.

The data being signed is included in the CMS_ContentInfo structure, unless **CMS_DETACHED** is set in which case it is omitted. This is used for CMS_ContentInfo detached signatures which are used in S/MIME plaintext signed messages for example.

Normally the supplied content is translated into MIME canonical format (as required by the S/MIME specifications) if **CMS_BINARY** is set no translation occurs. This option should be used if the supplied data is in binary format otherwise the translation will corrupt it.

The SignedData structure includes several CMS signedAttributes including the signing time, the CMS content type and the supported list of ciphers in an SMIMECapabilities attribute. If **CMS_NOATTR** is set then no signedAttributes will be used. If **CMS_NOSMIMECAP** is set then just the SMIMECapabilities are omitted.

If present the SMIMECapabilities attribute indicates support for the following algorithms in preference order: 256 bit AES, Gost R3411-94, Gost 28147-89, 192 bit AES, 128 bit AES, triple DES, 128 bit RC2, 64 bit RC2, DES and 40 bit RC2. If any of these algorithms is not available then it will not be included: for example the GOST algorithms will not be included if the GOST ENGINE is not loaded.

OpenSSL will by default identify signing certificates using issuer name and serial number. If **CMS_USE_KEYID** is set it will use the subject key identifier value instead. An error occurs if the signing certificate does not have a subject key identifier extension.

If the flags **CMS_STREAM** is set then the returned **CMS_ContentInfo** structure is just initialized ready to perform the signing operation. The signing is however **not** performed and the data to be signed is not read from the **data** parameter. Signing is deferred until after the data has been written. In this way data can be signed in a single pass.

If the **CMS_PARTIAL** flag is set a partial **CMS_ContentInfo** structure is output to which additional signers and capabilities can be added before finalization.

If the flag **CMS_STREAM** is set the returned **CMS_ContentInfo** structure is **not** complete and outputting its contents via a function that does not properly finalize the **CMS_ContentInfo** structure will give unpredictable results.

Several functions including SMIME_write_CMS(), i2d_CMS_bio_stream(), PEM_write_bio_CMS_stream() finalize the structure. Alternatively finalization can be performed by obtaining the streaming ASN1 **BIO** directly using BIO_new_CMS().

If a signer is specified it will use the default digest for the signing algorithm. This is **SHA1** for both RSA and DSA keys.

If **signcert** and **pkey** are NULL then a certificates only CMS structure is output.

The function CMS_sign() is a basic CMS signing function whose output will be suitable for many purposes. For finer control of the output format the **certs**, **signcert** and **pkey** parameters can all be **NULL** and the **CMS_PARTIAL** flag set. Then one or more signers can be added using the function CMS_sign_add1_signer(), non default digests can be used and custom attributes added. **CMS_final()** must then be called to finalize the structure if streaming is not enabled.

BUGS

Some attributes such as counter signatures are not supported.

RETURN VALUES

CMS_sign() returns either a valid CMS_ContentInfo structure or NULL if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), CMS_verify(3)

HISTORY

CMS_sign() was added to OpenSSL 0.9.8

The **CMS_STREAM** flag is only supported for detached data in OpenSSL 0.9.8, it is supported for embedded data in OpenSSL 1.0.0 and later.

Name

CMS_sign_receipt — create a CMS signed receipt

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_ContentInfo *CMS_sign_receipt(CMS_SignerInfo *si, X509 *signcert, EVP_PKEY *pkey,
    STACK_OF(X509) *certs, unsigned int flags);
```

DESCRIPTION

CMS_sign_receipt() creates and returns a CMS signed receipt structure. **si** is the **CMS_SignerInfo** structure containing the signed receipt request. **signcert** is the certificate to sign with, **pkey** is the corresponding private key. **certs** is an optional additional set of certificates to include in the CMS structure (for example any intermediate CAs in the chain).

flags is an optional set of flags.

NOTES

This functions behaves in a similar way to CMS_sign() except the flag values **CMS_DETACHED**, **CMS_BINARY**, **CMS_NOATTR**, **CMS_TEXT** and **CMS_STREAM** are not supported since they do not make sense in the context of signed receipts.

RETURN VALUES

CMS_sign_receipt() returns either a valid CMS_ContentInfo structure or NULL if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), CMS_verify_receipt(3), CMS_sign(3)

HISTORY

CMS_sign_receipt() was added to OpenSSL 0.9.8

Name

CMS_uncompress — uncompress a CMS CompressedData structure

Synopsis

```
#include  <openssl/cms.h>
```

```
int CMS_uncompress(CMS_ContentInfo *cms, BIO *dcont, BIO *out, unsigned int flags);
```

DESCRIPTION

CMS_uncompress() extracts and uncompresses the content from a CMS CompressedData structure **cms**. **data** is a BIO to write the content to and **flags** is an optional set of flags.

The **dcont** parameter is used in the rare case where the compressed content is detached. It will normally be set to NULL.

NOTES

The only currently supported compression algorithm is zlib: if the structure indicates the use of any other algorithm an error is returned.

If zlib support is not compiled into OpenSSL then CMS_uncompress() will always return an error.

The following flags can be passed in the **flags** parameter.

If the **CMS_TEXT** flag is set MIME headers for type **text/plain** are deleted from the content. If the content is not of type **text/plain** then an error is returned.

RETURN VALUES

CMS_uncompress() returns either 1 for success or 0 for failure. The error can be obtained from ERR_get_error(3)

BUGS

The lack of single pass processing and the need to hold all data in memory as mentioned in CMS_verify() also applies to CMS_decompress().

SEE ALSO

ERR_get_error(3), CMS_compress(3)

HISTORY

CMS_uncompress() was added to OpenSSL 0.9.8

Name

CMS_verify — verify a CMS SignedData structure

Synopsis

```
#include  <openssl/cms.h>
```

```
int CMS_verify(CMS_ContentInfo *cms, STACK_OF(X509) *certs, X509_STORE *store, BIO *indata,
    BIO *out, unsigned int flags);
```

```
STACK_OF(X509) *CMS_get0_signers(CMS_ContentInfo *cms);
```

DESCRIPTION

CMS_verify() verifies a CMS SignedData structure. **cms** is the CMS_ContentInfo structure to verify. **certs** is a set of certificates in which to search for the signing certificate(s). **store** is a trusted certificate store used for chain verification. **indata** is the detached content if the content is not present in **cms**. The content is written to **out** if it is not NULL.

flags is an optional set of flags, which can be used to modify the verify operation.

CMS_get0_signers() retrieves the signing certificate(s) from **cms**, it must be called after a successful CMS_verify() operation.

VERIFY PROCESS

Normally the verify process proceeds as follows.

Initially some sanity checks are performed on **cms**. The type of **cms** must be SignedData. There must be at least one signature on the data and if the content is detached **indata** cannot be **NULL**.

An attempt is made to locate all the signing certificate(s), first looking in the **certs** parameter (if it is not NULL) and then looking in any certificates contained in the **cms** structure itself. If any signing certificate cannot be located the operation fails.

Each signing certificate is chain verified using the **smimesign** purpose and the supplied trusted certificate store. Any internal certificates in the message are used as untrusted CAs. If CRL checking is enabled in **store** any internal CRLs are used in addition to attempting to look them up in **store**. If any chain verify fails an error code is returned.

Finally the signed content is read (and written to **out** is it is not NULL) and the signature's checked.

If all signature's verify correctly then the function is successful.

Any of the following flags (ored together) can be passed in the **flags** parameter to change the default verify behaviour.

If **CMS_NOINTERN** is set the certificates in the message itself are not searched when locating the signing certificate(s). This means that all the signing certificates must be in the **certs** parameter.

If **CMS_NOCRL** is set and CRL checking is enabled in **store** then any CRLs in the message itself are ignored.

If the **CMS_TEXT** flag is set MIME headers for type **text/plain** are deleted from the content. If the content is not of type **text/plain** then an error is returned.

If **CMS_NO_SIGNER_CERT_VERIFY** is set the signing certificates are not verified.

If **CMS_NO_ATTR_VERIFY** is set the signed attributes signature is not verified.

If **CMS_NO_CONTENT_VERIFY** is set then the content digest is not checked.

NOTES

One application of **CMS_NOINTERN** is to only accept messages signed by a small number of certificates. The acceptable certificates would be passed in the **certs** parameter. In this case if the signer is not one of the certificates supplied in **certs** then the verify will fail because the signer cannot be found.

In some cases the standard techniques for looking up and validating certificates are not appropriate: for example an application may wish to lookup certificates in a database or perform customised verification. This can be achieved by setting and verifying the signers certificates manually using the signed data utility functions.

Care should be taken when modifying the default verify behaviour, for example setting **CMS_NO_CONTENT_VERIFY** will totally disable all content verification and any modified content will be considered valid. This combination is however useful if one merely wishes to write the content to **out** and its validity is not considered important.

Chain verification should arguably be performed using the signing time rather than the current time. However since the signing time is supplied by the signer it cannot be trusted without additional evidence (such as a trusted timestamp).

RETURN VALUES

CMS_verify() returns 1 for a successful verification and zero if an error occurred.

CMS_get0_signers() returns all signers or NULL if an error occurred.

The error can be obtained from ERR_get_error(3)

BUGS

The trusted certificate store is not searched for the signing certificate, this is primarily due to the inadequacies of the current **X509_STORE** functionality.

The lack of single pass processing means that the signed content must all be held in memory if it is not detached.

ERR_get_error(3), CMS_sign(3)

HISTORY

CMS_verify() was added to OpenSSL 0.9.8

Name

CMS_verify_receipt — verify a CMS signed receipt

Synopsis

```
#include  <openssl/cms.h>
```

```
int CMS_verify_receipt(CMS_ContentInfo *rcms, CMS_ContentInfo *ocms, STACK_OF(X509) *certs,
    X509_STORE *store, unsigned int flags);
```

DESCRIPTION

CMS_verify_receipt() verifies a CMS signed receipt. **rcms** is the signed receipt to verify. **ocms** is the original SignedData structure containing the receipt request. **certs** is a set of certificates in which to search for the signing certificate. **store** is a trusted certificate store (used for chain verification).

flags is an optional set of flags, which can be used to modify the verify operation.

NOTES

This functions behaves in a similar way to CMS_verify() except the flag values **CMS_DETACHED**, **CMS_BINARY**, **CMS_TEXT** and **CMS_STREAM** are not supported since they do not make sense in the context of signed receipts.

RETURN VALUES

CMS_verify_receipt() returns 1 for a successful verification and zero if an error occurred.

The error can be obtained from ERR_get_error(3)

SEE ALSO

HISTORY

CMS_verify_receipt() was added to OpenSSL 0.9.8

Name

CONF_modules_free, CONF_modules_finish and CONF_modules_unload — OpenSSL configuration cleanup functions

Synopsis

```
#include  <openssl/conf.h>
```

```
void CONF_modules_free(void);
void CONF_modules_finish(void);
void CONF_modules_unload(int all);
```

DESCRIPTION

CONF_modules_free() closes down and frees up all memory allocated by all configuration modules.

CONF_modules_finish() calls each configuration modules **finish** handler to free up any configuration that module may have performed.

CONF_modules_unload() finishes and unloads configuration modules. If **all** is set to **0** only modules loaded from DSOs will be unloads. If **all** is **1** all modules, including builtin modules will be unloaded.

NOTES

Normally applications will only call CONF_modules_free() at application to tidy up any configuration performed.

RETURN VALUE

None of the functions return a value.

SEE ALSO

conf(5), OPENSSL_config(3), CONF_modules_load_file(3)

HISTORY

CONF_modules_free(), CONF_modules_unload(), and CONF_modules_finish() first appeared in OpenSSL 0.9.7.

Name

CONF_modules_load_file and CONF_modules_load — OpenSSL configuration functions

Synopsis

```
#include  <openssl/conf.h>
```

```
int CONF_modules_load_file(const char *filename, const char *appname,
                                       unsigned long flags);
int CONF_modules_load(const CONF *cnf, const char *appname,
                              unsigned long flags);
```

DESCRIPTION

The function CONF_modules_load_file() configures OpenSSL using file **filename** and application name **appname**. If **filename** is NULL the standard OpenSSL configuration file is used. If **appname** is NULL the standard OpenSSL application name **openssl_conf** is used. The behaviour can be cutomized using **flags**.

CONF_modules_load() is idential to CONF_modules_load_file() except it reads configuration information from **cnf**.

NOTES

The following **flags** are currently recognized:

CONF_MFLAGS_IGNORE_ERRORS if set errors returned by individual configuration modules are ignored. If not set the first module error is considered fatal and no further modules are loaded.

Normally any modules errors will add error information to the error queue. If **CONF_MFLAGS_SILENT** is set no error information is added.

If **CONF_MFLAGS_NO_DSO** is set configuration module loading from DSOs is disabled.

CONF_MFLAGS_IGNORE_MISSING_FILE if set will make CONF_load_modules_file() ignore missing configuration files. Normally a missing configuration file return an error.

CONF_MFLAGS_DEFAULT_SECTION if set and **appname** is not NULL will use the default section pointed to by **openssl_conf** if **appname** does not exist.

Applications should call these functions after loading builtin modules using OPENSSL_load_builtin_modules(), any ENGINEs for example using ENGINE_load_builtin_engines(), any algorithms for example OPENSSL_add_all_algorithms() and (if the application uses libssl) SSL_library_init().

By using CONF_modules_load_file() with appropriate flags an application can customise application configuration to best suit its needs. In some cases the use of a configuration file is optional and its absence is not an error: in this case **CONF_MFLAGS_IGNORE_MISSING_FILE** would be set.

Errors during configuration may also be handled differently by different applications. For example in some cases an error may simply print out a warning message and the application continue. In other cases an application might consider a configuration file error as fatal and exit immediately.

Applications can use the CONF_modules_load() function if they wish to load a configuration file themselves and have finer control over how errors are treated.

EXAMPLES

Load a configuration file and print out any errors and exit (missing file considered fatal):

```
if (CONF_modules_load_file(NULL, NULL, 0) <= 0) {
   fprintf(stderr, "FATAL: error loading configuration file\n");
   ERR_print_errors_fp(stderr);
   exit(1);
}
```

Load default configuration file using the section indicated by "myapp", tolerate missing files, but exit on other errors:

```
if (CONF_modules_load_file(NULL, "myapp",
                           CONF_MFLAGS_IGNORE_MISSING_FILE) <= 0) {
   fprintf(stderr, "FATAL: error loading configuration file\n");
   ERR_print_errors_fp(stderr);
   exit(1);
}
```

Load custom configuration file and section, only print warnings on error, missing configuration file ignored:

```
if (CONF_modules_load_file("/something/app.cnf", "myapp",
                           CONF_MFLAGS_IGNORE_MISSING_FILE) <= 0) {
   fprintf(stderr, "WARNING: error loading configuration file\n");
   ERR_print_errors_fp(stderr);
}
```

Load and parse configuration file manually, custom error handling:

```
FILE *fp;
CONF *cnf = NULL;
long eline;
fp = fopen("/somepath/app.cnf", "r");
if (fp == NULL) {
   fprintf(stderr, "Error opening configuration file\n");
   /* Other missing configuration file behaviour */
} else {
   cnf = NCONF_new(NULL);
   if (NCONF_load_fp(cnf, fp, &eline) == 0) {
       fprintf(stderr, "Error on line %ld of configuration file\n", eline);
       ERR_print_errors_fp(stderr);
       /* Other malformed configuration file behaviour */
   } else if (CONF_modules_load(cnf, "appname", 0) <= 0) {
     fprintf(stderr, "Error configuring application\n");
     ERR_print_errors_fp(stderr);
     /* Other configuration error behaviour */
   }
   fclose(fp);
   NCONF_free(cnf);
 }
```

RETURN VALUES

These functions return 1 for success and a zero or negative value for failure. If module errors are not ignored the return code will reflect the return value of the failing module (this will always be zero or negative).

SEE ALSO

conf(5), OPENSSL_config(3), CONF_free(3), err(3)

HISTORY

CONF_modules_load_file and CONF_modules_load first appeared in OpenSSL 0.9.7.

Name

CRYPTO_set_ex_data and CRYPTO_get_ex_data — internal application specific data functions

Synopsis

```
#include  <openssl/crypto.h>
```

```
int CRYPTO_set_ex_data(CRYPTO_EX_DATA *r, int idx, void *arg);
```

```
void *CRYPTO_get_ex_data(CRYPTO_EX_DATA *r, int idx);
```

DESCRIPTION

Several OpenSSL structures can have application specific data attached to them. These functions are used internally by OpenSSL to manipulate application specific data attached to a specific structure.

These functions should only be used by applications to manipulate **CRYPTO_EX_DATA** structures passed to the **new_func()**, **free_func()** and **dup_func()** callbacks: as passed to **RSA_get_ex_new_index()** for example.

CRYPTO_set_ex_data() is used to set application specific data, the data is supplied in the **arg** parameter and its precise meaning is up to the application.

CRYPTO_get_ex_data() is used to retrieve application specific data. The data is returned to the application, this will be the same value as supplied to a previous **CRYPTO_set_ex_data()** call.

RETURN VALUES

CRYPTO_set_ex_data() returns 1 on success or 0 on failure.

CRYPTO_get_ex_data() returns the application data or 0 on failure. 0 may also be valid application data but currently it can only fail if given an invalid **idx** parameter.

On failure an error code can be obtained from ERR_get_error(3).

SEE ALSO

RSA_get_ex_new_index(3), DSA_get_ex_new_index(3), DH_get_ex_new_index(3)

HISTORY

CRYPTO_set_ex_data() and CRYPTO_get_ex_data() have been available since SSLeay 0.9.0.

Name

d2i_ASN1_OBJECT and i2d_ASN1_OBJECT — ASN1 OBJECT IDENTIFIER functions

Synopsis

```
#include  <openssl/objects.h>
```

```
ASN1_OBJECT *d2i_ASN1_OBJECT(ASN1_OBJECT **a, unsigned char **pp, long length);
int i2d_ASN1_OBJECT(ASN1_OBJECT *a, unsigned char **pp);
```

DESCRIPTION

These functions decode and encode an ASN1 OBJECT IDENTIFIER.

Othewise these behave in a similar way to d2i_X509() and i2d_X509() described in the d2i_X509(3) manual page.

Synopsis

```
#include  <openssl/dsa.h>
#include  <openssl/x509.h>
```

```
DSA * d2i_DSAPublicKey(DSA **a, const unsigned char **pp, long length);
```

```
int i2d_DSAPublicKey(const DSA *a, unsigned char **pp);
```

```
DSA * d2i_DSA_PUBKEY(DSA **a, const unsigned char **pp, long length);
```

```
int i2d_DSA_PUBKEY(const DSA *a, unsigned char **pp);
```

```
DSA * d2i_DSAPrivateKey(DSA **a, const unsigned char **pp, long length);
```

```
int i2d_DSAPrivateKey(const DSA *a, unsigned char **pp);
```

```
DSA * d2i_DSAparams(DSA **a, const unsigned char **pp, long length);
```

```
int i2d_DSAparams(const DSA *a, unsigned char **pp);
```

```
DSA * d2i_DSA_SIG(DSA_SIG **a, const unsigned char **pp, long length);
```

```
int i2d_DSA_SIG(const DSA_SIG *a, unsigned char **pp);
```

DESCRIPTION

d2i_DSAPublicKey() and i2d_DSAPublicKey() decode and encode the DSA public key components structure.

d2i_DSA_PUBKEY() and i2d_DSA_PUBKEY() decode and encode an DSA public key using a SubjectPublicKeyInfo (certificate public key) structure.

d2i_DSAPrivateKey(), i2d_DSAPrivateKey() decode and encode the DSA private key components.

d2i_DSAparams(), i2d_DSAparams() decode and encode the DSA parameters using a **Dss-Parms** structure as defined in RFC2459.

d2i_DSA_SIG(), i2d_DSA_SIG() decode and encode a DSA signature using a **Dss-Sig-Value** structure as defined in RFC2459.

The usage of all of these functions is similar to the d2i_X509() and i2d_X509() described in the d2i_X509(3) manual page.

NOTES

The **DSA** structure passed to the private key encoding functions should have all the private key components present.

The data encoded by the private key functions is unencrypted and therefore offers no private key security.

The **DSA_PUBKEY** functions should be used in preference to the **DSAPublicKey** functions when encoding public keys because they use a standard format.

The **DSAPublicKey** functions use an non standard format the actual data encoded depends on the value of the **write_params** field of the **a** key parameter. If **write_params** is zero then only the **pub_key** field is encoded as an **INTEGER**. If **write_params** is 1 then a **SEQUENCE** consisting of the **p**, **q**, **g** and **pub_key** respectively fields are encoded.

The **DSAPrivateKey** functions also use a non standard structure consiting consisting of a SEQUENCE containing the **p**, **q**, **g** and **pub_key** and **priv_key** fields respectively.

HISTORY

TBA

Name

i2d_ECPrivateKey and d2i_ECPrivate_key — Encode and decode functions for saving and reading EC_KEY structures

Synopsis

```
#include  <openssl/ec.h>
```

```
EC_KEY *d2i_ECPrivateKey(EC_KEY **key, const unsigned char **in, long len);
int i2d_ECPrivateKey(EC_KEY *key, unsigned char **out);
```

```
unsigned int EC_KEY_get_enc_flags(const EC_KEY *key);
void EC_KEY_set_enc_flags(EC_KEY *eckey, unsigned int flags);
```

DESCRIPTION

The ECPrivateKey encode and decode routines encode and parse an **EC_KEY** structure into a binary format (ASN.1 DER) and back again.

These functions are similar to the d2i_X509() functions, and you should refer to that page for a detailed description (see d2i_X509(3)).

The format of the external representation of the public key written by i2d_ECPrivateKey (such as whether it is stored in a compressed form or not) is described by the point_conversion_form. See EC_GROUP_copy(3) for a description of point_conversion_form.

When reading a private key encoded without an associated public key (e.g. if EC_PKEY_NO_PUBKEY has been used - see below), then d2i_ECPrivateKey generates the missing public key automatically. Private keys encoded without parameters (e.g. if EC_PKEY_NO_PARAMETERS has been used - see below) cannot be loaded using d2i_ECPrivateKey.

The functions EC_KEY_get_enc_flags and EC_KEY_set_enc_flags get and set the value of the encoding flags for the **key**. There are two encoding flags currently defined - EC_PKEY_NO_PARAMETERS and EC_PKEY_NO_PUBKEY. These flags define the behaviour of how the **key** is converted into ASN1 in a call to i2d_ECPrivateKey. If EC_PKEY_NO_PARAMETERS is set then the public parameters for the curve are not encoded along with the private key. If EC_PKEY_NO_PUBKEY is set then the public key is not encoded along with the private key.

RETURN VALUES

d2i_ECPrivateKey() returns a valid **EC_KEY** structure or **NULL** if an error occurs. The error code that can be obtained by ERR_get_error(3).

i2d_ECPrivateKey() returns the number of bytes successfully encoded or a negative value if an error occurs. The error code can be obtained by ERR_get_error(3).

EC_KEY_get_enc_flags returns the value of the current encoding flags for the EC_KEY.

                                 char *kstr, int klen,
                                 pem_password_cb *cb, void *u);
```

```
int i2d_PKCS8PrivateKey_nid_fp(FILE *fp, EVP_PKEY *x, int nid,
                                 char *kstr, int klen,
                                 pem_password_cb *cb, void *u);
```

DESCRIPTION

The PKCS#8 functions encode and decode private keys in PKCS#8 format using both PKCS#5 v1.5 and PKCS#5 v2.0 password based encryption algorithms.

Other than the use of DER as opposed to PEM these functions are identical to the corresponding **PEM** function as described in the pem(3) manual page.

NOTES

Before using these functions OpenSSL_add_all_algorithms(3) should be called to initialize the internal algorithm lookup tables otherwise errors about unknown algorithms will occur if an attempt is made to decrypt a private key.

These functions are currently the only way to store encrypted private keys using DER format.

Currently all the functions use BIOs or FILE pointers, there are no functions which work directly on memory: this can be readily worked around by converting the buffers to memory BIOs, see BIO_s_mem(3) for details.

SEE ALSO

pem(3)

Name

d2i_Private_key, d2i_AutoPrivateKey and i2d_PrivateKey — decode and encode functions for reading and saving EVP_PKEY structures.

Synopsis

```
#include  <openssl/evp.h>
```

```
EVP_PKEY *d2i_PrivateKey(int type, EVP_PKEY **a, const unsigned char **pp,
                         long length);
EVP_PKEY *d2i_AutoPrivateKey(EVP_PKEY **a, const unsigned char **pp,
                             long length);
int i2d_PrivateKey(EVP_PKEY *a, unsigned char **pp);
```

DESCRIPTION

d2i_PrivateKey() decodes a private key using algorithm **type**. It attempts to use any key specific format or PKCS#8 unencrypted PrivateKeyInfo format. The **type** parameter should be a public key algorithm constant such as **EVP_PKEY_RSA**. An error occurs if the decoded key does not match **type**.

d2i_AutoPrivateKey() is similar to d2i_PrivateKey() except it attempts to automatically detect the private key format.

i2d_PrivateKey() encodes **key**. It uses a key specific format or, if none is defined for that key type, PKCS#8 unencrypted PrivateKeyInfo format.

These functions are similar to the d2i_X509() functions, and you should refer to that page for a detailed description (see d2i_X509(3)).

NOTES

All these functions use DER format and unencrypted keys. Applications wishing to encrypt or decrypt private keys should use other functions such as d2i_PKC8PrivateKey() instead.

If the ***a** is not NULL when calling d2i_PrivateKey() or d2i_AutoPrivateKey() (i.e. an existing structure is being reused) and the key format is PKCS#8 then ***a** will be freed and replaced on a successful call.

RETURN VALUES

d2i_PrivateKey() and d2i_AutoPrivateKey() return a valid **EVP_KEY** structure or **NULL** if an error occurs. The error code can be obtained by calling ERR_get_error(3).

i2d_PrivateKey() returns the number of bytes successfully encoded or a negative value if an error occurs. The error code can be obtained by calling ERR_get_error(3).

SEE ALSO

Name

d2i_RSAPublicKey, i2d_RSAPublicKey, d2i_RSAPrivateKey, i2d_RSAPrivateKey, d2i_RSA_PUBKEY, i2d_RSA_PUBKEY, i2d_Netscape_RSA and d2i_Netscape_RSA — RSA public and private key encoding functions.

Synopsis

```
#include  <openssl/rsa.h>
#include  <openssl/x509.h>
```

```
RSA * d2i_RSAPublicKey(RSA **a, const unsigned char **pp, long length);
```

```
int i2d_RSAPublicKey(RSA *a, unsigned char **pp);
```

```
RSA * d2i_RSA_PUBKEY(RSA **a, const unsigned char **pp, long length);
```

```
int i2d_RSA_PUBKEY(RSA *a, unsigned char **pp);
```

```
RSA * d2i_RSAPrivateKey(RSA **a, const unsigned char **pp, long length);
```

```
int i2d_RSAPrivateKey(RSA *a, unsigned char **pp);
```

```
int i2d_Netscape_RSA(RSA *a, unsigned char **pp, int (*cb)());
```

```
RSA * d2i_Netscape_RSA(RSA **a, const unsigned char **pp, long length, int (*cb)());
```

DESCRIPTION

d2i_RSAPublicKey() and i2d_RSAPublicKey() decode and encode a PKCS#1 RSAPublicKey structure.

d2i_RSA_PUBKEY() and i2d_RSA_PUBKEY() decode and encode an RSA public key using a SubjectPublicKeyInfo (certificate public key) structure.

d2i_RSAPrivateKey(), i2d_RSAPrivateKey() decode and encode a PKCS#1 RSAPrivateKey structure.

d2i_Netscape_RSA(), i2d_Netscape_RSA() decode and encode an RSA private key in NET format.

The usage of all of these functions is similar to the d2i_X509() and i2d_X509() described in the d2i_X509(3) manual page.

NOTES

The **RSA** structure passed to the private key encoding functions should have all the PKCS#1 private key components present.

The data encoded by the private key functions is unencrypted and therefore offers no private key security.

The NET format functions are present to provide compatibility with certain very old software. This format has some severe security weaknesses and should be avoided if possible.

```

DESCRIPTION

These functions decode and encode an **X509_ALGOR** structure which is equivalent to the **AlgorithmIdentifier** structure.

Othewise these behave in a similar way to d2i_X509() and i2d_X509() described in the d2i_X509(3) manual page.

Synopsis

```
#include  <openssl/x509.h>
```

```
X509_CRL *d2i_X509_CRL(X509_CRL **a, const unsigned char **pp, long length);
int i2d_X509_CRL(X509_CRL *a, unsigned char **pp);
```

```
X509_CRL *d2i_X509_CRL_bio(BIO *bp, X509_CRL **x);
X509_CRL *d2i_X509_CRL_fp(FILE *fp, X509_CRL **x);
```

```
int i2d_X509_CRL_bio(BIO *bp, X509_CRL *x);
int i2d_X509_CRL_fp(FILE *fp, X509_CRL *x);
```

DESCRIPTION

These functions decode and encode an X509 CRL (certificate revocation list).

Othewise the functions behave in a similar way to d2i_X509() and i2d_X509() described in the d2i_X509(3) manual page.

X509 *d2i_X509_fp(FILE *fp, X509 **x);
```

```
int i2d_X509_bio(BIO *bp, X509 *x);
int i2d_X509_fp(FILE *fp, X509 *x);
```

DESCRIPTION

The X509 encode and decode routines encode and parse an **X509** structure, which represents an X509 certificate.

d2i_X509() attempts to decode **len** bytes at ***in**. If successful a pointer to the **X509** structure is returned. If an error occurred then **NULL** is returned. If **px** is not **NULL** then the returned structure is written to ***px**. If ***px** is not **NULL** then it is assumed that ***px** contains a valid **X509** structure and an attempt is made to reuse it. This "reuse" capability is present for historical compatibility but its use is **strongly discouraged** (see BUGS below, and the discussion in the RETURN VALUES section).

If the call is successful ***in** is incremented to the byte following the parsed data.

i2d_X509() encodes the structure pointed to by **x** into DER format. If **out** is not **NULL** is writes the DER encoded data to the buffer at ***out**, and increments it to point after the data just written. If the return value is negative an error occurred, otherwise it returns the length of the encoded data.

For OpenSSL 0.9.7 and later if ***out** is **NULL** memory will be allocated for a buffer and the encoded data written to it. In this case ***out** is not incremented and it points to the start of the data just written.

d2i_X509_bio() is similar to d2i_X509() except it attempts to parse data from BIO **bp**.

d2i_X509_fp() is similar to d2i_X509() except it attempts to parse data from FILE pointer **fp**.

i2d_X509_bio() is similar to i2d_X509() except it writes the encoding of the structure **x** to BIO **bp** and it returns 1 for success and 0 for failure.

i2d_X509_fp() is similar to i2d_X509() except it writes the encoding of the structure **x** to BIO **bp** and it returns 1 for success and 0 for failure.

NOTES

The letters **i** and **d** in for example **i2d_X509** stand for "internal" (that is an internal C structure) and "DER". So that **i2d_X509** converts from internal to DER.

The functions can also understand **BER** forms.

The actual X509 structure passed to i2d_X509() must be a valid populated **X509** structure it can **not** simply be fed with an empty structure such as that returned by X509_new().

The encoded data is in binary form and may contain embedded zeroes. Therefore any FILE pointers or BIOs should be opened in binary mode. Functions such as **strlen()** will **not** return the correct length of the encoded structure.

The ways that ***in** and ***out** are incremented after the operation can trap the unwary. See the **WARNINGS** section for some common errors.

The reason for the auto increment behaviour is to reflect a typical usage of ASN1 functions: after one structure is encoded or decoded another will processed after it.

EXAMPLES

Allocate and encode the DER encoding of an X509 structure:

```
int len;
unsigned char *buf, *p;

len = i2d_X509(x, NULL);

buf = OPENSSL_malloc(len);

if (buf == NULL)
       /* error */

p = buf;

i2d_X509(x, &p);
```

If you are using OpenSSL 0.9.7 or later then this can be simplified to:

```
int len;
unsigned char *buf;

buf = NULL;

len = i2d_X509(x, &buf);

if (len < 0)
       /* error */
```

Attempt to decode a buffer:

```
X509 *x;

unsigned char *buf, *p;

int len;

/* Something to setup buf and len */

p = buf;

x = d2i_X509(NULL, &p, len);

if (x == NULL)
   /* Some error */
```

Alternative technique:

```
X509 *x;

unsigned char *buf, *p;

int len;

/* Something to setup buf and len */

p = buf;
```

```
x = NULL;

if(!d2i_X509(&x, &p, len))
   /* Some error */
```

WARNINGS

The use of temporary variable is mandatory. A common mistake is to attempt to use a buffer directly as follows:

```
int len;
unsigned char *buf;

len = i2d_X509(x, NULL);

buf = OPENSSL_malloc(len);

if (buf == NULL)
       /* error */

i2d_X509(x, &buf);

/* Other stuff … */

OPENSSL_free(buf);
```

This code will result in **buf** apparently containing garbage because it was incremented after the call to point after the data just written. Also **buf** will no longer contain the pointer allocated by **OPENSSL_malloc()** and the subsequent call to **OPENSSL_free()** may well crash.

The auto allocation feature (setting buf to NULL) only works on OpenSSL 0.9.7 and later. Attempts to use it on earlier versions will typically cause a segmentation violation.

Another trap to avoid is misuse of the **xp** argument to **d2i_X509()**:

```
X509 *x;

if (!d2i_X509(&x, &p, len))
       /* Some error */
```

This will probably crash somewhere in **d2i_X509()**. The reason for this is that the variable **x** is uninitialized and an attempt will be made to interpret its (invalid) value as an **X509** structure, typically causing a segmentation violation. If **x** is set to NULL first then this will not happen.

BUGS

In some versions of OpenSSL the "reuse" behaviour of d2i_X509() when ***px** is valid is broken and some parts of the reused structure may persist if they are not present in the new one. As a result the use of this "reuse" behaviour is strongly discouraged.

i2d_X509() will not return an error in many versions of OpenSSL, if mandatory fields are not initialized due to a programming error then the encoded structure may contain invalid data or omit the fields entirely and will not be parsed by d2i_X509(). This may be fixed in future so code should not assume that i2d_X509() will always succeed.

RETURN VALUES

d2i_X509(), d2i_X509_bio() and d2i_X509_fp() return a valid **X509** structure or **NULL** if an error occurs. The error code that can be obtained by ERR_get_error(3). If the "reuse" capability has been used with a valid X509 structure being passed in via **px** then the object is not freed in the event of error but may be in a potentially invalid or inconsistent state.

i2d_X509() returns the number of bytes successfully encoded or a negative value if an error occurs. The error code can be obtained by ERR_get_error(3).

i2d_X509_bio() and i2d_X509_fp() return 1 for success and 0 if an error occurs The error code can be obtained by ERR_get_error(3).

DESCRIPTION

This library contains a fast implementation of the DES encryption algorithm.

There are two phases to the use of DES encryption. The first is the generation of a *DES_key_schedule* from a key, the second is the actual encryption. A DES key is of type *DES_cblock*. This type is consists of 8 bytes with odd parity. The least significant bit in each byte is the parity bit. The key schedule is an expanded form of the key; it is used to speed the encryption process.

DES_random_key() generates a random key. The PRNG must be seeded prior to using this function (see rand(3)). If the PRNG could not generate a secure key, 0 is returned.

Before a DES key can be used, it must be converted into the architecture dependent *DES_key_schedule* via the DES_set_key_checked() or DES_set_key_unchecked() function.

DES_set_key_checked() will check that the key passed is of odd parity and is not a week or semi-weak key. If the parity is wrong, then -1 is returned. If the key is a weak key, then -2 is returned. If an error is returned, the key schedule is not generated.

DES_set_key() works like DES_set_key_checked() if the *DES_check_key* flag is non-zero, otherwise like DES_set_key_unchecked(). These functions are available for compatibility; it is recommended to use a function that does not depend on a global variable.

DES_set_odd_parity() sets the parity of the passed *key* to odd.

DES_is_weak_key() returns 1 if the passed key is a weak key, 0 if it is ok.

The following routines mostly operate on an input and output stream of *DES_cblock*s.

DES_ecb_encrypt() is the basic DES encryption routine that encrypts or decrypts a single 8-byte *DES_cblock* in *electronic code book* (ECB) mode. It always transforms the input data, pointed to by *input*, into the output data, pointed to by the *output* argument. If the *encrypt* argument is non-zero (DES_ENCRYPT), the *input* (cleartext) is encrypted in to the *output* (ciphertext) using the key_schedule specified by the *schedule* argument, previously set via *DES_set_key*. If *encrypt* is zero (DES_DECRYPT), the *input* (now ciphertext) is decrypted into the *output* (now cleartext). Input and output may overlap. DES_ecb_encrypt() does not return a value.

DES_ecb3_encrypt() encrypts/decrypts the *input* block by using three-key Triple-DES encryption in ECB mode. This involves encrypting the input with *ks1*, decrypting with the key schedule *ks2*, and then encrypting with *ks3*. This routine greatly reduces the chances of brute force breaking of DES and has the advantage of if *ks1*, *ks2* and *ks3* are the same, it is equivalent to just encryption using ECB mode and *ks1* as the key.

The macro DES_ecb2_encrypt() is provided to perform two-key Triple-DES encryption by using *ks1* for the final encryption.

DES_ncbc_encrypt() encrypts/decrypts using the *cipher-block-chaining* (CBC) mode of DES. If the *encrypt* argument is non-zero, the routine cipher-block-chain encrypts the cleartext data pointed to by the *input* argument into the ciphertext pointed to by the *output* argument, using the key schedule provided by the *schedule* argument, and initialization vector provided by the *ivec* argument. If the *length* argument is not an integral multiple of eight bytes, the last block is copied to a temporary area and zero filled. The output is always an integral multiple of eight bytes.

DES_xcbc_encrypt() is RSA's DESX mode of DES. It uses *inw* and *outw* to 'whiten' the encryption. *inw* and *outw* are secret (unlike the iv) and are as such, part of the key. So the key is sort of 24 bytes. This is much better than CBC DES.

DES_ede3_cbc_encrypt() implements outer triple CBC DES encryption with three keys. This means that each DES operation inside the CBC mode is an `C=E(ks3,D(ks2,E(ks1,M)))`. This mode is used by SSL.

The DES_ede2_cbc_encrypt() macro implements two-key Triple-DES by reusing *ks1* for the final encryption. `C=E(ks1,D(ks2,E(ks1,M)))`. This form of Triple-DES is used by the RSAREF library.

DES_pcbc_encrypt() encrypt/decrypts using the propagating cipher block chaining mode used by Kerberos v4. Its parameters are the same as DES_ncbc_encrypt().

DES_cfb_encrypt() encrypt/decrypts using cipher feedback mode. This method takes an array of characters as input and outputs and array of characters. It does not require any padding to 8 character groups. Note: the *ivec* variable is changed and the new changed value needs to be passed to the next call to this function. Since this function runs a complete DES ECB encryption per *numbits*, this function is only suggested for use when sending small numbers of characters.

DES_cfb64_encrypt() implements CFB mode of DES with 64bit feedback. Why is this useful you ask? Because this routine will allow you to encrypt an arbitrary number of bytes, no 8 byte padding. Each call to this routine will encrypt the input bytes to output and then update ivec and num. num contains 'how far' we are though ivec. If this does not make much sense, read more about cfb mode of DES :-).

DES_ede3_cfb64_encrypt() and DES_ede2_cfb64_encrypt() is the same as DES_cfb64_encrypt() except that Triple-DES is used.

DES_ofb_encrypt() encrypts using output feedback mode. This method takes an array of characters as input and outputs and array of characters. It does not require any padding to 8 character groups. Note: the *ivec* variable is changed and the new changed value needs to be passed to the next call to this function. Since this function runs a complete DES ECB encryption per numbits, this function is only suggested for use when sending small numbers of characters.

DES_ofb64_encrypt() is the same as DES_cfb64_encrypt() using Output Feed Back mode.

DES_ede3_ofb64_encrypt() and DES_ede2_ofb64_encrypt() is the same as DES_ofb64_encrypt(), using Triple-DES.

The following functions are included in the DES library for compatibility with the MIT Kerberos library.

DES_cbc_cksum() produces an 8 byte checksum based on the input stream (via CBC encryption). The last 4 bytes of the checksum are returned and the complete 8 bytes are placed in *output*. This function is used by Kerberos v4. Other applications should use EVP_DigestInit(3) etc. instead.

DES_quad_cksum() is a Kerberos v4 function. It returns a 4 byte checksum from the input bytes. The algorithm can be iterated over the input, depending on *out_count*, 1, 2, 3 or 4 times. If *output* is non-NULL, the 8 bytes generated by each pass are written into *output*.

The following are DES-based transformations:

DES_fcrypt() is a fast version of the Unix crypt(3) function. This version takes only a small amount of space relative to other fast crypt() implementations. This is different to the normal crypt in that the third parameter is the buffer that the return value is written into. It needs to be at least 14 bytes long. This function is thread safe, unlike the normal crypt.

DES_crypt() is a faster replacement for the normal system crypt(). This function calls DES_fcrypt() with a static array passed as the third parameter. This emulates the normal non-thread safe semantics of crypt(3).

DES_enc_write() writes *len* bytes to file descriptor *fd* from buffer *buf*. The data is encrypted via *pcbc_encrypt* (default) using *sched* for the key and *iv* as a starting vector. The actual data send down *fd* consists of 4 bytes (in network byte order) containing the length of the following encrypted data. The encrypted data then follows, padded with random data out to a multiple of 8 bytes.

DES_enc_read() is used to read *len* bytes from file descriptor *fd* into buffer *buf*. The data being read from *fd* is assumed to have come from DES_enc_write() and is decrypted using *sched* for the key schedule and *iv* for the initial vector.

Warning: The data format used by DES_enc_write() and DES_enc_read() has a cryptographic weakness: When asked to write more than MAXWRITE bytes, DES_enc_write() will split the data into several chunks that are all encrypted using the same IV. So don't use these functions unless you are sure you know what you do (in which case you might not want to use them anyway). They cannot handle non-blocking sockets. DES_enc_read() uses an internal state and thus cannot be used on multiple files.

DES_rw_mode is used to specify the encryption mode to use with DES_enc_read() and DES_end_write(). If set to *DES_PCBC_MODE* (the default), DES_pcbc_encrypt is used. If set to *DES_CBC_MODE* DES_cbc_encrypt is used.

NOTES

Single-key DES is insecure due to its short key size. ECB mode is not suitable for most applications; see des_modes(7).

The evp(3) library provides higher-level encryption functions.

BUGS

DES_3cbc_encrypt() is flawed and must not be used in applications.

DES_cbc_encrypt() does not modify **ivec**; use DES_ncbc_encrypt() instead.

DES_cfb_encrypt() and DES_ofb_encrypt() operates on input of 8 bits. What this means is that if you set numbits to 12, and length to 2, the first 12 bits will come from the 1st input byte and the low half of the second input byte. The second 12 bits will have the low 8 bits taken from the 3rd input byte and the top 4 bits taken from the 4th input byte. The same holds for output. This function has been implemented this way because most people will be using a multiple of 8 and because once you get into pulling bytes input bytes apart things get ugly!

DES_string_to_key() is available for backward compatibility with the MIT library. New applications should use a cryptographic hash function. The same applies for DES_string_to_2key().

CONFORMING TO

ANSI X3.106

The **des** library was written to be source code compatible with the MIT Kerberos library.

SEE ALSO

crypt(3), des_modes(7), evp(3), rand(3)

HISTORY

In OpenSSL 0.9.7, all des_ functions were renamed to DES_ to avoid clashes with older versions of libdes. Compatibility des_ functions are provided for a short while, as well as crypt(). Declarations for these are in <openssl/des_old.h>. There is no DES_ variant for des_random_seed(). This will happen to other functions as well if they are deemed redundant (des_random_seed() just calls RAND_seed() and is present for backward compatibility only), buggy or already scheduled for removal.

des_cbc_cksum(), des_cbc_encrypt(), des_ecb_encrypt(), des_is_weak_key(), des_key_sched(), des_pcbc_encrypt(), des_quad_cksum(), des_random_key() and des_string_to_key() are available in the MIT Kerberos library; des_check_key_parity(), des_fixup_key_parity() and des_is_weak_key() are available in newer versions of that library.

des_set_key_checked() and des_set_key_unchecked() were added in OpenSSL 0.9.5.

des_generate_random_block(), des_init_random_number_generator(), des_new_random_key(), des_set_random_generator_seed() and des_set_sequence_number() and des_rand_data() are used in newer versions of Kerberos but are not implemented here.

des_random_key() generated cryptographically weak random data in SSLeay and in OpenSSL prior version 0.9.5, as well as in the original MIT library.

AUTHOR

Eric Young (eay@cryptsoft.com). Modified for the OpenSSL project (http://www.openssl.org).

Name

des_modes — the variants of DES and other crypto algorithms of OpenSSL

DESCRIPTION

Several crypto algorithms for OpenSSL can be used in a number of modes. Those are used for using block ciphers in a way similar to stream ciphers, among other things.

OVERVIEW

Electronic Codebook Mode (ECB)

Normally, this is found as the function *algorithm*_ecb_encrypt().

- 64 bits are enciphered at a time.
- The order of the blocks can be rearranged without detection.
- The same plaintext block always produces the same ciphertext block (for the same key) making it vulnerable to a 'dictionary attack'.
- An error will only affect one ciphertext block.

Cipher Block Chaining Mode (CBC)

Normally, this is found as the function *algorithm*_cbc_encrypt(). Be aware that des_cbc_encrypt() is not really DES CBC (it does not update the IV); use des_ncbc_encrypt() instead.

- a multiple of 64 bits are enciphered at a time.
- The CBC mode produces the same ciphertext whenever the same plaintext is encrypted using the same key and starting variable.
- The chaining operation makes the ciphertext blocks dependent on the current and all preceding plaintext blocks and therefore blocks can not be rearranged.
- The use of different starting variables prevents the same plaintext enciphering to the same ciphertext.
- An error will affect the current and the following ciphertext blocks.

Cipher Feedback Mode (CFB)

Normally, this is found as the function *algorithm*_cfb_encrypt().

- a number of bits (j) <= 64 are enciphered at a time.
- The CFB mode produces the same ciphertext whenever the same plaintext is encrypted using the same key and starting variable.
- The chaining operation makes the ciphertext variables dependent on the current and all preceding variables and therefore j-bit variables are chained together and can not be rearranged.
- The use of different starting variables prevents the same plaintext enciphering to the same ciphertext.
- The strength of the CFB mode depends on the size of k (maximal if j == k). In my implementation this is always the case.
- Selection of a small value for j will require more cycles through the encipherment algorithm per unit of plaintext and thus cause greater processing overheads.

- Only multiples of j bits can be enciphered.
- An error will affect the current and the following ciphertext variables.

Output Feedback Mode (OFB)

Normally, this is found as the function *algorithm*_ofb_encrypt().

- a number of bits (j) <= 64 are enciphered at a time.
- The OFB mode produces the same ciphertext whenever the same plaintext enciphered using the same key and starting variable. More over, in the OFB mode the same key stream is produced when the same key and start variable are used. Consequently, for security reasons a specific start variable should be used only once for a given key.
- The absence of chaining makes the OFB more vulnerable to specific attacks.
- The use of different start variables values prevents the same plaintext enciphering to the same ciphertext, by producing different key streams.
- Selection of a small value for j will require more cycles through the encipherment algorithm per unit of plaintext and thus cause greater processing overheads.
- Only multiples of j bits can be enciphered.
- OFB mode of operation does not extend ciphertext errors in the resultant plaintext output. Every bit error in the ciphertext causes only one bit to be in error in the deciphered plaintext.
- OFB mode is not self-synchronizing. If the two operation of encipherment and decipherment get out of synchronism, the system needs to be re-initialized.
- Each re-initialization should use a value of the start variable different from the start variable values used before with the same key. The reason for this is that an identical bit stream would be produced each time from the same parameters. This would be susceptible to a 'known plaintext' attack.

Triple ECB Mode

Normally, this is found as the function *algorithm*_ecb3_encrypt().

- Encrypt with key1, decrypt with key2 and encrypt with key3 again.
- As for ECB encryption but increases the key length to 168 bits. There are theoretic attacks that can be used that make the effective key length 112 bits, but this attack also requires 2^56 blocks of memory, not very likely, even for the NSA.
- If both keys are the same it is equivalent to encrypting once with just one key.
- If the first and last key are the same, the key length is 112 bits. There are attacks that could reduce the effective key strength to only slightly more than 56 bits, but these require a lot of memory.
- If all 3 keys are the same, this is effectively the same as normal ecb mode.

Triple CBC Mode

Normally, this is found as the function *algorithm*_ede3_cbc_encrypt().

- Encrypt with key1, decrypt with key2 and then encrypt with key3.
- As for CBC encryption but increases the key length to 168 bits with the same restrictions as for triple ecb mode.

```

```
int    DHparams_print_fp(FILE *fp, const DH *x);
int    DHparams_print(BIO *bp, const DH *x);
```

DESCRIPTION

These functions implement the Diffie-Hellman key agreement protocol. The generation of shared DH parameters is described in DH_generate_parameters(3); DH_generate_key(3) describes how to perform a key agreement.

The **DH** structure consists of several BIGNUM components.

```
struct
       {
       BIGNUM *p;              // prime number (shared)
       BIGNUM *g;              // generator of Z_p (shared)
       BIGNUM *priv_key;       // private DH value x
       BIGNUM *pub_key;        // public DH value g^x
       // ...
       };
DH
```

Note that DH keys may use non-standard **DH_METHOD** implementations, either directly or by the use of **ENGINE** modules. In some cases (eg. an ENGINE providing support for hardware-embedded keys), these BIGNUM values will not be used by the implementation or may be used for alternative data storage. For this reason, applications should generally avoid using DH structure elements directly and instead use API functions to query or modify keys.

Name

DH_generate_key and DH_compute_key — perform Diffie-Hellman key exchange

Synopsis

```
#include  <openssl/dh.h>
```

```
int DH_generate_key(DH *dh);
```

```
int DH_compute_key(unsigned char *key, BIGNUM *pub_key, DH *dh);
```

DESCRIPTION

DH_generate_key() performs the first step of a Diffie-Hellman key exchange by generating private and public DH values. By calling DH_compute_key(), these are combined with the other party's public value to compute the shared key.

DH_generate_key() expects **dh** to contain the shared parameters **dh->p** and **dh->g**. It generates a random private DH value unless **dh->priv_key** is already set, and computes the corresponding public value **dh->pub_key**, which can then be published.

DH_compute_key() computes the shared secret from the private DH value in **dh** and the other party's public value in **pub_key** and stores it in **key**. **key** must point to **DH_size(dh)** bytes of memory.

RETURN VALUES

DH_generate_key() returns 1 on success, 0 otherwise.

DH_compute_key() returns the size of the shared secret on success, -1 on error.

The error codes can be obtained by ERR_get_error(3).

SEE ALSO

dh(3), ERR_get_error(3), rand(3), DH_size(3)

HISTORY

DH_generate_key() and DH_compute_key() are available in all versions of SSLeay and OpenSSL.

Name

DH_generate_parameters and DH_check — generate and check Diffie-Hellman parameters

Synopsis

```
#include  <openssl/dh.h>
```

```
DH *DH_generate_parameters(int prime_len, int generator,
    void (*callback)(int, int, void *), void *cb_arg);
```

```
int DH_check(DH *dh, int *codes);
```

DESCRIPTION

DH_generate_parameters() generates Diffie-Hellman parameters that can be shared among a group of users, and returns them in a newly allocated **DH** structure. The pseudo-random number generator must be seeded prior to calling DH_generate_parameters().

prime_len is the length in bits of the safe prime to be generated. **generator** is a small number > 1, typically 2 or 5.

A callback function may be used to provide feedback about the progress of the key generation. If **callback** is not **NULL**, it will be called as described in BN_generate_prime(3) while a random prime number is generated, and when a prime has been found, **callback(3, 0, cb_arg)** is called.

DH_check() validates Diffie-Hellman parameters. It checks that **p** is a safe prime, and that **g** is a suitable generator. In the case of an error, the bit flags DH_CHECK_P_NOT_SAFE_PRIME or DH_NOT_SUITABLE_GENERATOR are set in ***codes**. DH_UNABLE_TO_CHECK_GENERATOR is set if the generator cannot be checked, i.e. it does not equal 2 or 5.

RETURN VALUES

DH_generate_parameters() returns a pointer to the DH structure, or NULL if the parameter generation fails. The error codes can be obtained by ERR_get_error(3).

DH_check() returns 1 if the check could be performed, 0 otherwise.

NOTES

DH_generate_parameters() may run for several hours before finding a suitable prime.

The parameters generated by DH_generate_parameters() are not to be used in signature schemes.

BUGS

If **generator** is not 2 or 5, **dh->g=generator** is not a usable generator.

SEE ALSO

dh(3), ERR_get_error(3), rand(3), DH_free(3)

HISTORY

DH_check() is available in all versions of SSLeay and OpenSSL. The **cb_arg** argument to DH_generate_parameters() was added in SSLeay 0.9.0.

In versions before OpenSSL 0.9.5, DH_CHECK_P_NOT_STRONG_PRIME is used instead of DH_CHECK_P_NOT_SAFE_PRIME.

Name

DH_get_ex_new_index, DH_set_ex_data and DH_get_ex_data — add application specific data to DH structures

Synopsis

```
#include  <openssl/dh.h>
```

```
int DH_get_ex_new_index(long argl, void *argp,
               CRYPTO_EX_new *new_func,
               CRYPTO_EX_dup *dup_func,
               CRYPTO_EX_free *free_func);
```

```
int DH_set_ex_data(DH *d, int idx, void *arg);
```

```
char *DH_get_ex_data(DH *d, int idx);
```

DESCRIPTION

These functions handle application specific data in DH structures. Their usage is identical to that of RSA_get_ex_new_index(), RSA_set_ex_data() and RSA_get_ex_data() as described in RSA_get_ex_new_index(3).

SEE ALSO

RSA_get_ex_new_index(3), dh(3)

HISTORY

DH_get_ex_new_index(), DH_set_ex_data() and DH_get_ex_data() are available since OpenSSL 0.9.5.

Name

DH_new and DH_free — allocate and free DH objects

Synopsis

```
#include  <openssl/dh.h>
```

```
DH* DH_new(void);
```

```
void DH_free(DH *dh);
```

DESCRIPTION

DH_new() allocates and initializes a **DH** structure.

DH_free() frees the **DH** structure and its components. The values are erased before the memory is returned to the system.

RETURN VALUES

If the allocation fails, DH_new() returns **NULL** and sets an error code that can be obtained by ERR_get_error(3). Otherwise it returns a pointer to the newly allocated structure.

DH_free() returns no value.

SEE ALSO

dh(3), ERR_get_error(3), DH_generate_parameters(3), DH_generate_key(3)

HISTORY

DH_new() and DH_free() are available in all versions of SSLeay and OpenSSL.

Name

DH_set_default_method, DH_get_default_method, DH_set_method, DH_new_method and DH_OpenSSL — select DH method

Synopsis

```
#include  <openssl/dh.h>
#include  <openssl/engine.h>
```

```
void DH_set_default_method(const DH_METHOD *meth);
```

```
const DH_METHOD *DH_get_default_method(void);
```

```
int DH_set_method(DH *dh, const DH_METHOD *meth);
```

```
DH *DH_new_method(ENGINE *engine);
```

```
const DH_METHOD *DH_OpenSSL(void);
```

DESCRIPTION

A **DH_METHOD** specifies the functions that OpenSSL uses for Diffie-Hellman operations. By modifying the method, alternative implementations such as hardware accelerators may be used. IMPORTANT: See the NOTES section for important information about how these DH API functions are affected by the use of **ENGINE** API calls.

Initially, the default DH_METHOD is the OpenSSL internal implementation, as returned by DH_OpenSSL().

DH_set_default_method() makes **meth** the default method for all DH structures created later. **NB**: This is true only whilst no ENGINE has been set as a default for DH, so this function is no longer recommended.

DH_get_default_method() returns a pointer to the current default DH_METHOD. However, the meaningfulness of this result is dependent on whether the ENGINE API is being used, so this function is no longer recommended.

DH_set_method() selects **meth** to perform all operations using the key **dh**. This will replace the DH_METHOD used by the DH key and if the previous method was supplied by an ENGINE, the handle to that ENGINE will be released during the change. It is possible to have DH keys that only work with certain DH_METHOD implementations (eg. from an ENGINE module that supports embedded hardware-protected keys), and in such cases attempting to change the DH_METHOD for the key can have unexpected results.

DH_new_method() allocates and initializes a DH structure so that **engine** will be used for the DH operations. If **engine** is NULL, the default ENGINE for DH operations is used, and if no default ENGINE is set, the DH_METHOD controlled by DH_set_default_method() is used.

THE DH_METHOD STRUCTURE

```
typedef struct dh_meth_st
{
    /* name of the implementation */
       const char *name;

/* generate private and public DH values for key agreement */
   int (*generate_key)(DH *dh);

/* compute shared secret */
   int (*compute_key)(unsigned char *key, BIGNUM *pub_key, DH *dh);

/* compute r = a ^ p mod m (May be NULL for some implementations) */
   int (*bn_mod_exp)(DH *dh, BIGNUM *r, BIGNUM *a, const BIGNUM *p,
                           const BIGNUM *m, BN_CTX *ctx,
                           BN_MONT_CTX *m_ctx);
/* called at DH_new */
   int (*init)(DH *dh);

/* called at DH_free */
   int (*finish)(DH *dh);

int flags;

char *app_data; /* ?? */

} DH_METHOD;
```

RETURN VALUES

DH_OpenSSL() and DH_get_default_method() return pointers to the respective **DH_METHOD**s.

DH_set_default_method() returns no value.

DH_set_method() returns non-zero if the provided **meth** was successfully set as the method for **dh** (including unloading the ENGINE handle if the previous method was supplied by an ENGINE).

DH_new_method() returns NULL and sets an error code that can be obtained by ERR_get_error(3) if the allocation fails. Otherwise it returns a pointer to the newly allocated structure.

NOTES

As of version 0.9.7, DH_METHOD implementations are grouped together with other algorithmic APIs (eg. RSA_METHOD, EVP_CIPHER, etc) in **ENGINE** modules. If a default ENGINE is specified for DH functionality using an ENGINE API function, that will override any DH defaults set using the DH API (ie. DH_set_default_method()). For this reason, the ENGINE API is the recommended way to control default implementations for use in DH and other cryptographic algorithms.

SEE ALSO

dh(3), DH_new(3)

HISTORY

DH_set_default_method(), DH_get_default_method(), DH_set_method(), DH_new_method() and DH_OpenSSL() were added in OpenSSL 0.9.4.

DH_set_default_openssl_method() and DH_get_default_openssl_method() replaced DH_set_default_method() and DH_get_default_method() respectively, and DH_set_method() and DH_new_method() were altered to use **ENGINE**s rather than **DH_METHOD**s during development of the engine version of OpenSSL 0.9.6. For 0.9.7, the handling of defaults in the ENGINE API was restructured so that this change was reversed, and behaviour of the other functions resembled more closely the previous behaviour. The behaviour of defaults in the ENGINE API now transparently overrides the behaviour of defaults in the DH API without requiring changing these function prototypes.

Name

DH_size — get Diffie-Hellman prime size

Synopsis

```
#include  <openssl/dh.h>
```

```
int DH_size(DH *dh);
```

DESCRIPTION

This function returns the Diffie-Hellman size in bytes. It can be used to determine how much memory must be allocated for the shared secret computed by DH_compute_key().

dh->p must not be **NULL**.

RETURN VALUE

The size in bytes.

SEE ALSO

dh(3), DH_generate_key(3)

HISTORY

DH_size() is available in all versions of SSLeay and OpenSSL.

int     DSA_print(BIO *bp, const DSA *x, int off);
int     DSA_print_fp(FILE *bp, const DSA *x, int off);
```

DESCRIPTION

These functions implement the Digital Signature Algorithm (DSA). The generation of shared DSA parameters is described in DSA_generate_parameters(3); DSA_generate_key(3) describes how to generate a signature key. Signature generation and verification are described in DSA_sign(3).

The **DSA** structure consists of several BIGNUM components.

```
struct
       {
       BIGNUM *p;              // prime number (public)
       BIGNUM *q;              // 160-bit subprime, q | p-1 (public)
       BIGNUM *g;              // generator of subgroup (public)
       BIGNUM *priv_key;       // private key x
       BIGNUM *pub_key;        // public key y = g^x
       // ...
       }
DSA;
```

In public keys, **priv_key** is NULL.

Note that DSA keys may use non-standard **DSA_METHOD** implementations, either directly or by the use of **ENGINE** modules. In some cases (eg. an ENGINE providing support for hardware-embedded keys), these BIGNUM values will not be used by the implementation or may be used for alternative data storage. For this reason, applications should generally avoid using DSA structure elements directly and instead use API functions to query or modify keys.

CONFORMING TO

Name

DSA_do_sign and DSA_do_verify — raw DSA signature operations

Synopsis

```
#include  <openssl/dsa.h>
```

```
DSA_SIG *DSA_do_sign(const unsigned char *dgst, int dlen, DSA *dsa);
```

```
int DSA_do_verify(const unsigned char *dgst, int dgst_len,
            DSA_SIG *sig, DSA *dsa);
```

DESCRIPTION

DSA_do_sign() computes a digital signature on the **len** byte message digest **dgst** using the private key **dsa** and returns it in a newly allocated **DSA_SIG** structure.

DSA_sign_setup(3) may be used to precompute part of the signing operation in case signature generation is time-critical.

DSA_do_verify() verifies that the signature **sig** matches a given message digest **dgst** of size **len**. **dsa** is the signer's public key.

RETURN VALUES

DSA_do_sign() returns the signature, NULL on error. DSA_do_verify() returns 1 for a valid signature, 0 for an incorrect signature and -1 on error. The error codes can be obtained by ERR_get_error(3).

SEE ALSO

dsa(3), ERR_get_error(3), rand(3), DSA_SIG_new(3), DSA_sign(3)

HISTORY

DSA_do_sign() and DSA_do_verify() were added in OpenSSL 0.9.3.

Name

DSA_dup_DH — create a DH structure out of DSA structure

Synopsis

```
#include  <openssl/dsa.h>
```

```
DH * DSA_dup_DH(const DSA *r);
```

DESCRIPTION

DSA_dup_DH() duplicates DSA parameters/keys as DH parameters/keys. q is lost during that conversion, but the resulting DH parameters contain its length.

RETURN VALUE

DSA_dup_DH() returns the new **DH** structure, and NULL on error. The error codes can be obtained by ERR_get_error(3).

NOTE

Be careful to avoid small subgroup attacks when using this.

SEE ALSO

dh(3), dsa(3), ERR_get_error(3)

HISTORY

DSA_dup_DH() was added in OpenSSL 0.9.4.

Name

DSA_generate_key — generate DSA key pair

Synopsis

```
#include  <openssl/dsa.h>
```

```
int DSA_generate_key(DSA *a);
```

DESCRIPTION

DSA_generate_key() expects **a** to contain DSA parameters. It generates a new key pair and stores it in **a->pub_key** and **a->priv_key**.

The PRNG must be seeded prior to calling DSA_generate_key().

RETURN VALUE

DSA_generate_key() returns 1 on success, 0 otherwise. The error codes can be obtained by ERR_get_error(3).

SEE ALSO

dsa(3), ERR_get_error(3), rand(3), DSA_generate_parameters(3)

HISTORY

DSA_generate_key() is available since SSLeay 0.8.

Name

DSA_generate_parameters — generate DSA parameters

Synopsis

```
#include  <openssl/dsa.h>
```

```
DSA *DSA_generate_parameters(int bits, unsigned char *seed,
               int seed_len, int *counter_ret, unsigned long *h_ret,
               void (*callback)(int, int, void *), void *cb_arg);
```

DESCRIPTION

DSA_generate_parameters() generates primes p and q and a generator g for use in the DSA.

bits is the length of the prime to be generated; the DSS allows a maximum of 1024 bits.

If **seed** is **NULL** or **seed_len** < 20, the primes will be generated at random. Otherwise, the seed is used to generate them. If the given seed does not yield a prime q, a new random seed is chosen.

DSA_generate_parameters() places the iteration count in ***counter_ret** and a counter used for finding a generator in ***h_ret**, unless these are **NULL**.

A callback function may be used to provide feedback about the progress of the key generation. If **callback** is not **NULL**, it will be called as follows:

- When a candidate for q is generated, **callback(0, m++, cb_arg)** is called (m is 0 for the first candidate).
- When a candidate for q has passed a test by trial division, **callback(1, -1, cb_arg)** is called. While a candidate for q is tested by Miller-Rabin primality tests, **callback(1, i, cb_arg)** is called in the outer loop (once for each witness that confirms that the candidate may be prime); i is the loop counter (starting at 0).
- When a prime q has been found, **callback(2, 0, cb_arg)** and **callback(3, 0, cb_arg)** are called.
- Before a candidate for p (other than the first) is generated and tested, **callback(0, counter, cb_arg)** is called.
- When a candidate for p has passed the test by trial division, **callback(1, -1, cb_arg)** is called. While it is tested by the Miller-Rabin primality test, **callback(1, i, cb_arg)** is called in the outer loop (once for each witness that confirms that the candidate may be prime). i is the loop counter (starting at 0).
- When p has been found, **callback(2, 1, cb_arg)** is called.
- When the generator has been found, **callback(3, 1, cb_arg)** is called.

RETURN VALUE

DSA_generate_parameters() returns a pointer to the DSA structure, or **NULL** if the parameter generation fails. The error codes can be obtained by ERR_get_error(3).

BUGS

Seed lengths > 20 are not supported.

SEE ALSO

dsa(3), ERR_get_error(3), rand(3), DSA_free(3)

HISTORY

DSA_generate_parameters() appeared in SSLeay 0.8. The **cb_arg** argument was added in SSLeay 0.9.0. In versions up to OpenSSL 0.9.4, **callback(1, ...)** was called in the inner loop of the Miller-Rabin test whenever it reached the squaring step (the parameters to **callback** did not reveal how many witnesses had been tested); since OpenSSL 0.9.5, **callback(1, ...)** is called as in BN_is_prime(3), i.e. once for each witness. =cut

Name

DSA_get_ex_new_index, DSA_set_ex_data and DSA_get_ex_data — add application specific data to DSA structures

Synopsis

```
#include  <openssl/dsa.h>
```

```
int DSA_get_ex_new_index(long argl, void *argp,
               CRYPTO_EX_new *new_func,
               CRYPTO_EX_dup *dup_func,
               CRYPTO_EX_free *free_func);
```

```
int DSA_set_ex_data(DSA *d, int idx, void *arg);
```

```
char *DSA_get_ex_data(DSA *d, int idx);
```

DESCRIPTION

These functions handle application specific data in DSA structures. Their usage is identical to that of RSA_get_ex_new_index(), RSA_set_ex_data() and RSA_get_ex_data() as described in RSA_get_ex_new_index(3).

SEE ALSO

RSA_get_ex_new_index(3), dsa(3)

HISTORY

DSA_get_ex_new_index(), DSA_set_ex_data() and DSA_get_ex_data() are available since OpenSSL 0.9.5.

Name

DSA_new and DSA_free — allocate and free DSA objects

Synopsis

```
#include  <openssl/dsa.h>
```

```
DSA* DSA_new(void);
```

```
void DSA_free(DSA *dsa);
```

DESCRIPTION

DSA_new() allocates and initializes a **DSA** structure. It is equivalent to calling DSA_new_method(NULL).

DSA_free() frees the **DSA** structure and its components. The values are erased before the memory is returned to the system.

RETURN VALUES

If the allocation fails, DSA_new() returns **NULL** and sets an error code that can be obtained by ERR_get_error(3). Otherwise it returns a pointer to the newly allocated structure.

DSA_free() returns no value.

SEE ALSO

dsa(3), ERR_get_error(3), DSA_generate_parameters(3), DSA_generate_key(3)

HISTORY

DSA_new() and DSA_free() are available in all versions of SSLeay and OpenSSL.

Name

DSA_set_default_method, DSA_get_default_method, DSA_set_method, DSA_new_method and DSA_OpenSSL — select DSA method

Synopsis

```
#include  <openssl/dsa.h>
#include  <openssl/engine.h>
```

```
void DSA_set_default_method(const DSA_METHOD *meth);
```

```
const DSA_METHOD *DSA_get_default_method(void);
```

```
int DSA_set_method(DSA *dsa, const DSA_METHOD *meth);
```

```
DSA *DSA_new_method(ENGINE *engine);
```

```
DSA_METHOD *DSA_OpenSSL(void);
```

DESCRIPTION

A **DSA_METHOD** specifies the functions that OpenSSL uses for DSA operations. By modifying the method, alternative implementations such as hardware accelerators may be used. IMPORTANT: See the NOTES section for important information about how these DSA API functions are affected by the use of **ENGINE** API calls.

Initially, the default DSA_METHOD is the OpenSSL internal implementation, as returned by DSA_OpenSSL().

DSA_set_default_method() makes **meth** the default method for all DSA structures created later. **NB**: This is true only whilst no ENGINE has been set as a default for DSA, so this function is no longer recommended.

DSA_get_default_method() returns a pointer to the current default DSA_METHOD. However, the meaningfulness of this result is dependent on whether the ENGINE API is being used, so this function is no longer recommended.

DSA_set_method() selects **meth** to perform all operations using the key **rsa**. This will replace the DSA_METHOD used by the DSA key and if the previous method was supplied by an ENGINE, the handle to that ENGINE will be released during the change. It is possible to have DSA keys that only work with certain DSA_METHOD implementations (eg. from an ENGINE module that supports embedded hardware-protected keys), and in such cases attempting to change the DSA_METHOD for the key can have unexpected results.

DSA_new_method() allocates and initializes a DSA structure so that **engine** will be used for the DSA operations. If **engine** is NULL, the default engine for DSA operations is used, and if no default ENGINE is set, the DSA_METHOD controlled by DSA_set_default_method() is used.

THE DSA_METHOD STRUCTURE

struct { /* name of the implementation */ const char *name;

```
/* sign */
   DSA_SIG *(*dsa_do_sign)(const unsigned char *dgst, int dlen,
                            DSA *dsa);

/* pre-compute k^-1 and r */
   int (*dsa_sign_setup)(DSA *dsa, BN_CTX *ctx_in, BIGNUM **kinvp,
                            BIGNUM **rp);

/* verify */
   int (*dsa_do_verify)(const unsigned char *dgst, int dgst_len,
                            DSA_SIG *sig, DSA *dsa);

/* compute rr = a1^p1 * a2^p2 mod m (May be NULL for some
                                     implementations) */
   int (*dsa_mod_exp)(DSA *dsa, BIGNUM *rr, BIGNUM *a1, BIGNUM *p1,
                            BIGNUM *a2, BIGNUM *p2, BIGNUM *m,
                            BN_CTX *ctx, BN_MONT_CTX *in_mont);

/* compute r = a ^ p mod m (May be NULL for some implementations) */
   int (*bn_mod_exp)(DSA *dsa, BIGNUM *r, BIGNUM *a,
                            const BIGNUM *p, const BIGNUM *m,
                            BN_CTX *ctx, BN_MONT_CTX *m_ctx);

/* called at DSA_new */
   int (*init)(DSA *DSA);

/* called at DSA_free */
   int (*finish)(DSA *DSA);

int flags;

char *app_data; /* ?? */

} DSA_METHOD;
```

RETURN VALUES

DSA_OpenSSL() and DSA_get_default_method() return pointers to the respective **DSA_METHOD**s.

DSA_set_default_method() returns no value.

DSA_set_method() returns non-zero if the provided **meth** was successfully set as the method for **dsa** (including unloading the ENGINE handle if the previous method was supplied by an ENGINE).

DSA_new_method() returns NULL and sets an error code that can be obtained by ERR_get_error(3) if the allocation fails. Otherwise it returns a pointer to the newly allocated structure.

NOTES

As of version 0.9.7, DSA_METHOD implementations are grouped together with other algorithmic APIs (eg. RSA_METHOD, EVP_CIPHER, etc) in **ENGINE** modules. If a default ENGINE is specified for DSA functionality using an ENGINE API function, that will override any DSA defaults set using the DSA API (ie. DSA_set_default_method()). For this reason, the ENGINE API is the recommended way to control default implementations for use in DSA and other cryptographic algorithms.

SEE ALSO

dsa(3), DSA_new(3)

HISTORY

DSA_set_default_method(), DSA_get_default_method(), DSA_set_method(), DSA_new_method() and DSA_OpenSSL() were added in OpenSSL 0.9.4.

DSA_set_default_openssl_method() and DSA_get_default_openssl_method() replaced DSA_set_default_method() and DSA_get_default_method() respectively, and DSA_set_method() and DSA_new_method() were altered to use **ENGINE**s rather than **DSA_METHOD**s during development of the engine version of OpenSSL 0.9.6. For 0.9.7, the handling of defaults in the ENGINE API was restructured so that this change was reversed, and behaviour of the other functions resembled more closely the previous behaviour. The behaviour of defaults in the ENGINE API now transparently overrides the behaviour of defaults in the DSA API without requiring changing these function prototypes.

Name

DSA_SIG_new and DSA_SIG_free — allocate and free DSA signature objects

Synopsis

```
#include  <openssl/dsa.h>
```

```
DSA_SIG *DSA_SIG_new(void);
```

```
void   DSA_SIG_free(DSA_SIG *a);
```

DESCRIPTION

DSA_SIG_new() allocates and initializes a **DSA_SIG** structure.

DSA_SIG_free() frees the **DSA_SIG** structure and its components. The values are erased before the memory is returned to the system.

RETURN VALUES

If the allocation fails, DSA_SIG_new() returns **NULL** and sets an error code that can be obtained by ERR_get_error(3). Otherwise it returns a pointer to the newly allocated structure.

DSA_SIG_free() returns no value.

SEE ALSO

dsa(3), ERR_get_error(3), DSA_do_sign(3)

HISTORY

DSA_SIG_new() and DSA_SIG_free() were added in OpenSSL 0.9.3.

Name

DSA_sign, DSA_sign_setup and DSA_verify — DSA signatures

Synopsis

```
#include  <openssl/dsa.h>

int    DSA_sign(int type, const unsigned char *dgst, int len,
               unsigned char *sigret, unsigned int *siglen, DSA *dsa);

int    DSA_sign_setup(DSA *dsa, BN_CTX *ctx, BIGNUM **kinvp,
               BIGNUM **rp);

int    DSA_verify(int type, const unsigned char *dgst, int len,
               unsigned char *sigbuf, int siglen, DSA *dsa);
```

DESCRIPTION

DSA_sign() computes a digital signature on the **len** byte message digest **dgst** using the private key **dsa** and places its ASN.1 DER encoding at **sigret**. The length of the signature is places in ***siglen**. **sigret** must point to DSA_size(**dsa**) bytes of memory.

DSA_sign_setup() may be used to precompute part of the signing operation in case signature generation is time-critical. It expects **dsa** to contain DSA parameters. It places the precomputed values in newly allocated **BIGNUM**s at ***kinvp** and ***rp**, after freeing the old ones unless ***kinvp** and ***rp** are NULL. These values may be passed to DSA_sign() in **dsa->kinv** and **dsa->r**. **ctx** is a pre-allocated **BN_CTX** or NULL.

DSA_verify() verifies that the signature **sigbuf** of size **siglen** matches a given message digest **dgst** of size **len**. **dsa** is the signer's public key.

The **type** parameter is ignored.

The PRNG must be seeded before DSA_sign() (or DSA_sign_setup()) is called.

RETURN VALUES

DSA_sign() and DSA_sign_setup() return 1 on success, 0 on error. DSA_verify() returns 1 for a valid signature, 0 for an incorrect signature and -1 on error. The error codes can be obtained by ERR_get_error(3).

CONFORMING TO

US Federal Information Processing Standard FIPS 186 (Digital Signature Standard, DSS), ANSI X9.30

SEE ALSO

dsa(3), ERR_get_error(3), rand(3), DSA_do_sign(3)

HISTORY

DSA_sign() and DSA_verify() are available in all versions of SSLeay. DSA_sign_setup() was added in SSLeay 0.8.

Name

DSA_size — get DSA signature size

Synopsis

```
#include  <openssl/dsa.h>
```

```
int DSA_size(const DSA *dsa);
```

DESCRIPTION

This function returns the size of an ASN.1 encoded DSA signature in bytes. It can be used to determine how much memory must be allocated for a DSA signature.

dsa->q must not be **NULL**.

RETURN VALUE

The size in bytes.

SEE ALSO

dsa(3), DSA_sign(3)

HISTORY

DSA_size() is available in all versions of SSLeay and OpenSSL.

Name

```

```
int            ECDSA_get_ex_new_index(long argl, void *argp,
                       CRYPTO_EX_new *new_func,
                       CRYPTO_EX_dup *dup_func,
                       CRYPTO_EX_free *free_func);
int            ECDSA_set_ex_data(EC_KEY *d, int idx, void *arg);
void*          ECDSA_get_ex_data(EC_KEY *d, int idx);
```

DESCRIPTION

The **ECDSA_SIG** structure consists of two BIGNUMs for the r and s value of a ECDSA signature (see X9.62 or FIPS 186-2).

```
struct
       {
       BIGNUM *r;
       BIGNUM *s;
} ECDSA_SIG;
```

ECDSA_SIG_new() allocates a new **ECDSA_SIG** structure (note: this function also allocates the BIGNUMs) and initialize it.

ECDSA_SIG_free() frees the **ECDSA_SIG** structure **sig**.

i2d_ECDSA_SIG() creates the DER encoding of the ECDSA signature **sig** and writes the encoded signature to ***pp** (note: if **pp** is NULL **i2d_ECDSA_SIG** returns the expected length in bytes of the DER encoded signature). **i2d_ECDSA_SIG** returns the length of the DER encoded signature (or 0 on error).

d2i_ECDSA_SIG() decodes a DER encoded ECDSA signature and returns the decoded signature in a newly allocated **ECDSA_SIG** structure. ***sig** points to the buffer containing the DER encoded signature of size **len**.

ECDSA_size() returns the maximum length of a DER encoded ECDSA signature created with the private EC key **eckey**.

ECDSA_sign_setup() may be used to precompute parts of the signing operation. **eckey** is the private EC key and **ctx** is a pointer to **BN_CTX** structure (or NULL). The precomputed values or returned in **kinv** and **rp** and can be used in a later call to **ECDSA_sign_ex** or **ECDSA_do_sign_ex**.

ECDSA_sign() is wrapper function for ECDSA_sign_ex with **kinv** and **rp** set to NULL.

ECDSA_sign_ex() computes a digital signature of the **dgstlen** bytes hash value **dgst** using the private EC key **eckey** and the optional pre-computed values **kinv** and **rp**. The DER encoded signatures is stored in **sig** and it's length is returned in **sig_len**. Note: **sig** must point to **ECDSA_size** bytes of memory. The parameter **type** is ignored.

ECDSA_verify() verifies that the signature in **sig** of size **siglen** is a valid ECDSA signature of the hash value **dgst** of size **dgstlen** using the public key **eckey**. The parameter **type** is ignored.

ECDSA_do_sign() is wrapper function for ECDSA_do_sign_ex with **kinv** and **rp** set to NULL.

ECDSA_do_sign_ex() computes a digital signature of the **dgst_len** bytes hash value **dgst** using the private key **eckey** and the optional pre-computed values **kinv** and **rp**. The signature is returned in a newly allocated **ECDSA_SIG** structure (or NULL on error).

ECDSA_do_verify() verifies that the signature **sig** is a valid ECDSA signature of the hash value **dgst** of size **dgst_len** using the public key **eckey**.

RETURN VALUES

ECDSA_size() returns the maximum length signature or 0 on error.

ECDSA_sign_setup() and ECDSA_sign() return 1 if successful or 0 on error.

ECDSA_verify() and ECDSA_do_verify() return 1 for a valid signature, 0 for an invalid signature and -1 on error. The error codes can be obtained by ERR_get_error(3).

EXAMPLES

Creating a ECDSA signature of given SHA-1 hash value using the named curve secp192k1.

First step: create a EC_KEY object (note: this part is **not** ECDSA specific)

```
int        ret;
ECDSA_SIG *sig;
EC_KEY    *eckey;
eckey = EC_KEY_new_by_curve_name(NID_secp192k1);
if (eckey == NULL)
       {
       /* error */
       }
if (!EC_KEY_generate_key(eckey))
       {
       /* error */
       }
```

Second step: compute the ECDSA signature of a SHA-1 hash value using **ECDSA_do_sign**

```
sig = ECDSA_do_sign(digest, 20, eckey);
if (sig == NULL)
```

```
       {
       /* error */
       }
```

or using **ECDSA_sign**

```
unsigned char *buffer, *pp;
int            buf_len;
buf_len = ECDSA_size(eckey);
buffer  = OPENSSL_malloc(buf_len);
pp = buffer;
if (!ECDSA_sign(0, dgst, dgstlen, pp, &buf_len, eckey);
       {
       /* error */
       }
```

Third step: verify the created ECDSA signature using **ECDSA_do_verify**

```
ret = ECDSA_do_verify(digest, 20, sig, eckey);
```

or using **ECDSA_verify**

```
ret = ECDSA_verify(0, digest, 20, buffer, buf_len, eckey);
```

and finally evaluate the return value:

```
if (ret == -1)
       {
       /* error */
       }
else if (ret == 0)
       {
       /* incorrect signature */
       }
else   /* ret == 1 */
       {
       /* signature ok */
       }
```

DESCRIPTION

These functions create, manipulate, and use cryptographic modules in the form of **ENGINE** objects. These objects act as containers for implementations of cryptographic algorithms, and support a reference-counted mechanism to allow them to be dynamically loaded in and out of the running application.

The cryptographic functionality that can be provided by an **ENGINE** implementation includes the following abstractions;

```
RSA_METHOD - for providing alternative RSA implementations
DSA_METHOD, DH_METHOD, RAND_METHOD, ECDH_METHOD, ECDSA_METHOD,
      STORE_METHOD - similarly for other OpenSSL APIs
EVP_CIPHER - potentially multiple cipher algorithms (indexed by 'nid')
EVP_DIGEST - potentially multiple hash algorithms (indexed by 'nid')
key-loading - loading public and/or private EVP_PKEY keys
```

Reference counting and handles

Due to the modular nature of the ENGINE API, pointers to ENGINEs need to be treated as handles - ie. not only as pointers, but also as references to the underlying ENGINE object. Ie. one should obtain a new reference when making copies of an ENGINE pointer if the copies will be used (and released) independently.

ENGINE objects have two levels of reference-counting to match the way in which the objects are used. At the most basic level, each ENGINE pointer is inherently a **structural** reference - a structural reference is required to use the pointer value at all, as this kind of reference is a guarantee that the structure can not be deallocated until the reference is released.

However, a structural reference provides no guarantee that the ENGINE is initiliased and able to use any of its cryptographic implementations. Indeed it's quite possible that most ENGINEs will not initialise at all in typical environments, as ENGINEs are typically used to support specialised hardware. To use an ENGINE's functionality, you need a **functional** reference. This kind of reference can be considered a specialised form of structural reference, because each functional reference implicitly contains a structural reference as well - however to avoid difficult-to-find programming bugs, it is recommended to treat the two kinds of reference independently. If you have a functional reference to an ENGINE, you have a guarantee that the ENGINE has been initialised ready to perform cryptographic operations and will remain uninitialised until after you have released your reference.

Structural references

This basic type of reference is used for instantiating new ENGINEs, iterating across OpenSSL's internal linked-list of loaded ENGINEs, reading information about an ENGINE, etc. Essentially a structural reference is sufficient if you only need to query or manipulate the data of an ENGINE implementation rather than use its functionality.

The ENGINE_new() function returns a structural reference to a new (empty) ENGINE object. There are other ENGINE API functions that return structural references such as; ENGINE_by_id(), ENGINE_get_first(), ENGINE_get_last(), ENGINE_get_next(), ENGINE_get_prev(). All structural references should be released by a corresponding to call to the ENGINE_free() function - the ENGINE object itself will only actually be cleaned up and deallocated when the last structural reference is released.

It should also be noted that many ENGINE API function calls that accept a structural reference will internally obtain another reference - typically this happens whenever the supplied ENGINE will be needed by OpenSSL after the function has returned. Eg. the function to add a new ENGINE to OpenSSL's internal list is ENGINE_add() - if this function returns success, then OpenSSL will have stored a new structural reference internally so the caller is still responsible for freeing their own reference with ENGINE_free() when they are finished with it. In a similar way, some functions will automatically release the structural reference passed to it if part of the function's job is to do so. Eg. the ENGINE_get_next() and ENGINE_get_prev() functions are used for iterating across the internal ENGINE list - they will return a new structural reference to the next (or previous) ENGINE in the list or NULL if at the end (or beginning) of the list, but in either case the structural reference passed to the function is released on behalf of the caller.

To clarify a particular function's handling of references, one should always consult that function's documentation "man" page, or failing that the openssl/engine.h header file includes some hints.

Functional references

As mentioned, functional references exist when the cryptographic functionality of an ENGINE is required to be available. A functional reference can be obtained in one of two ways; from an existing structural reference to the required ENGINE, or by asking OpenSSL for the default operational ENGINE for a given cryptographic purpose.

To obtain a functional reference from an existing structural reference, call the ENGINE_init() function. This returns zero if the ENGINE was not already operational and couldn't be successfully initialised (eg. lack of system drivers, no special hardware attached, etc), otherwise it will return non-zero to indicate that the ENGINE is now operational and will have allocated a new **functional** reference to the ENGINE. All functional references are released by calling ENGINE_finish() (which removes the implicit structural reference as well).

The second way to get a functional reference is by asking OpenSSL for a default implementation for a given task, eg. by ENGINE_get_default_RSA(), ENGINE_get_default_cipher_engine(), etc. These are discussed in the next section, though they are not usually required by application programmers as they are used automatically when creating and using the relevant algorithm-specific types in OpenSSL, such as RSA, DSA, EVP_CIPHER_CTX, etc.

Default implementations

For each supported abstraction, the ENGINE code maintains an internal table of state to control which implementations are available for a given abstraction and which should be used by default. These implementations are registered in the tables and indexed by an 'nid' value, because abstractions like EVP_CIPHER and EVP_DIGEST support many distinct algorithms and modes, and ENGINEs can support arbitrarily many of them. In the case of other abstractions like RSA, DSA, etc, there is only one "algorithm" so all implementations implicitly register using the same 'nid' index.

When a default ENGINE is requested for a given abstraction/algorithm/mode, (eg. when calling RSA_new_method(NULL)), a "get_default" call will be made to the ENGINE subsystem to process the corresponding state table and return a functional reference to an initialised ENGINE whose implementation should be used. If no ENGINE should (or can) be used, it will return NULL and the caller will operate with a NULL ENGINE handle - this usually equates to using the conventional software implementation. In the latter case, OpenSSL will from then on behave the way it used to before the ENGINE API existed.

Each state table has a flag to note whether it has processed this "get_default" query since the table was last modified, because to process this question it must iterate across all the registered ENGINEs in the table trying to initialise each of them in turn, in case one of them is operational. If it returns a functional reference to an ENGINE, it will also cache another reference to speed up processing future queries (without needing to iterate across the table). Likewise, it will cache a NULL response if no ENGINE was available so that future queries won't repeat the same iteration unless the state table changes. This behaviour can also be changed; if the ENGINE_TABLE_FLAG_NOINIT flag is set (using ENGINE_set_table_flags()), no attempted initialisations will take place, instead the only way for the state table to return a non-NULL ENGINE to the "get_default" query will be if one is expressly set in the table. Eg. ENGINE_set_default_RSA() does the same job as ENGINE_register_RSA() except that it also sets the state table's cached response for the "get_default" query. In the case of abstractions like EVP_CIPHER, where implementations are indexed by 'nid', these flags and cached-responses are distinct for each 'nid' value.

Application requirements

This section will explain the basic things an application programmer should support to make the most useful elements of the ENGINE functionality available to the user. The first thing to consider is whether the programmer wishes to make alternative ENGINE modules available to the application and user. OpenSSL maintains an internal linked list of "visible" ENGINEs from which it has to operate - at start-up, this list is empty and in fact if an application does not call any ENGINE API calls and it uses static linking against openssl, then the resulting application binary will not contain any alternative ENGINE code at all. So the first consideration is whether any/all available ENGINE implementations should be made visible to OpenSSL - this is controlled by calling the various "load" functions, eg.

```
/* Make the "dynamic" ENGINE available */
void ENGINE_load_dynamic(void);
/* Make the CryptoSwift hardware acceleration support available */
void ENGINE_load_cswift(void);
/* Make support for nCipher's "CHIL" hardware available */
void ENGINE_load_chil(void);
…
/* Make ALL ENGINE implementations bundled with OpenSSL available */
void ENGINE_load_builtin_engines(void);
```

Having called any of these functions, ENGINE objects would have been dynamically allocated and populated with these implementations and linked into OpenSSL's internal linked list. At this point it is important to mention an important API function;

```
void ENGINE_cleanup(void);
```

If no ENGINE API functions are called at all in an application, then there are no inherent memory leaks to worry about from the ENGINE functionality, however if any ENGINEs are loaded, even if they are never registered or used, it is necessary to use the ENGINE_cleanup() function to correspondingly cleanup before program exit, if the caller wishes to avoid memory leaks. This mechanism uses an internal callback registration table so that any ENGINE API functionality that knows it requires cleanup can register its cleanup details to be called during ENGINE_cleanup(). This approach allows ENGINE_cleanup() to clean up after any ENGINE functionality at all that your program uses, yet doesn't automatically create linker dependencies to all possible ENGINE functionality - only the cleanup callbacks required by the functionality you do use will be required by the linker.

The fact that ENGINEs are made visible to OpenSSL (and thus are linked into the program and loaded into memory at run-time) does not mean they are "registered" or called into use by OpenSSL automatically - that behaviour is something for the application to control. Some applications will want to allow the user to specify exactly which ENGINE they want used if any is to be used at all. Others may prefer to load all support and have OpenSSL automatically use at run-time any ENGINE that is able to successfully initialise - ie. to assume that this corresponds to acceleration hardware attached to the machine or some such thing. There are probably numerous other ways in which applications may prefer to handle things, so we will simply illustrate the consequences as they apply to a couple of simple cases and leave developers to consider these and the source code to openssl's builtin utilities as guides.

Using a specific ENGINE implementation

Here we'll assume an application has been configured by its user or admin to want to use the "ACME" ENGINE if it is available in the version of OpenSSL the application was compiled with. If it is available, it should be used by default for all RSA, DSA, and symmetric cipher operation, otherwise OpenSSL should use its builtin software as per usual. The following code illustrates how to approach this;

```
ENGINE *e;
const char *engine_id = "ACME";
ENGINE_load_builtin_engines();
e = ENGINE_by_id(engine_id);
if(!e)
```

```
    /* the engine isn't available */
    return;
if(!ENGINE_init(e)) {
    /* the engine couldn't initialise, release 'e' */
    ENGINE_free(e);
    return;
}
if(!ENGINE_set_default_RSA(e))
    /* This should only happen when 'e' can't initialise, but the previous
     * statement suggests it did. */
    abort();
ENGINE_set_default_DSA(e);
ENGINE_set_default_ciphers(e);
/* Release the functional reference from ENGINE_init() */
ENGINE_finish(e);
/* Release the structural reference from ENGINE_by_id() */
ENGINE_free(e);
```

Automatically using builtin ENGINE implementations

Here we'll assume we want to load and register all ENGINE implementations bundled with OpenSSL, such that for any cryptographic algorithm required by OpenSSL - if there is an ENGINE that implements it and can be initialise, it should be used. The following code illustrates how this can work;

```
/* Load all bundled ENGINEs into memory and make them visible */
ENGINE_load_builtin_engines();
/* Register all of them for every algorithm they collectively implement */
ENGINE_register_all_complete();
```

That's all that's required. Eg. the next time OpenSSL tries to set up an RSA key, any bundled ENGINEs that implement RSA_METHOD will be passed to ENGINE_init() and if any of those succeed, that ENGINE will be set as the default for RSA use from then on.

Advanced configuration support

There is a mechanism supported by the ENGINE framework that allows each ENGINE implementation to define an arbitrary set of configuration "commands" and expose them to OpenSSL and any applications based on OpenSSL. This mechanism is entirely based on the use of name-value pairs and assumes ASCII input (no unicode or UTF for now!), so it is ideal if applications want to provide a transparent way for users to provide arbitrary configuration "directives" directly to such ENGINEs. It is also possible for the application to dynamically interrogate the loaded ENGINE implementations for the names, descriptions, and input flags of their available "control commands", providing a more flexible configuration scheme. However, if the user is expected to know which ENGINE device he/she is using (in the case of specialised hardware, this goes without saying) then applications may not need to concern themselves with discovering the supported control commands and simply prefer to pass settings into ENGINEs exactly as they are provided by the user.

Before illustrating how control commands work, it is worth mentioning what they are typically used for. Broadly speaking there are two uses for control commands; the first is to provide the necessary details to the implementation (which may know nothing at all specific to the host system) so that it can be initialised for use. This could include the path to any driver or config files it needs to load, required network addresses, smart-card identifiers, passwords to initialise protected devices, logging information, etc etc. This class of commands typically needs to be passed to an ENGINE **before** attempting to initialise it, ie. before calling ENGINE_init(). The other class of commands consist of settings or operations that tweak certain behaviour or cause certain operations to take place, and these commands may work either before or after ENGINE_init(), or in some cases both. ENGINE implementations should provide indications of this in the descriptions attached to builtin control commands and/or in external product documentation.

Issuing control commands to an ENGINE

Let's illustrate by example; a function for which the caller supplies the name of the ENGINE it wishes to use, a table of string-pairs for use before initialisation, and another table for use after initialisation. Note that the string-pairs used for control commands consist of a command "name" followed by the command "parameter" - the parameter could be NULL in some cases but the name can not. This function should initialise the ENGINE (issuing the "pre" commands beforehand and the "post" commands afterwards) and set it as the default for everything except RAND and then return a boolean success or failure.

```
int generic_load_engine_fn(const char *engine_id,
                           const char **pre_cmds, int pre_num,
                           const char **post_cmds, int post_num)
{
    ENGINE *e = ENGINE_by_id(engine_id);
    if(!e) return 0;
    while(pre_num--) {
        if(!ENGINE_ctrl_cmd_string(e, pre_cmds[0], pre_cmds[1], 0)) {
            fprintf(stderr, "Failed command (%s - %s:%s)\n", engine_id,
                pre_cmds[0], pre_cmds[1] ? pre_cmds[1] : "(NULL)");
            ENGINE_free(e);
            return 0;
        }
        pre_cmds += 2;
    }
    if(!ENGINE_init(e)) {
        fprintf(stderr, "Failed initialisation\n");
        ENGINE_free(e);
        return 0;
    }
    /* ENGINE_init() returned a functional reference, so free the structural
     * reference from ENGINE_by_id(). */
    ENGINE_free(e);
    while(post_num--) {
        if(!ENGINE_ctrl_cmd_string(e, post_cmds[0], post_cmds[1], 0)) {
            fprintf(stderr, "Failed command (%s - %s:%s)\n", engine_id,
                post_cmds[0], post_cmds[1] ? post_cmds[1] : "(NULL)");
            ENGINE_finish(e);
            return 0;
        }
        post_cmds += 2;
    }
    ENGINE_set_default(e, ENGINE_METHOD_ALL & ~ENGINE_METHOD_RAND);
    /* Success */
    return 1;
}
```

Note that ENGINE_ctrl_cmd_string() accepts a boolean argument that can relax the semantics of the function - if set non-zero it will only return failure if the ENGINE supported the given command name but failed while executing it, if the ENGINE doesn't support the command name it will simply return success without doing anything. In this case we assume the user is only supplying commands specific to the given ENGINE so we set this to FALSE.

Discovering supported control commands

It is possible to discover at run-time the names, numerical-ids, descriptions and input parameters of the control commands supported by an ENGINE using a structural reference. Note that some control commands are defined by OpenSSL itself and it will intercept and handle these control commands on behalf of the ENGINE, ie. the ENGINE's ctrl() handler is not used for the control command. openssl/engine.h defines an index, ENGINE_CMD_BASE, that all control commands implemented by ENGINEs should be numbered from. Any command value lower than this symbol is considered a "generic" command is handled directly by the OpenSSL core routines.

It is using these "core" control commands that one can discover the the control commands implemented by a given ENGINE, specifically the commands;

```
#define ENGINE_HAS_CTRL_FUNCTION                10
#define ENGINE_CTRL_GET_FIRST_CMD_TYPE          11
#define ENGINE_CTRL_GET_NEXT_CMD_TYPE           12
#define ENGINE_CTRL_GET_CMD_FROM_NAME           13
#define ENGINE_CTRL_GET_NAME_LEN_FROM_CMD       14
#define ENGINE_CTRL_GET_NAME_FROM_CMD           15
#define ENGINE_CTRL_GET_DESC_LEN_FROM_CMD       16
```

```
#define ENGINE_CTRL_GET_DESC_FROM_CMD           17
#define ENGINE_CTRL_GET_CMD_FLAGS               18
```

Whilst these commands are automatically processed by the OpenSSL framework code, they use various properties exposed by each ENGINE to process these queries. An ENGINE has 3 properties it exposes that can affect how this behaves; it can supply a ctrl() handler, it can specify ENGINE_FLAGS_MANUAL_CMD_CTRL in the ENGINE's flags, and it can expose an array of control command descriptions. If an ENGINE specifies the ENGINE_FLAGS_MANUAL_CMD_CTRL flag, then it will simply pass all these "core" control commands directly to the ENGINE's ctrl() handler (and thus, it must have supplied one), so it is up to the ENGINE to reply to these "discovery" commands itself. If that flag is not set, then the OpenSSL framework code will work with the following rules;

```
if no ctrl() handler supplied;
    ENGINE_HAS_CTRL_FUNCTION returns FALSE (zero),
    all other commands fail.
if a ctrl() handler was supplied but no array of control commands;
    ENGINE_HAS_CTRL_FUNCTION returns TRUE,
    all other commands fail.
if a ctrl() handler and array of control commands was supplied;
    ENGINE_HAS_CTRL_FUNCTION returns TRUE,
    all other commands proceed processing …
```

If the ENGINE's array of control commands is empty then all other commands will fail, otherwise; ENGINE_CTRL_GET_FIRST_CMD_TYPE returns the identifier of the first command supported by the ENGINE, ENGINE_GET_NEXT_CMD_TYPE takes the identifier of a command supported by the ENGINE and returns the next command identifier or fails if there are no more, ENGINE_CMD_FROM_NAME takes a string name for a command and returns the corresponding identifier or fails if no such command name exists, and the remaining commands take a command identifier and return properties of the corresponding commands. All except ENGINE_CTRL_GET_FLAGS return the string length of a command name or description, or populate a supplied character buffer with a copy of the command name or description. ENGINE_CTRL_GET_FLAGS returns a bitwise-OR'd mask of the following possible values;

```
#define ENGINE_CMD_FLAG_NUMERIC                 (unsigned int)0x0001
#define ENGINE_CMD_FLAG_STRING                  (unsigned int)0x0002
#define ENGINE_CMD_FLAG_NO_INPUT                (unsigned int)0x0004
#define ENGINE_CMD_FLAG_INTERNAL                (unsigned int)0x0008
```

If the ENGINE_CMD_FLAG_INTERNAL flag is set, then any other flags are purely informational to the caller - this flag will prevent the command being usable for any higher-level ENGINE functions such as ENGINE_ctrl_cmd_string(). "INTERNAL" commands are not intended to be exposed to text-based configuration by applications, administrations, users, etc. These can support arbitrary operations via ENGINE_ctrl(), including passing to and/or from the control commands data of any arbitrary type. These commands are supported in the discovery mechanisms simply to allow applications determinie if an ENGINE supports certain specific commands it might want to use (eg. application "foo" might query various ENGINEs to see if they implement "FOO_GET_VENDOR_LOGO_GIF" - and ENGINE could therefore decide whether or not to support this "foo"-specific extension).

Future developments

The ENGINE API and internal architecture is currently being reviewed. Slated for possible release in 0.9.8 is support for transparent loading of "dynamic" ENGINEs (built as self-contained shared-libraries). This would allow ENGINE implementations to be provided independently of OpenSSL libraries and/or OpenSSL-based applications, and would also remove any requirement for applications to explicitly use the "dynamic" ENGINE to bind to shared-library implementations.

DESCRIPTION

When a call to the OpenSSL library fails, this is usually signalled by the return value, and an error code is stored in an error queue associated with the current thread. The **err** library provides functions to obtain these error codes and textual error messages.

The ERR_get_error(3) manpage describes how to access error codes.

Error codes contain information about where the error occurred, and what went wrong. ERR_GET_LIB(3) describes how to extract this information. A method to obtain human-readable error messages is described in ERR_error_string(3).

ERR_clear_error(3) can be used to clear the error queue.

Note that ERR_remove_state(3) should be used to avoid memory leaks when threads are terminated.

ADDING NEW ERROR CODES TO OPENSSL

See ERR_put_error(3) if you want to record error codes in the OpenSSL error system from within your application.

The remainder of this section is of interest only if you want to add new error codes to OpenSSL or add error codes from external libraries.

Reporting errors

Each sub-library has a specific macro XXXerr() that is used to report errors. Its first argument is a function code **XXX_F_...**, the second argument is a reason code **XXX_R_...**. Function codes are derived from the function names; reason codes consist of textual error descriptions. For example, the function ssl23_read() reports a "handshake failure" as follows:

```
SSLerr(SSL_F_SSL23_READ, SSL_R_SSL_HANDSHAKE_FAILURE);
```

Function and reason codes should consist of upper case characters, numbers and underscores only. The error file generation script translates function codes into function names by looking in the header files for an appropriate function name, if none is found it just uses the capitalized form such as "SSL23_READ" in the above example.

The trailing section of a reason code (after the "_R_") is translated into lower case and underscores changed to spaces.

When you are using new function or reason codes, run **make errors**. The necessary **#define**s will then automatically be added to the sub-library's header file.

Although a library will normally report errors using its own specific XXXerr macro, another library's macro can be used. This is normally only done when a library wants to include ASN1 code which must use the ASN1err() macro.

Adding new libraries

When adding a new sub-library to OpenSSL, assign it a library number **ERR_LIB_XXX**, define a macro XXXerr() (both in **err.h**), add its name to **ERR_str_libraries[]** (in **crypto/err/err.c**), and add `ERR_load_XXX_strings()` to the ERR_load_crypto_strings() function (in **crypto/err/err_all.c**). Finally, add an entry

```
L       XXX     xxx.h   xxx_err.c
```

to **crypto/err/openssl.ec**, and add **xxx_err.c** to the Makefile. Running **make errors** will then generate a file **xxx_err.c**, and add all error codes used in the library to **xxx.h**.

Additionally the library include file must have a certain form. Typically it will initially look like this:

```
#ifndef HEADER_XXX_H
#define HEADER_XXX_H

#ifdef __cplusplus
extern "C" {
#endif

/* Include files */

#include <openssl/bio.h>
#include <openssl/x509.h>

/* Macros, structures and function prototypes */

/* BEGIN ERROR CODES */
```

The **BEGIN ERROR CODES** sequence is used by the error code generation script as the point to place new error codes, any text after this point will be overwritten when **make errors** is run. The closing #endif etc will be automatically added by the script.

The generated C error code file **xxx_err.c** will load the header files **stdio.h**, **openssl/err.h** and **openssl/xxx.h** so the header file must load any additional header files containing any definitions it uses.

USING ERROR CODES IN EXTERNAL LIBRARIES

It is also possible to use OpenSSL's error code scheme in external libraries. The library needs to load its own codes and call the OpenSSL error code insertion script **mkerr.pl** explicitly to add codes to the header file and generate the C error code file. This will normally be done if the external library needs to generate new ASN1 structures but it can also be used to add more general purpose error code handling.

TBA more details

INTERNALS

The error queues are stored in a hash table with one **ERR_STATE** entry for each pid. ERR_get_state() returns the current thread's **ERR_STATE**. An **ERR_STATE** can hold up to **ERR_NUM_ERRORS** error codes. When more error codes are added, the old ones are overwritten, on the assumption that the most recent errors are most important.

Error strings are also stored in hash table. The hash tables can be obtained by calling ERR_get_err_state_table(void) and ERR_get_string_table(void) respectively.

CRYPTO_set_locking_callback(3), ERR_get_error(3), ERR_GET_LIB(3), ERR_clear_error(3), ERR_error_string(3), ERR_print_errors(3), ERR_load_crypto_strings(3), ERR_remove_state(3), ERR_put_error(3), ERR_load_strings(3), SSL_get_error(3)

Name

ERR_clear_error — clear the error queue

Synopsis

```
#include  <openssl/err.h>
```

```
void ERR_clear_error(void);
```

DESCRIPTION

ERR_clear_error() empties the current thread's error queue.

RETURN VALUES

ERR_clear_error() has no return value.

SEE ALSO

err(3), ERR_get_error(3)

HISTORY

ERR_clear_error() is available in all versions of SSLeay and OpenSSL.

Name

ERR_error_string, ERR_error_string_n, ERR_lib_error_string, ERR_func_error_string and ERR_reason_error_string — obtain human-readable error message

Synopsis

```
#include  <openssl/err.h>
```

```
char *ERR_error_string(unsigned long e, char *buf);
void ERR_error_string_n(unsigned long e, char *buf, size_t len);
```

```
const char *ERR_lib_error_string(unsigned long e);
const char *ERR_func_error_string(unsigned long e);
const char *ERR_reason_error_string(unsigned long e);
```

DESCRIPTION

ERR_error_string() generates a human-readable string representing the error code *e*, and places it at *buf*. *buf* must be at least 120 bytes long. If *buf* is **NULL**, the error string is placed in a static buffer. ERR_error_string_n() is a variant of ERR_error_string() that writes at most *len* characters (including the terminating 0) and truncates the string if necessary. For ERR_error_string_n(), *buf* may not be **NULL**.

The string will have the following format:

```
error:[error code]:[library name]:[function name]:[reason string]
```

error code is an 8 digit hexadecimal number, *library name*, *function name* and *reason string* are ASCII text.

ERR_lib_error_string(), ERR_func_error_string() and ERR_reason_error_string() return the library name, function name and reason string respectively.

The OpenSSL error strings should be loaded by calling ERR_load_crypto_strings(3) or, for SSL applications, SSL_load_error_strings(3) first. If there is no text string registered for the given error code, the error string will contain the numeric code.

ERR_print_errors(3) can be used to print all error codes currently in the queue.

RETURN VALUES

ERR_error_string() returns a pointer to a static buffer containing the string if *buf* **== NULL**, *buf* otherwise.

ERR_lib_error_string(), ERR_func_error_string() and ERR_reason_error_string() return the strings, and **NULL** if none is registered for the error code.

SEE ALSO

err(3), ERR_get_error(3), ERR_load_crypto_strings(3), SSL_load_error_strings(3), ERR_print_errors(3)

HISTORY

ERR_error_string() is available in all versions of SSLeay and OpenSSL. ERR_error_string_n() was added in OpenSSL 0.9.6.

Name

ERR_get_error, ERR_peek_error, ERR_peek_last_error, ERR_get_error_line, ERR_peek_error_line, ERR_peek_last_error_line, ERR_get_error_line_data, ERR_peek_error_line_data and ERR_peek_last_error_line_data — obtain error code and data

Synopsis

```
#include  <openssl/err.h>
```

```
unsigned long ERR_get_error(void);
unsigned long ERR_peek_error(void);
unsigned long ERR_peek_last_error(void);
```

```
unsigned long ERR_get_error_line(const char **file, int *line);
unsigned long ERR_peek_error_line(const char **file, int *line);
unsigned long ERR_peek_last_error_line(const char **file, int *line);
```

```
unsigned long ERR_get_error_line_data(const char **file, int *line,
        const char **data, int *flags);
unsigned long ERR_peek_error_line_data(const char **file, int *line,
        const char **data, int *flags);
unsigned long ERR_peek_last_error_line_data(const char **file, int *line,
        const char **data, int *flags);
```

DESCRIPTION

ERR_get_error() returns the earliest error code from the thread's error queue and removes the entry. This function can be called repeatedly until there are no more error codes to return.

ERR_peek_error() returns the earliest error code from the thread's error queue without modifying it.

ERR_peek_last_error() returns the latest error code from the thread's error queue without modifying it.

See ERR_GET_LIB(3) for obtaining information about location and reason of the error, and ERR_error_string(3) for human-readable error messages.

ERR_get_error_line(), ERR_peek_error_line() and ERR_peek_last_error_line() are the same as the above, but they additionally store the file name and line number where the error occurred in ***file** and ***line**, unless these are **NULL**.

ERR_get_error_line_data(), ERR_peek_error_line_data() and ERR_peek_last_error_line_data() store additional data and flags associated with the error code in ***data** and ***flags**, unless these are **NULL**. ***data** contains a string if ***flags&ERR_TXT_STRING** is true.

An application **MUST NOT** free the ***data** pointer (or any other pointers returned by these functions) with OPENSSL_free() as freeing is handled automatically by the error library.

RETURN VALUES

The error code, or 0 if there is no error in the queue.

SEE ALSO

err(3), ERR_error_string(3), ERR_GET_LIB(3)

HISTORY

ERR_get_error(), ERR_peek_error(), ERR_get_error_line() and ERR_peek_error_line() are available in all versions of SSLeay and OpenSSL. ERR_get_error_line_data() and ERR_peek_error_line_data() were added in SSLeay 0.9.0. ERR_peek_last_error(), ERR_peek_last_error_line() and ERR_peek_last_error_line_data() were added in OpenSSL 0.9.7.

Name

ERR_GET_LIB, ERR_GET_FUNC and ERR_GET_REASON — get library, function and reason code

Synopsis

```
#include  <openssl/err.h>
```

```
int ERR_GET_LIB(unsigned long e);
```

```
int ERR_GET_FUNC(unsigned long e);
```

```
int ERR_GET_REASON(unsigned long e);
```

DESCRIPTION

The error code returned by ERR_get_error() consists of a library number, function code and reason code. ERR_GET_LIB(), ERR_GET_FUNC() and ERR_GET_REASON() can be used to extract these.

The library number and function code describe where the error occurred, the reason code is the information about what went wrong.

Each sub-library of OpenSSL has a unique library number; function and reason codes are unique within each sub-library. Note that different libraries may use the same value to signal different functions and reasons.

ERR_R_... reason codes such as **ERR_R_MALLOC_FAILURE** are globally unique. However, when checking for sub-library specific reason codes, be sure to also compare the library number.

ERR_GET_LIB(), ERR_GET_FUNC() and ERR_GET_REASON() are macros.

RETURN VALUES

The library number, function code and reason code respectively.

SEE ALSO

err(3), ERR_get_error(3)

HISTORY

ERR_GET_LIB(), ERR_GET_FUNC() and ERR_GET_REASON() are available in all versions of SSLeay and OpenSSL.

Name

ERR_load_crypto_strings, SSL_load_error_strings and ERR_free_strings — load and free error strings

Synopsis

```
#include  <openssl/err.h>
```

```
void ERR_load_crypto_strings(void);
void ERR_free_strings(void);
```

```
#include  <openssl/ssl.h>
```

```
void SSL_load_error_strings(void);
```

DESCRIPTION

ERR_load_crypto_strings() registers the error strings for all **libcrypto** functions. SSL_load_error_strings() does the same, but also registers the **libssl** error strings.

One of these functions should be called before generating textual error messages. However, this is not required when memory usage is an issue.

ERR_free_strings() frees all previously loaded error strings.

RETURN VALUES

ERR_load_crypto_strings(), SSL_load_error_strings() and ERR_free_strings() return no values.

SEE ALSO

err(3), ERR_error_string(3)

HISTORY

ERR_load_error_strings(), SSL_load_error_strings() and ERR_free_strings() are available in all versions of SSLeay and OpenSSL.

Name

ERR_load_strings, ERR_PACK and ERR_get_next_error_library — load arbitrary error strings

Synopsis

```
#include  <openssl/err.h>
```

```
void ERR_load_strings(int lib, ERR_STRING_DATA str[]);
```

```
int ERR_get_next_error_library(void);
```

```
unsigned long ERR_PACK(int lib, int func, int reason);
```

DESCRIPTION

ERR_load_strings() registers error strings for library number **lib**.

str is an array of error string data:

```
typedef struct ERR_string_data_st
{
       unsigned long error;
       char *string;
} ERR_STRING_DATA;
```

and reason code: **error** = ERR_PACK(**lib**, **func**, **reason**). ERR_PACK() is a macro.

The last entry in the array is {0,0}.

ERR_get_next_error_library() can be used to assign library numbers to user libraries at runtime.

RETURN VALUE

ERR_load_strings() returns no value. ERR_PACK() return the error code. ERR_get_next_error_library() returns a new library number.

SEE ALSO

err(3), ERR_load_strings(3)

HISTORY

ERR_load_error_strings() and ERR_PACK() are available in all versions of SSLeay and OpenSSL. ERR_get_next_error_library() was added in SSLeay 0.9.0.

Name

ERR_print_errors and ERR_print_errors_fp — print error messages

Synopsis

```
#include  <openssl/err.h>
```

```
void ERR_print_errors(BIO *bp);
void ERR_print_errors_fp(FILE *fp);
```

DESCRIPTION

ERR_print_errors() is a convenience function that prints the error strings for all errors that OpenSSL has recorded to **bp**, thus emptying the error queue.

ERR_print_errors_fp() is the same, except that the output goes to a **FILE**.

The error strings will have the following format:

```
[pid]:error:[error code]:[library name]:[function name]:[reason string]:[file name]:[line]:[optional text message]
```

error code is an 8 digit hexadecimal number. *library name*, *function name* and *reason string* are ASCII text, as is *optional text message* if one was set for the respective error code.

If there is no text string registered for the given error code, the error string will contain the numeric code.

RETURN VALUES

ERR_print_errors() and ERR_print_errors_fp() return no values.

SEE ALSO

err(3), ERR_error_string(3), ERR_get_error(3), ERR_load_crypto_strings(3), SSL_load_error_strings(3)

HISTORY

ERR_print_errors() and ERR_print_errors_fp() are available in all versions of SSLeay and OpenSSL.

Name

ERR_put_error and ERR_add_error_data — record an error

Synopsis

```
#include  <openssl/err.h>
```

```
void ERR_put_error(int lib, int func, int reason, const char *file,
        int line);
```

```
void ERR_add_error_data(int num, …);
```

DESCRIPTION

ERR_put_error() adds an error code to the thread's error queue. It signals that the error of reason code **reason** occurred in function **func** of library **lib**, in line number **line** of **file**. This function is usually called by a macro.

ERR_add_error_data() associates the concatenation of its **num** string arguments with the error code added last.

ERR_load_strings(3) can be used to register error strings so that the application can a generate human-readable error messages for the error code.

RETURN VALUES

ERR_put_error() and ERR_add_error_data() return no values.

SEE ALSO

err(3), ERR_load_strings(3)

HISTORY

ERR_put_error() is available in all versions of SSLeay and OpenSSL. ERR_add_error_data() was added in SSLeay 0.9.0.

Name

ERR_remove_state — free a thread's error queue

Synopsis

```
#include  <openssl/err.h>
```

```
void ERR_remove_state(unsigned long pid);
```

DESCRIPTION

ERR_remove_state() frees the error queue associated with thread **pid**. If **pid** == 0, the current thread will have its error queue removed.

Since error queue data structures are allocated automatically for new threads, they must be freed when threads are terminated in order to avoid memory leaks.

RETURN VALUE

ERR_remove_state() returns no value.

SEE ALSO

err(3)

HISTORY

ERR_remove_state() is available in all versions of SSLeay and OpenSSL.

Name

ERR_set_mark and ERR_pop_to_mark — set marks and pop errors until mark

Synopsis

```
#include  <openssl/err.h>
```

```
int ERR_set_mark(void);
```

```
int ERR_pop_to_mark(void);
```

DESCRIPTION

ERR_set_mark() sets a mark on the current topmost error record if there is one.

ERR_pop_to_mark() will pop the top of the error stack until a mark is found. The mark is then removed. If there is no mark, the whole stack is removed.

RETURN VALUES

ERR_set_mark() returns 0 if the error stack is empty, otherwise 1.

ERR_pop_to_mark() returns 0 if there was no mark in the error stack, which implies that the stack became empty, otherwise 1.

SEE ALSO

err(3)

HISTORY

ERR_set_mark() and ERR_pop_to_mark() were added in OpenSSL 0.9.8.

Name

evp — high-level cryptographic functions

Synopsis

```
#include  <openssl/evp.h>
```

DESCRIPTION

The EVP library provides a high-level interface to cryptographic functions.

EVP_Seal… and **EVP_Open**… provide public key encryption and decryption to implement digital "envelopes".

The **EVP_Sign**… and **EVP_Verify**… functions implement digital signatures.

Symmetric encryption is available with the **EVP_Encrypt**… functions. The **EVP_Digest**… functions provide message digests.

The **EVP_PKEY**… functions provide a high level interface to asymmetric algorithms.

The **EVP_Encode**… and **EVP_Decode**… functions implement base 64 encoding and decoding.

Algorithms are loaded with OpenSSL_add_all_algorithms(3).

All the symmetric algorithms (ciphers), digests and asymmetric algorithms (public key algorithms) can be replaced by ENGINE modules providing alternative implementations. If ENGINE implementations of ciphers or digests are registered as defaults, then the various EVP functions will automatically use those implementations automatically in preference to built in software implementations. For more information, consult the engine(3) man page.

Although low level algorithm specific functions exist for many algorithms their use is discouraged. They cannot be used with an ENGINE and ENGINE versions of new algorithms cannot be accessed using the low level functions. Also makes code harder to adapt to new algorithms and some options are not cleanly supported at the low level and some operations are more efficient using the high level interface.

SEE ALSO

EVP_DigestInit(3), EVP_EncryptInit(3), EVP_OpenInit(3), EVP_SealInit(3), EVP_SignInit(3), EVP_VerifyInit(3), EVP_EncodeInit(3), OpenSSL_add_all_algorithms(3), engine(3)

Name

EVP_BytesToKey — password based encryption routine

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_BytesToKey(const EVP_CIPHER *type,const EVP_MD *md,
                      const unsigned char *salt,
                      const unsigned char *data, int datal, int count,
                      unsigned char *key,unsigned char *iv);
```

DESCRIPTION

EVP_BytesToKey() derives a key and IV from various parameters. **type** is the cipher to derive the key and IV for. **md** is the message digest to use. The **salt** parameter is used as a salt in the derivation: it should point to an 8 byte buffer or NULL if no salt is used. **data** is a buffer containing **datal** bytes which is used to derive the keying data. **count** is the iteration count to use. The derived key and IV will be written to **key** and **iv** respectively.

NOTES

A typical application of this function is to derive keying material for an encryption algorithm from a password in the **data** parameter.

Increasing the **count** parameter slows down the algorithm which makes it harder for an attacker to peform a brute force attack using a large number of candidate passwords.

If the total key and IV length is less than the digest length and **MD5** is used then the derivation algorithm is compatible with PKCS#5 v1.5 otherwise a non standard extension is used to derive the extra data.

Newer applications should use more standard algorithms such as PKCS#5 v2.0 for key derivation.

KEY DERIVATION ALGORITHM

The key and IV is derived by concatenating D_1, D_2, etc until enough data is available for the key and IV. D_i is defined as:

```
D_i = HASH^count(D_(i-1) || data || salt)
```

where || denotes concatentaion, D_0 is empty, HASH is the digest algorithm in use, HASH^1(data) is simply HASH(data), HASH^2(data) is HASH(HASH(data)) and so on.

The initial bytes are used for the key and the subsequent bytes for the IV.

RETURN VALUES

EVP_BytesToKey() returns the size of the derived key in bytes.

```

DESCRIPTION

The EVP digest routines are a high level interface to message digests.

EVP_MD_CTX_init() initializes digest context **ctx**.

EVP_MD_CTX_create() allocates, initializes and returns a digest context.

EVP_DigestInit_ex() sets up digest context **ctx** to use a digest **type** from ENGINE **impl**. **ctx** must be initialized before calling this function. **type** will typically be supplied by a functionsuch as EVP_sha1(). If **impl** is NULL then the default implementation of digest **type** is used.

EVP_DigestUpdate() hashes **cnt** bytes of data at **d** into the digest context **ctx**. This function can be called several times on the same **ctx** to hash additional data.

EVP_DigestFinal_ex() retrieves the digest value from **ctx** and places it in **md**. If the **s** parameter is not NULL then the number of bytes of data written (i.e. the length of the digest) will be written to the integer at **s**, at most **EVP_MAX_MD_SIZE** bytes will be written. After calling EVP_DigestFinal_ex() no additional calls to EVP_DigestUpdate() can be made, but EVP_DigestInit_ex() can be called to initialize a new digest operation.

EVP_MD_CTX_cleanup() cleans up digest context **ctx**, it should be called after a digest context is no longer needed.

EVP_MD_CTX_destroy() cleans up digest context **ctx** and frees up the space allocated to it, it should be called only on a context created using EVP_MD_CTX_create().

EVP_MD_CTX_copy_ex() can be used to copy the message digest state from **in** to **out**. This is useful if large amounts of data are to be hashed which only differ in the last few bytes. **out** must be initialized before calling this function.

EVP_DigestInit() behaves in the same way as EVP_DigestInit_ex() except the passed context **ctx** does not have to be initialized, and it always uses the default digest implementation.

EVP_DigestFinal() is similar to EVP_DigestFinal_ex() except the digest context **ctx** is automatically cleaned up.

EVP_MD_CTX_copy() is similar to EVP_MD_CTX_copy_ex() except the destination **out** does not have to be initialized.

EVP_MD_size() and EVP_MD_CTX_size() return the size of the message digest when passed an **EVP_MD** or an **EVP_MD_CTX** structure, i.e. the size of the hash.

EVP_MD_block_size() and EVP_MD_CTX_block_size() return the block size of the message digest when passed an **EVP_MD** or an **EVP_MD_CTX** structure.

EVP_MD_type() and EVP_MD_CTX_type() return the NID of the OBJECT IDENTIFIER representing the given message digest when passed an **EVP_MD** structure. For example EVP_MD_type(EVP_sha1()) returns **NID_sha1**. This function is normally used when setting ASN1 OIDs.

EVP_MD_CTX_md() returns the **EVP_MD** structure corresponding to the passed **EVP_MD_CTX**.

EVP_MD_pkey_type() returns the NID of the public key signing algorithm associated with this digest. For example EVP_sha1() is associated with RSA so this will return **NID_sha1WithRSAEncryption**. Since digests and signature algorithms are no longer linked this function is only retained for compatibility reasons.

EVP_md2(), EVP_md5(), EVP_sha(), EVP_sha1(), EVP_sha224(), EVP_sha256(), EVP_sha384(), EVP_sha512(), EVP_mdc2() and EVP_ripemd160() return **EVP_MD** structures for the MD2, MD5, SHA, SHA1, SHA224, SHA256, SHA384, SHA512, MDC2 and RIPEMD160 digest algorithms respectively.

EVP_dss() and EVP_dss1() return **EVP_MD** structures for SHA and SHA1 digest algorithms but using DSS (DSA) for the signature algorithm. Note: there is no need to use these pseudo-digests in OpenSSL 1.0.0 and later, they are however retained for compatibility.

EVP_md_null() is a "null" message digest that does nothing: i.e. the hash it returns is of zero length.

EVP_get_digestbyname(), EVP_get_digestbynid() and EVP_get_digestbyobj() return an **EVP_MD** structure when passed a digest name, a digest NID or an ASN1_OBJECT structure respectively. The digest table must be initialized using, for example, OpenSSL_add_all_digests() for these functions to work.

RETURN VALUES

EVP_DigestInit_ex(), EVP_DigestUpdate() and EVP_DigestFinal_ex() return 1 for success and 0 for failure.

EVP_MD_CTX_copy_ex() returns 1 if successful or 0 for failure.

EVP_MD_type(), EVP_MD_pkey_type() and EVP_MD_type() return the NID of the corresponding OBJECT IDENTIFIER or NID_undef if none exists.

EVP_MD_size(), EVP_MD_block_size(), EVP_MD_CTX_size() and EVP_MD_CTX_block_size() return the digest or block size in bytes.

EVP_md_null(), EVP_md2(), EVP_md5(), EVP_sha(), EVP_sha1(), EVP_dss(), EVP_dss1(), EVP_mdc2() and EVP_ripemd160() return pointers to the corresponding EVP_MD structures.

EVP_get_digestbyname(), EVP_get_digestbynid() and EVP_get_digestbyobj() return either an **EVP_MD** structure or NULL if an error occurs.

NOTES

The **EVP** interface to message digests should almost always be used in preference to the low level interfaces. This is because the code then becomes transparent to the digest used and much more flexible.

New applications should use the SHA2 digest algorithms such as SHA256. The other digest algorithms are still in common use.

For most applications the **impl** parameter to EVP_DigestInit_ex() will be set to NULL to use the default digest implementation.

The functions EVP_DigestInit(), EVP_DigestFinal() and EVP_MD_CTX_copy() are obsolete but are retained to maintain compatibility with existing code. New applications should use EVP_DigestInit_ex(), EVP_DigestFinal_ex() and EVP_MD_CTX_copy_ex() because they can efficiently reuse a digest context instead of initializing and cleaning it up on each call and allow non default implementations of digests to be specified.

In OpenSSL 0.9.7 and later if digest contexts are not cleaned up after use memory leaks will occur.

Stack allocation of EVP_MD_CTX structures is common, for example:

```
EVP_MD_CTX mctx;
EVP_MD_CTX_init(&mctx);
```

This will cause binary compatibility issues if the size of EVP_MD_CTX structure changes (this will only happen with a major release of OpenSSL). Applications wishing to avoid this should use EVP_MD_CTX_create() instead:

```
EVP_MD_CTX *mctx;
mctx = EVP_MD_CTX_create();
```

EXAMPLE

This example digests the data "Test Message\n" and "Hello World\n", using the digest name passed on the command line.

```
#include <stdio.h>
#include <openssl/evp.h>

main(int argc, char *argv[])
{
```

```
EVP_MD_CTX *mdctx;
const EVP_MD *md;
char mess1[] = "Test Message\n";
char mess2[] = "Hello World\n";
unsigned char md_value[EVP_MAX_MD_SIZE];
int md_len, i;

OpenSSL_add_all_digests();

if(!argv[1]) {
       printf("Usage: mdtest digestname\n");
       exit(1);
}

md = EVP_get_digestbyname(argv[1]);

if(!md) {
       printf("Unknown message digest %s\n", argv[1]);
       exit(1);
}

mdctx = EVP_MD_CTX_create();
EVP_DigestInit_ex(mdctx, md, NULL);
EVP_DigestUpdate(mdctx, mess1, strlen(mess1));
EVP_DigestUpdate(mdctx, mess2, strlen(mess2));
EVP_DigestFinal_ex(mdctx, md_value, &md_len);
EVP_MD_CTX_destroy(mdctx);

printf("Digest is: ");
for(i = 0; i < md_len; i++)
       printf("%02x", md_value[i]);
printf("\n");

/* Call this once before exit. */
EVP_cleanup();
exit(0);
}
```

HISTORY

EVP_DigestInit(), EVP_DigestUpdate() and EVP_DigestFinal() are available in all versions of SSLeay and OpenSSL.

EVP_MD_CTX_init(), EVP_MD_CTX_create(), EVP_MD_CTX_copy_ex(), EVP_MD_CTX_cleanup(), EVP_MD_CTX_destroy(), EVP_DigestInit_ex() and EVP_DigestFinal_ex() were added in OpenSSL 0.9.7.

EVP_md_null(), EVP_md2(), EVP_md5(), EVP_sha(), EVP_sha1(), EVP_dss(), EVP_dss1(), EVP_mdc2() and EVP_ripemd160() were changed to return truely const EVP_MD * in OpenSSL 0.9.7.

The link between digests and signing algorithms was fixed in OpenSSL 1.0 and later, so now EVP_sha1() can be used with RSA and DSA; there is no need to use EVP_dss1() any more.

OpenSSL 1.0 and later does not include the MD2 digest algorithm in the default configuration due to its security weaknesses.

Name

EVP_DigestSignInit, EVP_DigestSignUpdate and EVP_DigestSignFinal — EVP signing functions

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_DigestSignInit(EVP_MD_CTX *ctx, EVP_PKEY_CTX **pctx,
                       const EVP_MD *type, ENGINE *e, EVP_PKEY *pkey);
int EVP_DigestSignUpdate(EVP_MD_CTX *ctx, const void *d, unsigned int cnt);
int EVP_DigestSignFinal(EVP_MD_CTX *ctx, unsigned char *sig, size_t *siglen);
```

DESCRIPTION

The EVP signature routines are a high level interface to digital signatures.

EVP_DigestSignInit() sets up signing context **ctx** to use digest **type** from ENGINE **impl** and private key **pkey**. **ctx** must be initialized with EVP_MD_CTX_init() before calling this function. If **pctx** is not NULL the EVP_PKEY_CTX of the signing operation will be written to ***pctx**: this can be used to set alternative signing options.

EVP_DigestSignUpdate() hashes **cnt** bytes of data at **d** into the signature context **ctx**. This function can be called several times on the same **ctx** to include additional data. This function is currently implemented usig a macro.

EVP_DigestSignFinal() signs the data in **ctx** places the signature in **sig**. If **sig** is **NULL** then the maximum size of the output buffer is written to the **siglen** parameter. If **sig** is not **NULL** then before the call the **siglen** parameter should contain the length of the **sig** buffer, if the call is successful the signature is written to **sig** and the amount of data written to **siglen**.

RETURN VALUES

EVP_DigestSignInit() EVP_DigestSignUpdate() and EVP_DigestSignaFinal() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

The error codes can be obtained from ERR_get_error(3).

NOTES

The **EVP** interface to digital signatures should almost always be used in preference to the low level interfaces. This is because the code then becomes transparent to the algorithm used and much more flexible.

In previous versions of OpenSSL there was a link between message digest types and public key algorithms. This meant that "clone" digests such as EVP_dss1() needed to be used to sign using SHA1 and DSA. This is no longer necessary and the use of clone digest is now discouraged.

For some key types and parameters the random number generator must be seeded or the operation will fail.

The call to EVP_DigestSignFinal() internally finalizes a copy of the digest context. This means that calls to EVP_DigestSignUpdate() and EVP_DigestSignFinal() can be called later to digest and sign additional data.

Since only a copy of the digest context is ever finalized the context must be cleaned up after use by calling EVP_MD_CTX_cleanup() or a memory leak will occur.

The use of EVP_PKEY_size() with these functions is discouraged because some signature operations may have a signature length which depends on the parameters set. As a result EVP_PKEY_size() would have to return a value which indicates the maximum possible signature for any set of parameters.

SEE ALSO

HISTORY

EVP_DigestSignInit(), EVP_DigestSignUpdate() and EVP_DigestSignFinal() were first added to OpenSSL 1.0.0.

Name

EVP_DigestVerifyInit, EVP_DigestVerifyUpdate and EVP_DigestVerifyFinal — EVP signature verification functions

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_DigestVerifyInit(EVP_MD_CTX *ctx, EVP_PKEY_CTX **pctx,
                       const EVP_MD *type, ENGINE *e, EVP_PKEY *pkey);
int EVP_DigestVerifyUpdate(EVP_MD_CTX *ctx, const void *d, unsigned int cnt);
int EVP_DigestVerifyFinal(EVP_MD_CTX *ctx, unsigned char *sig, size_t siglen);
```

DESCRIPTION

The EVP signature routines are a high level interface to digital signatures.

EVP_DigestVerifyInit() sets up verification context **ctx** to use digest **type** from ENGINE **impl** and public key **pkey**. **ctx** must be initialized with EVP_MD_CTX_init() before calling this function. If **pctx** is not NULL the EVP_PKEY_CTX of the verification operation will be written to ***pctx**: this can be used to set alternative verification options.

EVP_DigestVerifyUpdate() hashes **cnt** bytes of data at **d** into the verification context **ctx**. This function can be called several times on the same **ctx** to include additional data. This function is currently implemented using a macro.

EVP_DigestVerifyFinal() verifies the data in **ctx** against the signature in **sig** of length **siglen**.

RETURN VALUES

EVP_DigestVerifyInit() and EVP_DigestVerifyUpdate() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EVP_DigestVerifyFinal() returns 1 for success; any other value indicates failure. A return value of zero indicates that the signature did not verify successfully (that is, tbs did not match the original data or the signature had an invalid form), while other values indicate a more serious error (and sometimes also indicate an invalid signature form).

The error codes can be obtained from ERR_get_error(3).

NOTES

The **EVP** interface to digital signatures should almost always be used in preference to the low level interfaces. This is because the code then becomes transparent to the algorithm used and much more flexible.

In previous versions of OpenSSL there was a link between message digest types and public key algorithms. This meant that "clone" digests such as EVP_dss1() needed to be used to sign using SHA1 and DSA. This is no longer necessary and the use of clone digest is now discouraged.

For some key types and parameters the random number generator must be seeded or the operation will fail.

The call to EVP_DigestVerifyFinal() internally finalizes a copy of the digest context. This means that EVP_VerifyUpdate() and EVP_VerifyFinal() can be called later to digest and verify additional data.

Since only a copy of the digest context is ever finalized the context must be cleaned up after use by calling EVP_MD_CTX_cleanup() or a memory leak will occur.

                    char *out, int *outl);
int EVP_DecodeBlock(unsigned char *t, const unsigned char *f, int n);
```

DESCRIPTION

The EVP encode routines provide a high level interface to base 64 encoding and decoding. Base 64 encoding converts binary data into a printable form that uses the characters A-Z, a-z, 0-9, "+" and "/" to represent the data. For every 3 bytes of binary data provided 4 bytes of base 64 encoded data will be produced plus some occasional newlines (see below). If the input data length is not a multiple of 3 then the output data will be padded at the end using the "=" character.

Encoding of binary data is performed in blocks of 48 input bytes (or less for the final block). For each 48 byte input block encoded 64 bytes of base 64 data is output plus an additional newline character (i.e. 65 bytes in total). The final block (which may be less than 48 bytes) will output 4 bytes for every 3 bytes of input. If the data length is not divisible by 3 then a full 4 bytes is still output for the final 1 or 2 bytes of input. Similarly a newline character will also be output.

EVP_EncodeInit() initialises **ctx** for the start of a new encoding operation.

EVP_EncodeUpdate() encode **inl** bytes of data found in the buffer pointed to by **in**. The output is stored in the buffer **out** and the number of bytes output is stored in ***outl**. It is the caller's responsibility to ensure that the buffer at **out** is sufficiently large to accommodate the output data. Only full blocks of data (48 bytes) will be immediately processed and output by this function. Any remainder is held in the **ctx** object and will be processed by a subsequent call to EVP_EncodeUpdate() or EVP_EncodeFinal(). To calculate the required size of the output buffer add together the value of **inl** with the amount of unprocessed data held in **ctx** and divide the result by 48 (ignore any remainder). This gives the number of blocks of data that will be processed. Ensure the output buffer contains 65 bytes of storage for each block, plus an additional byte for a NUL terminator. EVP_EncodeUpdate() may be called repeatedly to process large amounts of input data. In the event of an error EVP_EncodeUpdate() will set ***outl** to 0.

EVP_EncodeFinal() must be called at the end of an encoding operation. It will process any partial block of data remaining in the **ctx** object. The output data will be stored in **out** and the length of the data written will be stored in ***outl**. It is the caller's responsibility to ensure that **out** is sufficiently large to accommodate the output data which will never be more than 65 bytes plus an additional NUL terminator (i.e. 66 bytes in total).

EVP_EncodeBlock() encodes a full block of input data in **f** and of length **dlen** and stores it in **t**. For every 3 bytes of input provided 4 bytes of output data will be produced. If **dlen** is not divisible by 3 then the block is encoded as a final block of data and the output is padded such that it is always divisible by 4. Additionally a NUL terminator character will be added. For example if 16 bytes of input data is provided then 24 bytes of encoded data is created plus 1 byte for a NUL terminator (i.e. 25 bytes in total). The length of the data generated *without* the NUL terminator is returned from the function.

EVP_DecodeInit() initialises **ctx** for the start of a new decoding operation.

EVP_DecodeUpdate() decodes **inl** characters of data found in the buffer pointed to by **in**. The output is stored in the buffer **out** and the number of bytes output is stored in ***outl**. It is the caller's responsibility to ensure that the buffer at **out** is sufficiently large to accommodate the output data. This function will attempt to decode as much data as possible in 4 byte chunks. Any whitespace, newline or carriage return characters are ignored. Any partial chunk of unprocessed data (1, 2 or 3 bytes) that remains at the end will be held in the **ctx** object and processed by a subsequent call to EVP_DecodeUpdate(). If any illegal base 64 characters are encountered or if the base 64 padding character "=" is encountered in the middle of the data then the function returns -1 to indicate an error. A return value of 0 or 1 indicates successful processing of the data. A return value of 0 additionally indicates that the last input data characters processed included the base 64 padding character "=" and therefore no more non-padding character data is expected to be processed. For every 4 valid base 64 bytes processed (ignoring whitespace, carriage returns and line feeds), 3 bytes of binary output data will be produced (or less at the end of the data where the padding character "=" has been used).

EVP_DecodeFinal() must be called at the end of a decoding operation. If there is any unprocessed data still in **ctx** then the input data must not have been a multiple of 4 and therefore an error has occurred. The function will return -1 in this case. Otherwise the function returns 1 on success.

EVP_DecodeBlock() will decode the block of **n** characters of base 64 data contained in **f** and store the result in **t**. Any leading whitespace will be trimmed as will any trailing whitespace, newlines, carriage returns or EOF characters. After such trimming the length of the data in **f** must be divisbile by 4. For every 4 input bytes exactly 3 output bytes will be produced. The output will be padded with 0 bits if necessary to ensure that the output is always 3 bytes for every 4 input bytes. This function will return the length of the data decoded or -1 on error.

RETURN VALUES

EVP_EncodeBlock() returns the number of bytes encoded excluding the NUL terminator.

EVP_DecodeUpdate() returns -1 on error and 0 or 1 on success. If 0 is returned then no more non-padding base 64 characters are expected.

EVP_DecodeFinal() returns -1 on error or 1 on success.

EVP_DecodeBlock() returns the length of the data decoded or -1 on error.

```

DESCRIPTION

The EVP cipher routines are a high level interface to certain symmetric ciphers.

EVP_CIPHER_CTX_init() initializes cipher contex **ctx**.

EVP_EncryptInit_ex() sets up cipher context **ctx** for encryption with cipher **type** from ENGINE **impl**. **ctx** must be initialized before calling this function. **type** is normally supplied by a function such as EVP_des_cbc(). If **impl** is NULL then the default implementation is used. **key** is the symmetric key to use and **iv** is the IV to use (if necessary), the actual number of bytes used for the key and IV depends on the cipher. It is possible to set all parameters to NULL except **type** in an initial call and supply the remaining parameters in subsequent calls, all of which have **type** set to NULL. This is done when the default cipher parameters are not appropriate.

EVP_EncryptUpdate() encrypts **inl** bytes from the buffer **in** and writes the encrypted version to **out**. This function can be called multiple times to encrypt successive blocks of data. The amount of data written depends on the block alignment of the encrypted data: as a result the amount of data written may be anything from zero bytes to (inl + cipher_block_size - 1) so **out** should contain sufficient room. The actual number of bytes written is placed in **outl**.

If padding is enabled (the default) then EVP_EncryptFinal_ex() encrypts the "final" data, that is any data that remains in a partial block. It uses “standard block padding” (aka PKCS padding). The encrypted final data is written to **out** which should have sufficient space for one cipher block. The number of bytes written is placed in **outl**. After this function is called the encryption operation is finished and no further calls to EVP_EncryptUpdate() should be made.

If padding is disabled then EVP_EncryptFinal_ex() will not encrypt any more data and it will return an error if any data remains in a partial block: that is if the total data length is not a multiple of the block size.

EVP_DecryptInit_ex(), EVP_DecryptUpdate() and EVP_DecryptFinal_ex() are the corresponding decryption operations. EVP_DecryptFinal() will return an error code if padding is enabled and the final block is not correctly formatted. The parameters and restrictions are identical to the encryption operations except that if padding is enabled the decrypted data buffer **out** passed to EVP_DecryptUpdate() should have sufficient room for (**inl** + cipher_block_size) bytes unless the cipher block size is 1 in which case **inl** bytes is sufficient.

EVP_CipherInit_ex(), EVP_CipherUpdate() and EVP_CipherFinal_ex() are functions that can be used for decryption or encryption. The operation performed depends on the value of the **enc** parameter. It should be set to 1 for encryption, 0 for decryption and -1 to leave the value unchanged (the actual value of 'enc' being supplied in a previous call).

EVP_CIPHER_CTX_cleanup() clears all information from a cipher context and free up any allocated memory associate with it. It should be called after all operations using a cipher are complete so sensitive information does not remain in memory.

EVP_EncryptInit(), EVP_DecryptInit() and EVP_CipherInit() behave in a similar way to EVP_EncryptInit_ex(), EVP_DecryptInit_ex and EVP_CipherInit_ex() except the **ctx** parameter does not need to be initialized and they always use the default cipher implementation.

EVP_EncryptFinal(), EVP_DecryptFinal() and EVP_CipherFinal() behave in a similar way to EVP_EncryptFinal_ex(), EVP_DecryptFinal_ex() and EVP_CipherFinal_ex() except **ctx** is automatically cleaned up after the call.

EVP_get_cipherbyname(), EVP_get_cipherbynid() and EVP_get_cipherbyobj() return an EVP_CIPHER structure when passed a cipher name, a NID or an ASN1_OBJECT structure.

EVP_CIPHER_nid() and EVP_CIPHER_CTX_nid() return the NID of a cipher when passed an **EVP_CIPHER** or **EVP_CIPHER_CTX** structure. The actual NID value is an internal value which may not have a corresponding OBJECT IDENTIFIER.

EVP_CIPHER_CTX_set_padding() enables or disables padding. By default encryption operations are padded using standard block padding and the padding is checked and removed when decrypting. If the **pad** parameter is zero then no padding is performed, the total amount of data encrypted or decrypted must then be a multiple of the block size or an error will occur.

EVP_CIPHER_key_length() and EVP_CIPHER_CTX_key_length() return the key length of a cipher when passed an **EVP_CIPHER** or **EVP_CIPHER_CTX** structure. The constant **EVP_MAX_KEY_LENGTH** is the maximum key length for all ciphers. Note: although EVP_CIPHER_key_length() is fixed for a given cipher, the value of EVP_CIPHER_CTX_key_length() may be different for variable key length ciphers.

EVP_CIPHER_CTX_set_key_length() sets the key length of the cipher ctx. If the cipher is a fixed length cipher then attempting to set the key length to any value other than the fixed value is an error.

EVP_CIPHER_iv_length() and EVP_CIPHER_CTX_iv_length() return the IV length of a cipher when passed an **EVP_CIPHER** or **EVP_CIPHER_CTX**. It will return zero if the cipher does not use an IV. The constant **EVP_MAX_IV_LENGTH** is the maximum IV length for all ciphers.

EVP_CIPHER_block_size() and EVP_CIPHER_CTX_block_size() return the block size of a cipher when passed an **EVP_CIPHER** or **EVP_CIPHER_CTX** structure. The constant **EVP_MAX_IV_LENGTH** is also the maximum block length for all ciphers.

EVP_CIPHER_type() and EVP_CIPHER_CTX_type() return the type of the passed cipher or context. This "type" is the actual NID of the cipher OBJECT IDENTIFIER as such it ignores the cipher parameters and 40 bit RC2 and 128 bit RC2 have the same NID. If the cipher does not have an object identifier or does not have ASN1 support this function will return **NID_undef**.

EVP_CIPHER_CTX_cipher() returns the **EVP_CIPHER** structure when passed an **EVP_CIPHER_CTX** structure.

EVP_CIPHER_mode() and EVP_CIPHER_CTX_mode() return the block cipher mode: EVP_CIPH_ECB_MODE, EVP_CIPH_CBC_MODE, EVP_CIPH_CFB_MODE or EVP_CIPH_OFB_MODE. If the cipher is a stream cipher then EVP_CIPH_STREAM_CIPHER is returned.

EVP_CIPHER_param_to_asn1() sets the AlgorithmIdentifier "parameter" based on the passed cipher. This will typically include any parameters and an IV. The cipher IV (if any) must be set when this call is made. This call should be made before the cipher is actually "used" (before any EVP_EncryptUpdate(), EVP_DecryptUpdate() calls for example). This function may fail if the cipher does not have any ASN1 support.

EVP_CIPHER_asn1_to_param() sets the cipher parameters based on an ASN1 AlgorithmIdentifier "parameter". The precise effect depends on the cipher In the case of RC2, for example, it will set the IV and effective key length. This function should be called after the base cipher type is set but before the key is set. For example EVP_CipherInit() will be called with the IV and key set to NULL, EVP_CIPHER_asn1_to_param() will be called and finally EVP_CipherInit() again with all parameters except the key set to NULL. It is possible for this function to fail if the cipher does not have any ASN1 support or the parameters cannot be set (for example the RC2 effective key length is not supported.

EVP_CIPHER_CTX_ctrl() allows various cipher specific parameters to be determined and set. Currently only the RC2 effective key length and the number of rounds of RC5 can be set.

RETURN VALUES

EVP_EncryptInit_ex(), EVP_EncryptUpdate() and EVP_EncryptFinal_ex() return 1 for success and 0 for failure.

EVP_DecryptInit_ex() and EVP_DecryptUpdate() return 1 for success and 0 for failure. EVP_DecryptFinal_ex() returns 0 if the decrypt failed or 1 for success.

EVP_CipherInit_ex() and EVP_CipherUpdate() return 1 for success and 0 for failure. EVP_CipherFinal_ex() returns 0 for a decryption failure or 1 for success.

EVP_CIPHER_CTX_cleanup() returns 1 for success and 0 for failure.

EVP_get_cipherbyname(), EVP_get_cipherbynid() and EVP_get_cipherbyobj() return an **EVP_CIPHER** structure or NULL on error.

EVP_CIPHER_nid() and EVP_CIPHER_CTX_nid() return a NID.

EVP_CIPHER_block_size() and EVP_CIPHER_CTX_block_size() return the block size.

EVP_CIPHER_key_length() and EVP_CIPHER_CTX_key_length() return the key length.

EVP_CIPHER_CTX_set_padding() always returns 1.

EVP_CIPHER_iv_length() and EVP_CIPHER_CTX_iv_length() return the IV length or zero if the cipher does not use an IV.

EVP_CIPHER_type() and EVP_CIPHER_CTX_type() return the NID of the cipher's OBJECT IDENTIFIER or NID_undef if it has no defined OBJECT IDENTIFIER.

EVP_CIPHER_CTX_cipher() returns an **EVP_CIPHER** structure.

EVP_CIPHER_param_to_asn1() and EVP_CIPHER_asn1_to_param() return 1 for success or zero for failure.

CIPHER LISTING

All algorithms have a fixed key length unless otherwise stated.

EVP_enc_null()

> Null cipher: does nothing.

EVP_des_cbc(void)
EVP_des_ecb(void)
EVP_des_cfb(void)
EVP_des_ofb(void)

> DES in CBC, ECB, CFB and OFB modes respectively.

EVP_des_ede_cbc(void)
EVP_des_ede()
EVP_des_ede_ofb(void)
EVP_des_ede_cfb(void)

> Two key triple DES in CBC, ECB, CFB and OFB modes respectively.

EVP_des_ede3_cbc(void)
EVP_des_ede3()
EVP_des_ede3_ofb(void)
EVP_des_ede3_cfb(void)

Three key triple DES in CBC, ECB, CFB and OFB modes respectively.

EVP_desx_cbc(void)

DESX algorithm in CBC mode.

EVP_rc4(void)

RC4 stream cipher. This is a variable key length cipher with default key length 128 bits.

EVP_rc4_40(void)

RC4 stream cipher with 40 bit key length. This is obsolete and new code should use EVP_rc4() and the EVP_CIPHER_CTX_set_key_length() function.

EVP_idea_cbc() EVP_idea_ecb(void)
EVP_idea_cfb(void)
EVP_idea_ofb(void)
EVP_idea_cbc(void)

IDEA encryption algorithm in CBC, ECB, CFB and OFB modes respectively.

EVP_rc2_cbc(void)
EVP_rc2_ecb(void)
EVP_rc2_cfb(void)
EVP_rc2_ofb(void)

RC2 encryption algorithm in CBC, ECB, CFB and OFB modes respectively. This is a variable key length cipher with an additional parameter called "effective key bits" or "effective key length". By default both are set to 128 bits.

EVP_rc2_40_cbc(void)
EVP_rc2_64_cbc(void)

RC2 algorithm in CBC mode with a default key length and effective key length of 40 and 64 bits. These are obsolete and new code should use EVP_rc2_cbc(), EVP_CIPHER_CTX_set_key_length() and EVP_CIPHER_CTX_ctrl() to set the key length and effective key length.

EVP_bf_cbc(void)
EVP_bf_ecb(void)
EVP_bf_cfb(void)
EVP_bf_ofb(void);

Blowfish encryption algorithm in CBC, ECB, CFB and OFB modes respectively. This is a variable key length cipher.

EVP_cast5_cbc(void)
EVP_cast5_ecb(void)
EVP_cast5_cfb(void)
EVP_cast5_ofb(void)

CAST encryption algorithm in CBC, ECB, CFB and OFB modes respectively. This is a variable key length cipher.

EVP_rc5_32_12_16_cbc(void)
EVP_rc5_32_12_16_ecb(void)
EVP_rc5_32_12_16_cfb(void)
EVP_rc5_32_12_16_ofb(void)

RC5 encryption algorithm in CBC, ECB, CFB and OFB modes respectively. This is a variable key length cipher with an additional "number of rounds" parameter. By default the key length is set to 128 bits and 12 rounds.

NOTES

Where possible the **EVP** interface to symmetric ciphers should be used in preference to the low level interfaces. This is because the code then becomes transparent to the cipher used and much more flexible. Additionally, the **EVP** interface will ensure the use of platform specific cryptographic acceleration such as AES-NI (the low level interfaces do not provide the guarantee).

PKCS padding works by adding **n** padding bytes of value **n** to make the total length of the encrypted data a multiple of the block size. Padding is always added so if the data is already a multiple of the block size **n** will equal the block size. For example if the block size is 8 and 11 bytes are to be encrypted then 5 padding bytes of value 5 will be added.

When decrypting the final block is checked to see if it has the correct form.

Although the decryption operation can produce an error if padding is enabled, it is not a strong test that the input data or key is correct. A random block has better than 1 in 256 chance of being of the correct format and problems with the input data earlier on will not produce a final decrypt error.

If padding is disabled then the decryption operation will always succeed if the total amount of data decrypted is a multiple of the block size.

The functions EVP_EncryptInit(), EVP_EncryptFinal(), EVP_DecryptInit(), EVP_CipherInit() and EVP_CipherFinal() are obsolete but are retained for compatibility with existing code. New code should use EVP_EncryptInit_ex(), EVP_EncryptFinal_ex(), EVP_DecryptInit_ex(), EVP_DecryptFinal_ex(), EVP_CipherInit_ex() and EVP_CipherFinal_ex() because they can reuse an existing context without allocating and freeing it up on each call.

BUGS

For RC5 the number of rounds can currently only be set to 8, 12 or 16. This is a limitation of the current RC5 code rather than the EVP interface.

EVP_MAX_KEY_LENGTH and EVP_MAX_IV_LENGTH only refer to the internal ciphers with default key lengths. If custom ciphers exceed these values the results are unpredictable. This is because it has become standard practice to define a generic key as a fixed unsigned char array containing EVP_MAX_KEY_LENGTH bytes.

The ASN1 code is incomplete (and sometimes inaccurate) it has only been tested for certain common S/MIME ciphers (RC2, DES, triple DES) in CBC mode.

EXAMPLES

Encrypt a string using IDEA:

```
int do_crypt(char *outfile)
       {
       unsigned char outbuf[1024];
       int outlen, tmplen;
       /* Bogus key and IV: we'd normally set these from
        * another source.
        */
       unsigned char key[] = {0,1,2,3,4,5,6,7,8,9,10,11,12,13,14,15};
       unsigned char iv[] = {1,2,3,4,5,6,7,8};
       char intext[] = "Some Crypto Text";
       EVP_CIPHER_CTX ctx;
       FILE *out;

EVP_CIPHER_CTX_init(&ctx);
EVP_EncryptInit_ex(&ctx, EVP_idea_cbc(), NULL, key, iv);

if(!EVP_EncryptUpdate(&ctx, outbuf, &outlen, intext, strlen(intext)))
        {
        /* Error */
        return 0;
        }
/* Buffer passed to EVP_EncryptFinal() must be after data just
 * encrypted to avoid overwriting it.
 */
if(!EVP_EncryptFinal_ex(&ctx, outbuf + outlen, &tmplen))
        {
        /* Error */
        return 0;
        }
outlen += tmplen;
EVP_CIPHER_CTX_cleanup(&ctx);
/* Need binary mode for fopen because encrypted data is
 * binary data. Also cannot use strlen() on it because
 * it wont be null terminated and may contain embedded
 * nulls.
 */
out = fopen(outfile, "wb");
fwrite(outbuf, 1, outlen, out);
fclose(out);
return 1;
}
```

The ciphertext from the above example can be decrypted using the **openssl** utility with the command line (shown on two lines for clarity):

```
openssl idea -d <filename
         -K 000102030405060708090A0B0C0D0E0F -iv 0102030405060708
```

General encryption and decryption function example using FILE I/O and AES128 with a 128-bit key:

```
int do_crypt(FILE *in, FILE *out, int do_encrypt)
       {
       /* Allow enough space in output buffer for additional block */
       unsigned char inbuf[1024], outbuf[1024 + EVP_MAX_BLOCK_LENGTH];
       int inlen, outlen;
       EVP_CIPHER_CTX ctx;
       /* Bogus key and IV: we'd normally set these from
        * another source.
        */
       unsigned char key[] = "0123456789abcdeF";
       unsigned char iv[] = "1234567887654321";

/* Don't set key or IV right away; we want to check lengths */
EVP_CIPHER_CTX_init(&ctx);
EVP_CipherInit_ex(&ctx, EVP_aes_128_cbc(), NULL, NULL, NULL,
        do_encrypt);
OPENSSL_assert(EVP_CIPHER_CTX_key_length(&ctx) == 16);
OPENSSL_assert(EVP_CIPHER_CTX_iv_length(&ctx) == 16);

/* Now we can set key and IV */
EVP_CipherInit_ex(&ctx, NULL, NULL, key, iv, do_encrypt);

for(;;)
        {
        inlen = fread(inbuf, 1, 1024, in);
        if(inlen <= 0) break;
        if(!EVP_CipherUpdate(&ctx, outbuf, &outlen, inbuf, inlen))
                {
                /* Error */
                EVP_CIPHER_CTX_cleanup(&ctx);
                return 0;
                }
        fwrite(outbuf, 1, outlen, out);
        }
if(!EVP_CipherFinal_ex(&ctx, outbuf, &outlen))
        {
        /* Error */
        EVP_CIPHER_CTX_cleanup(&ctx);
        return 0;
        }
fwrite(outbuf, 1, outlen, out);

EVP_CIPHER_CTX_cleanup(&ctx);
return 1;
}
```

HISTORY

EVP_CIPHER_CTX_init(), EVP_EncryptInit_ex(), EVP_EncryptFinal_ex(), EVP_DecryptInit_ex(), EVP_DecryptFinal_ex(), EVP_CipherInit_ex(), EVP_CipherFinal_ex() and EVP_CIPHER_CTX_set_padding() appeared in OpenSSL 0.9.7.

IDEA appeared in OpenSSL 0.9.7 but was often disabled due to patent concerns; the last patents expired in 2012.

Name

EVP_OpenInit, EVP_OpenUpdate and EVP_OpenFinal — EVP envelope decryption

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_OpenInit(EVP_CIPHER_CTX *ctx,EVP_CIPHER *type,unsigned char *ek,
               int ekl,unsigned char *iv,EVP_PKEY *priv);
int EVP_OpenUpdate(EVP_CIPHER_CTX *ctx, unsigned char *out,
        int *outl, unsigned char *in, int inl);
int EVP_OpenFinal(EVP_CIPHER_CTX *ctx, unsigned char *out,
        int *outl);
```

DESCRIPTION

The EVP envelope routines are a high level interface to envelope decryption. They decrypt a public key encrypted symmetric key and then decrypt data using it.

EVP_OpenInit() initializes a cipher context **ctx** for decryption with cipher **type**. It decrypts the encrypted symmetric key of length **ekl** bytes passed in the **ek** parameter using the private key **priv**. The IV is supplied in the **iv** parameter.

EVP_OpenUpdate() and EVP_OpenFinal() have exactly the same properties as the EVP_DecryptUpdate() and EVP_DecryptFinal() routines, as documented on the EVP_EncryptInit(3) manual page.

NOTES

It is possible to call EVP_OpenInit() twice in the same way as EVP_DecryptInit(). The first call should have **priv** set to NULL and (after setting any cipher parameters) it should be called again with **type** set to NULL.

If the cipher passed in the **type** parameter is a variable length cipher then the key length will be set to the value of the recovered key length. If the cipher is a fixed length cipher then the recovered key length must match the fixed cipher length.

RETURN VALUES

EVP_OpenInit() returns 0 on error or a non zero integer (actually the recovered secret key size) if successful.

EVP_OpenUpdate() returns 1 for success or 0 for failure.

EVP_OpenFinal() returns 0 if the decrypt failed or 1 for success.

HISTORY

Name

EVP_PKEY_copy_parameters, EVP_PKEY_missing_parameters, EVP_PKEY_cmp_parameters and EVP_PKEY_cmp — public key parameter and comparison functions

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_missing_parameters(const EVP_PKEY *pkey);
int EVP_PKEY_copy_parameters(EVP_PKEY *to, const EVP_PKEY *from);
```

```
int EVP_PKEY_cmp_parameters(const EVP_PKEY *a, const EVP_PKEY *b);
int EVP_PKEY_cmp(const EVP_PKEY *a, const EVP_PKEY *b);
```

DESCRIPTION

The function EVP_PKEY_missing_parameters() returns 1 if the public key parameters of **pkey** are missing and 0 if they are present or the algorithm doesn't use parameters.

The function EVP_PKEY_copy_parameters() copies the parameters from key **from** to key **to**.

The funcion EVP_PKEY_cmp_parameters() compares the parameters of keys **a** and **b**.

The funcion EVP_PKEY_cmp() compares the public key components and paramters (if present) of keys **a** and **b**.

NOTES

The main purpose of the functions EVP_PKEY_missing_parameters() and EVP_PKEY_copy_parameters() is to handle public keys in certificates where the parameters are sometimes omitted from a public key if they are inherited from the CA that signed it.

Since OpenSSL private keys contain public key components too the function EVP_PKEY_cmp() can also be used to determine if a private key matches a public key.

RETURN VALUES

The function EVP_PKEY_missing_parameters() returns 1 if the public key parameters of **pkey** are missing and 0 if they are present or the algorithm doesn't use parameters.

These functions EVP_PKEY_copy_parameters() returns 1 for success and 0 for failure.

The function EVP_PKEY_cmp_parameters() and EVP_PKEY_cmp() return 1 if the keys match, 0 if they don't match, -1 if the key types are different and -2 if the operation is not supported.

int EVP_PKEY_CTX_set_rsa_keygen_pubexp(EVP_PKEY_CTX *ctx, BIGNUM *pubexp);
```

```
#include  <openssl/dsa.h>
int EVP_PKEY_CTX_set_dsa_paramgen_bits(EVP_PKEY_CTX *ctx, int nbits);
```

```
#include  <openssl/dh.h>
int EVP_PKEY_CTX_set_dh_paramgen_prime_len(EVP_PKEY_CTX *ctx, int len);
int EVP_PKEY_CTX_set_dh_paramgen_generator(EVP_PKEY_CTX *ctx, int gen);
```

```
#include  <openssl/ec.h>
int EVP_PKEY_CTX_set_ec_paramgen_curve_nid(EVP_PKEY_CTX *ctx, int nid);
```

DESCRIPTION

The function EVP_PKEY_CTX_ctrl() sends a control operation to the context **ctx**. The key type used must match **keytype** if it is not -1. The parameter **optype** is a mask indicating which operations the control can be applied to. The control command is indicated in **cmd** and any additional arguments in **p1** and **p2**.

Applications will not normally call EVP_PKEY_CTX_ctrl() directly but will instead call one of the algorithm specific macros below.

The function EVP_PKEY_ctrl_str() allows an application to send an algorithm specific control operation to a context **ctx** in string form. This is intended to be used for options specified on the command line or in text files. The commands supported are documented in the openssl utility command line pages for the option **-pkeyopt** which is supported by the **pkeyutl**, **genpkey** and **req** commands.

All the remaining "functions" are implemented as macros.

The EVP_PKEY_CTX_set_signature_md() macro sets the message digest type used in a signature. It can be used with any public key algorithm supporting signature operations.

The macro EVP_PKEY_CTX_set_rsa_padding() sets the RSA padding mode for **ctx**. The **pad** parameter can take the value RSA_PKCS1_PADDING for PKCS#1 padding, RSA_SSLV23_PADDING for SSLv23 padding, RSA_NO_PADDING for no padding, RSA_PKCS1_OAEP_PADDING for OAEP padding (encrypt and decrypt only), RSA_X931_PADDING for X9.31 padding (signature operations only) and RSA_PKCS1_PSS_PADDING (sign and verify only).

Two RSA padding modes behave differently if EVP_PKEY_CTX_set_signature_md() is used. If this macro is called for PKCS#1 padding the plaintext buffer is an actual digest value and is encapsulated in a DigestInfo structure according to PKCS#1 when signing and this structure is expected (and stripped off) when verifying. If this control is not used with RSA and PKCS#1 padding then the supplied data is used directly and not encapsulated. In the case of X9.31 padding for RSA the algorithm identifier byte is added or checked and removed if this control is called. If it is not called then the first byte of the plaintext buffer is expected to be the algorithm identifier byte.

The EVP_PKEY_CTX_set_rsa_pss_saltlen() macro sets the RSA PSS salt length to **len** as its name implies it is only supported for PSS padding. Two special values are supported: -1 sets the salt length to the digest length. When signing -2 sets the salt length to the maximum permissible value. When verifying -2 causes the salt length to be automatically determined based on the **PSS** block structure. If this macro is not called a salt length value of -2 is used by default.

The EVP_PKEY_CTX_set_rsa_rsa_keygen_bits() macro sets the RSA key length for RSA key genration to **bits**. If not specified 1024 bits is used.

The EVP_PKEY_CTX_set_rsa_keygen_pubexp() macro sets the public exponent value for RSA key generation to **pubexp** currently it should be an odd integer. The **pubexp** pointer is used internally by this function so it should not be modified or free after the call. If this macro is not called then 65537 is used.

The macro EVP_PKEY_CTX_set_dsa_paramgen_bits() sets the number of bits used for DSA parameter generation to **bits**. If not specified 1024 is used.

The macro EVP_PKEY_CTX_set_dh_paramgen_prime_len() sets the length of the DH prime parameter **p** for DH parameter generation. If this macro is not called then 1024 is used.

The EVP_PKEY_CTX_set_dh_paramgen_generator() macro sets DH generator to **gen** for DH parameter generation. If not specified 2 is used.

The EVP_PKEY_CTX_set_ec_paramgen_curve_nid() sets the EC curve for EC parameter generation to **nid**. For EC parameter generation this macro must be called or an error occurs because there is no default curve.

RETURN VALUES

EVP_PKEY_CTX_ctrl() and its macros return a positive value for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EVP_PKEY_CTX_new(3), EVP_PKEY_encrypt(3), EVP_PKEY_decrypt(3), EVP_PKEY_sign(3), EVP_PKEY_verify(3), EVP_PKEY_verify_recover(3), EVP_PKEY_derive(3), EVP_PKEY_keygen(3)

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_CTX_new, EVP_PKEY_CTX_new_id, EVP_PKEY_CTX_dup and EVP_PKEY_CTX_free — public key algorithm context functions.

Synopsis

```
#include  <openssl/evp.h>
```

```
EVP_PKEY_CTX *EVP_PKEY_CTX_new(EVP_PKEY *pkey, ENGINE *e);
EVP_PKEY_CTX *EVP_PKEY_CTX_new_id(int id, ENGINE *e);
EVP_PKEY_CTX *EVP_PKEY_CTX_dup(EVP_PKEY_CTX *ctx);
void EVP_PKEY_CTX_free(EVP_PKEY_CTX *ctx);
```

DESCRIPTION

The EVP_PKEY_CTX_new() function allocates public key algorithm context using the algorithm specified in **pkey** and ENGINE **e**.

The EVP_PKEY_CTX_new_id() function allocates public key algorithm context using the algorithm specified by **id** and ENGINE **e**. It is normally used when no **EVP_PKEY** structure is associated with the operations, for example during parameter generation of key genration for some algorithms.

EVP_PKEY_CTX_dup() duplicates the context **ctx**.

EVP_PKEY_CTX_free() frees up the context **ctx**.

NOTES

The **EVP_PKEY_CTX** structure is an opaque public key algorithm context used by the OpenSSL high level public key API. Contexts **MUST NOT** be shared between threads: that is it is not permissible to use the same context simultaneously in two threads.

RETURN VALUES

EVP_PKEY_CTX_new(), EVP_PKEY_CTX_new_id(), EVP_PKEY_CTX_dup() returns either the newly allocated **EVP_PKEY_CTX** structure of **NULL** if an error occurred.

EVP_PKEY_CTX_free() does not return a value.

EVP_PKEY_new(3)

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_decrypt_init and EVP_PKEY_decrypt — decrypt using a public key algorithm

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_decrypt_init(EVP_PKEY_CTX *ctx);
int EVP_PKEY_decrypt(EVP_PKEY_CTX *ctx,
                       unsigned char *out, size_t *outlen,
                       const unsigned char *in, size_t inlen);
```

DESCRIPTION

The EVP_PKEY_decrypt_init() function initializes a public key algorithm context using key **pkey** for a decryption operation.

The EVP_PKEY_decrypt() function performs a public key decryption operation using **ctx**. The data to be decrypted is specified using the **in** and **inlen** parameters. If **out** is **NULL** then the maximum size of the output buffer is written to the **outlen** parameter. If **out** is not **NULL** then before the call the **outlen** parameter should contain the length of the **out** buffer, if the call is successful the decrypted data is written to **out** and the amount of data written to **outlen**.

NOTES

After the call to EVP_PKEY_decrypt_init() algorithm specific control operations can be performed to set any appropriate parameters for the operation.

The function EVP_PKEY_decrypt() can be called more than once on the same context if several operations are performed using the same parameters.

RETURN VALUES

EVP_PKEY_decrypt_init() and EVP_PKEY_decrypt() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EXAMPLE

Decrypt data using OAEP (for RSA keys):

```
#include <openssl/evp.h>
#include <openssl/rsa.h>

EVP_PKEY_CTX *ctx;
unsigned char *out, *in;
size_t outlen, inlen;
EVP_PKEY *key;
/* NB: assumes key in, inlen are already set up
 * and that key is an RSA private key
 */
ctx = EVP_PKEY_CTX_new(key);
if (!ctx)
       /* Error occurred */
if (EVP_PKEY_decrypt_init(ctx) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_rsa_padding(ctx, RSA_OAEP_PADDING) <= 0)
       /* Error */

/* Determine buffer length */
if (EVP_PKEY_decrypt(ctx, NULL, &outlen, in, inlen) <= 0)
       /* Error */
```

```
out = OPENSSL_malloc(outlen);

if (!out)
       /* malloc failure */

if (EVP_PKEY_decrypt(ctx, out, &outlen, in, inlen) <= 0)
       /* Error */

/* Decrypted data is outlen bytes written to buffer out */
```

SEE ALSO

EVP_PKEY_CTX_new(3), EVP_PKEY_encrypt(3), EVP_PKEY_sign(3), EVP_PKEY_verify(3), EVP_PKEY_verify_recover(3), EVP_PKEY_derive(3)

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_derive_init, EVP_PKEY_derive_set_peer and EVP_PKEY_derive — derive public key algorithm shared secret.

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_derive_init(EVP_PKEY_CTX *ctx);
int EVP_PKEY_derive_set_peer(EVP_PKEY_CTX *ctx, EVP_PKEY *peer);
int EVP_PKEY_derive(EVP_PKEY_CTX *ctx, unsigned char *key, size_t *keylen);
```

DESCRIPTION

The EVP_PKEY_derive_init() function initializes a public key algorithm context using key **pkey** for shared secret derivation.

The EVP_PKEY_derive_set_peer() function sets the peer key: this will normally be a public key.

The EVP_PKEY_derive() derives a shared secret using **ctx**. If **key** is **NULL** then the maximum size of the output buffer is written to the **keylen** parameter. If **key** is not **NULL** then before the call the **keylen** parameter should contain the length of the **key** buffer, if the call is successful the shared secret is written to **key** and the amount of data written to **keylen**.

NOTES

After the call to EVP_PKEY_derive_init() algorithm specific control operations can be performed to set any appropriate parameters for the operation.

The function EVP_PKEY_derive() can be called more than once on the same context if several operations are performed using the same parameters.

RETURN VALUES

EVP_PKEY_derive_init() and EVP_PKEY_derive() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EXAMPLE

Derive shared secret (for example DH or EC keys):

```
#include <openssl/evp.h>
#include <openssl/rsa.h>

EVP_PKEY_CTX *ctx;
unsigned char *skey;
size_t skeylen;
EVP_PKEY *pkey, *peerkey;
/* NB: assumes pkey, peerkey have been already set up */

ctx = EVP_PKEY_CTX_new(pkey);
if (!ctx)
       /* Error occurred */
if (EVP_PKEY_derive_init(ctx) <= 0)
       /* Error */
if (EVP_PKEY_derive_set_peer(ctx, peerkey) <= 0)
       /* Error */

/* Determine buffer length */
if (EVP_PKEY_derive(ctx, NULL, &skeylen) <= 0)
       /* Error */
```

```
skey = OPENSSL_malloc(skeylen);

if (!skey)
       /* malloc failure */

if (EVP_PKEY_derive(ctx, skey, &skeylen) <= 0)
       /* Error */

/* Shared secret is skey bytes written to buffer skey */
```

SEE ALSO

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_encrypt_init and EVP_PKEY_encrypt — encrypt using a public key algorithm

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_encrypt_init(EVP_PKEY_CTX *ctx);
int EVP_PKEY_encrypt(EVP_PKEY_CTX *ctx,
                       unsigned char *out, size_t *outlen,
                       const unsigned char *in, size_t inlen);
```

DESCRIPTION

The EVP_PKEY_encrypt_init() function initializes a public key algorithm context using key **pkey** for an encryption operation.

The EVP_PKEY_encrypt() function performs a public key encryption operation using **ctx**. The data to be encrypted is specified using the **in** and **inlen** parameters. If **out** is **NULL** then the maximum size of the output buffer is written to the **outlen** parameter. If **out** is not **NULL** then before the call the **outlen** parameter should contain the length of the **out** buffer, if the call is successful the encrypted data is written to **out** and the amount of data written to **outlen**.

NOTES

After the call to EVP_PKEY_encrypt_init() algorithm specific control operations can be performed to set any appropriate parameters for the operation.

The function EVP_PKEY_encrypt() can be called more than once on the same context if several operations are performed using the same parameters.

RETURN VALUES

EVP_PKEY_encrypt_init() and EVP_PKEY_encrypt() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EXAMPLE

Encrypt data using OAEP (for RSA keys). See also PEM_read_PUBKEY(3) or d2i_X509(3) for means to load a public key. You may also simply set 'eng = NULL;' to start with the default OpenSSL RSA implementation:

```
#include <openssl/evp.h>
#include <openssl/rsa.h>
#include <openssl/engine.h>

EVP_PKEY_CTX *ctx;
ENGINE *eng;
unsigned char *out, *in;
size_t outlen, inlen;
EVP_PKEY *key;
/* NB: assumes eng, key, in, inlen are already set up,
 * and that key is an RSA public key
 */
ctx = EVP_PKEY_CTX_new(key,eng);
if (!ctx)
       /* Error occurred */
if (EVP_PKEY_encrypt_init(ctx) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_rsa_padding(ctx, RSA_OAEP_PADDING) <= 0)
       /* Error */
/* Determine buffer length */
if (EVP_PKEY_encrypt(ctx, NULL, &outlen, in, inlen) <= 0)
       /* Error */

out = OPENSSL_malloc(outlen);

if (!out)
       /* malloc failure */

if (EVP_PKEY_encrypt(ctx, out, &outlen, in, inlen) <= 0)
       /* Error */

/* Encrypted data is outlen bytes written to buffer out */
```

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_get_default_digest_nid — get default signature digest

Synopsis

```
#include  <openssl/evp.h>
int EVP_PKEY_get_default_digest_nid(EVP_PKEY *pkey, int *pnid);
```

DESCRIPTION

The EVP_PKEY_get_default_digest_nid() function sets **pnid** to the default message digest NID for the public key signature operations associated with key **pkey**.

NOTES

For all current standard OpenSSL public key algorithms SHA1 is returned.

RETURN VALUES

The EVP_PKEY_get_default_digest_nid() function returns 1 if the message digest is advisory (that is other digests can be used) and 2 if it is mandatory (other digests can not be used). It returns 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EVP_PKEY_gen_cb *EVP_PKEY_CTX_get_cb(EVP_PKEY_CTX *ctx);
```

```
int EVP_PKEY_CTX_get_keygen_info(EVP_PKEY_CTX *ctx, int idx);
```

```
void EVP_PKEY_CTX_set_app_data(EVP_PKEY_CTX *ctx, void *data);
void *EVP_PKEY_CTX_get_app_data(EVP_PKEY_CTX *ctx);
```

DESCRIPTION

The EVP_PKEY_keygen_init() function initializes a public key algorithm context using key **pkey** for a key genration operation.

The EVP_PKEY_keygen() function performs a key generation operation, the generated key is written to **ppkey**.

The functions EVP_PKEY_paramgen_init() and EVP_PKEY_paramgen() are similar except parameters are generated.

The function EVP_PKEY_set_cb() sets the key or parameter generation callback to **cb**. The function EVP_PKEY_CTX_get_cb() returns the key or parameter generation callback.

The function EVP_PKEY_CTX_get_keygen_info() returns parameters associated with the generation operation. If **idx** is -1 the total number of parameters available is returned. Any non negative value returns the value of that parameter. EVP_PKEY_CTX_gen_keygen_info() with a non-negative value for **idx** should only be called within the generation callback.

If the callback returns 0 then the key genration operation is aborted and an error occurs. This might occur during a time consuming operation where a user clicks on a "cancel" button.

The functions EVP_PKEY_CTX_set_app_data() and EVP_PKEY_CTX_get_app_data() set and retrieve an opaque pointer. This can be used to set some application defined value which can be retrieved in the callback: for example a handle which is used to update a "progress dialog".

NOTES

After the call to EVP_PKEY_keygen_init() or EVP_PKEY_paramgen_init() algorithm specific control operations can be performed to set any appropriate parameters for the operation.

The functions EVP_PKEY_keygen() and EVP_PKEY_paramgen() can be called more than once on the same context if several operations are performed using the same parameters.

The meaning of the parameters passed to the callback will depend on the algorithm and the specifiic implementation of the algorithm. Some might not give any useful information at all during key or parameter generation. Others might not even call the callback.

The operation performed by key or parameter generation depends on the algorithm used. In some cases (e.g. EC with a supplied named curve) the "generation" option merely sets the appropriate fields in an EVP_PKEY structure.

In OpenSSL an EVP_PKEY structure containing a private key also contains the public key components and parameters (if any). An OpenSSL private key is equivalent to what some libraries call a "key pair". A private key can be used in functions which require the use of a public key or parameters.

RETURN VALUES

EVP_PKEY_keygen_init(), EVP_PKEY_paramgen_init(), EVP_PKEY_keygen() and EVP_PKEY_paramgen() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EXAMPLES

Generate a 2048 bit RSA key:

```
#include <openssl/evp.h>
#include <openssl/rsa.h>

EVP_PKEY_CTX *ctx;
EVP_PKEY *pkey = NULL;
ctx = EVP_PKEY_CTX_new_id(EVP_PKEY_RSA, NULL);
if (!ctx)
       /* Error occurred */
if (EVP_PKEY_keygen_init(ctx) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_rsa_keygen_bits(ctx, 2048) <= 0)
       /* Error */

/* Generate key */
if (EVP_PKEY_keygen(ctx, &pkey) <= 0)
       /* Error */
```

Generate a key from a set of parameters:

```
#include <openssl/evp.h>
#include <openssl/rsa.h>

EVP_PKEY_CTX *ctx;
EVP_PKEY *pkey = NULL, *param;
/* Assumed param is set up already */
ctx = EVP_PKEY_CTX_new(param);
if (!ctx)
       /* Error occurred */
if (EVP_PKEY_keygen_init(ctx) <= 0)
       /* Error */

/* Generate key */
if (EVP_PKEY_keygen(ctx, &pkey) <= 0)
       /* Error */
```

Example of generation callback for OpenSSL public key implementations:

```
/* Application data is a BIO to output status to */

EVP_PKEY_CTX_set_app_data(ctx, status_bio);

static int genpkey_cb(EVP_PKEY_CTX *ctx)
       {
       char c='*';
       BIO *b = EVP_PKEY_CTX_get_app_data(ctx);
       int p;
       p = EVP_PKEY_CTX_get_keygen_info(ctx, 0);
       if (p == 0) c='.';
       if (p == 1) c='+';
       if (p == 2) c='*';
       if (p == 3) c='\n';
       BIO_write(b,&c,1);
       (void)BIO_flush(b);
       return 1;
       }
```

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_new and EVP_PKEY_free — private key allocation functions.

Synopsis

```
#include  <openssl/evp.h>
```

```
EVP_PKEY *EVP_PKEY_new(void);
void EVP_PKEY_free(EVP_PKEY *key);
```

DESCRIPTION

The EVP_PKEY_new() function allocates an empty **EVP_PKEY** structure which is used by OpenSSL to store private keys.

EVP_PKEY_free() frees up the private key **key**.

NOTES

The **EVP_PKEY** structure is used by various OpenSSL functions which require a general private key without reference to any particular algorithm.

The structure returned by EVP_PKEY_new() is empty. To add a private key to this empty structure the functions described in EVP_PKEY_set1_RSA(3) should be used.

RETURN VALUES

EVP_PKEY_new() returns either the newly allocated **EVP_PKEY** structure of **NULL** if an error occurred.

EVP_PKEY_free() does not return a value.

SEE ALSO

EVP_PKEY_set1_RSA(3)

HISTORY

TBA

Name

EVP_PKEY_print_public, EVP_PKEY_print_private and EVP_PKEY_print_params — public key algorithm printing routines.

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_print_public(BIO *out, const EVP_PKEY *pkey,
                               int indent, ASN1_PCTX *pctx);
int EVP_PKEY_print_private(BIO *out, const EVP_PKEY *pkey,
                               int indent, ASN1_PCTX *pctx);
int EVP_PKEY_print_params(BIO *out, const EVP_PKEY *pkey,
                               int indent, ASN1_PCTX *pctx);
```

DESCRIPTION

The functions EVP_PKEY_print_public(), EVP_PKEY_print_private() and EVP_PKEY_print_params() print out the public, private or parameter components of key **pkey** respectively. The key is sent to BIO **out** in human readable form. The parameter **indent** indicated how far the printout should be indented.

The **pctx** parameter allows the print output to be finely tuned by using ASN1 printing options. If **pctx** is set to NULL then default values will be used.

NOTES

Currently no public key algorithms include any options in the **pctx** parameter parameter.

If the key does not include all the components indicated by the function then only those contained in the key will be printed. For example passing a public key to EVP_PKEY_print_private() will only print the public components.

RETURN VALUES

These functions all return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_set1_RSA(EVP_PKEY *pkey,RSA *key);
int EVP_PKEY_set1_DSA(EVP_PKEY *pkey,DSA *key);
int EVP_PKEY_set1_DH(EVP_PKEY *pkey,DH *key);
int EVP_PKEY_set1_EC_KEY(EVP_PKEY *pkey,EC_KEY *key);
```

```
RSA *EVP_PKEY_get1_RSA(EVP_PKEY *pkey);
DSA *EVP_PKEY_get1_DSA(EVP_PKEY *pkey);
DH *EVP_PKEY_get1_DH(EVP_PKEY *pkey);
EC_KEY *EVP_PKEY_get1_EC_KEY(EVP_PKEY *pkey);
```

```
int EVP_PKEY_assign_RSA(EVP_PKEY *pkey,RSA *key);
int EVP_PKEY_assign_DSA(EVP_PKEY *pkey,DSA *key);
int EVP_PKEY_assign_DH(EVP_PKEY *pkey,DH *key);
int EVP_PKEY_assign_EC_KEY(EVP_PKEY *pkey,EC_KEY *key);
```

```
int EVP_PKEY_type(int type);
```

DESCRIPTION

EVP_PKEY_set1_RSA(), EVP_PKEY_set1_DSA(), EVP_PKEY_set1_DH() and EVP_PKEY_set1_EC_KEY() set the key referenced by **pkey** to **key**.

EVP_PKEY_get1_RSA(), EVP_PKEY_get1_DSA(), EVP_PKEY_get1_DH() and EVP_PKEY_get1_EC_KEY() return the referenced key in **pkey** or **NULL** if the key is not of the correct type.

EVP_PKEY_assign_RSA(), EVP_PKEY_assign_DSA(), EVP_PKEY_assign_DH() and EVP_PKEY_assign_EC_KEY() also set the referenced key to **key** however these use the supplied **key** internally and so **key** will be freed when the parent **pkey** is freed.

EVP_PKEY_type() returns the type of key corresponding to the value **type**. The type of a key can be obtained with EVP_PKEY_type(pkey->type). The return value will be EVP_PKEY_RSA, EVP_PKEY_DSA, EVP_PKEY_DH or EVP_PKEY_EC for the corresponding key types or NID_undef if the key type is unassigned.

NOTES

In accordance with the OpenSSL naming convention the key obtained from or assigned to the **pkey** using the **1** functions must be freed as well as **pkey**.

EVP_PKEY_assign_RSA(), EVP_PKEY_assign_DSA(), EVP_PKEY_assign_DH() and EVP_PKEY_assign_EC_KEY() are implemented as macros.

RETURN VALUES

EVP_PKEY_set1_RSA(), EVP_PKEY_set1_DSA(), EVP_PKEY_set1_DH() and EVP_PKEY_set1_EC_KEY() return 1 for success or 0 for failure.

EVP_PKEY_get1_RSA(), EVP_PKEY_get1_DSA(), EVP_PKEY_get1_DH() and EVP_PKEY_get1_EC_KEY() return the referenced key or **NULL** if an error occurred.

EVP_PKEY_assign_RSA(), EVP_PKEY_assign_DSA(), EVP_PKEY_assign_DH() and EVP_PKEY_assign_EC_KEY() return 1 for success and 0 for failure.

SEE ALSO

EVP_PKEY_new(3)

HISTORY

TBA

Name

EVP_PKEY_sign_init and EVP_PKEY_sign — sign using a public key algorithm

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_sign_init(EVP_PKEY_CTX *ctx);
int EVP_PKEY_sign(EVP_PKEY_CTX *ctx,
                       unsigned char *sig, size_t *siglen,
                       const unsigned char *tbs, size_t tbslen);
```

DESCRIPTION

The EVP_PKEY_sign_init() function initializes a public key algorithm context using key **pkey** for a signing operation.

The EVP_PKEY_sign() function performs a public key signing operation using **ctx**. The data to be signed is specified using the **tbs** and **tbslen** parameters. If **sig** is **NULL** then the maximum size of the output buffer is written to the **siglen** parameter. If **sig** is not **NULL** then before the call the **siglen** parameter should contain the length of the **sig** buffer, if the call is successful the signature is written to **sig** and the amount of data written to **siglen**.

NOTES

EVP_PKEY_sign() does not hash the data to be signed, and therefore is normally used to sign digests. For signing arbitrary messages, see the EVP_DigestSignInit(3) and EVP_SignInit(3) signing interfaces instead.

After the call to EVP_PKEY_sign_init() algorithm specific control operations can be performed to set any appropriate parameters for the operation (see EVP_PKEY_CTX_ctrl(3)).

The function EVP_PKEY_sign() can be called more than once on the same context if several operations are performed using the same parameters.

RETURN VALUES

EVP_PKEY_sign_init() and EVP_PKEY_sign() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EXAMPLE

Sign data using RSA with PKCS#1 padding and SHA256 digest:

```
#include <openssl/evp.h>
#include <openssl/rsa.h>

EVP_PKEY_CTX *ctx;
/* md is a SHA-256 digest in this example. */
unsigned char *md, *sig;
size_t mdlen = 32, siglen;
EVP_PKEY *signing_key;

/*
 * NB: assumes signing_key and md are set up before the next
 * step. signing_key must be an RSA private key and md must
 * point to the SHA-256 digest to be signed.
 */
ctx = EVP_PKEY_CTX_new(signing_key, NULL /* no engine */);
if (!ctx)
       /* Error occurred */
```

```
if (EVP_PKEY_sign_init(ctx) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_rsa_padding(ctx, RSA_PKCS1_PADDING) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_signature_md(ctx, EVP_sha256()) <= 0)
       /* Error */

/* Determine buffer length */
if (EVP_PKEY_sign(ctx, NULL, &siglen, md, mdlen) <= 0)
       /* Error */

sig = OPENSSL_malloc(siglen);

if (!sig)
       /* malloc failure */

if (EVP_PKEY_sign(ctx, sig, &siglen, md, mdlen) <= 0)
       /* Error */

/* Signature is siglen bytes written to buffer sig */
```

SEE ALSO

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_verify_init and EVP_PKEY_verify — signature verification using a public key algorithm

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_verify_init(EVP_PKEY_CTX *ctx);
int EVP_PKEY_verify(EVP_PKEY_CTX *ctx,
                        const unsigned char *sig, size_t siglen,
                        const unsigned char *tbs, size_t tbslen);
```

DESCRIPTION

The EVP_PKEY_verify_init() function initializes a public key algorithm context using key **pkey** for a signature verification operation.

The EVP_PKEY_verify() function performs a public key verification operation using **ctx**. The signature is specified using the **sig** and **siglen** parameters. The verified data (i.e. the data believed originally signed) is specified using the **tbs** and **tbslen** parameters.

NOTES

After the call to EVP_PKEY_verify_init() algorithm specific control operations can be performed to set any appropriate parameters for the operation.

The function EVP_PKEY_verify() can be called more than once on the same context if several operations are performed using the same parameters.

RETURN VALUES

EVP_PKEY_verify_init() and EVP_PKEY_verify() return 1 if the verification was successful and 0 if it failed. Unlike other functions the return value 0 from EVP_PKEY_verify() only indicates that the signature did not not verify successfully (that is tbs did not match the original data or the signature was of invalid form) it is not an indication of a more serious error.

A negative value indicates an error other that signature verification failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EXAMPLE

Verify signature using PKCS#1 and SHA256 digest:

```
#include <openssl/evp.h>
#include <openssl/rsa.h>

EVP_PKEY_CTX *ctx;
unsigned char *md, *sig;
size_t mdlen, siglen;
EVP_PKEY *verify_key;
/* NB: assumes verify_key, sig, siglen md and mdlen are already set up
 * and that verify_key is an RSA public key
 */
ctx = EVP_PKEY_CTX_new(verify_key);
if (!ctx)
       /* Error occurred */
if (EVP_PKEY_verify_init(ctx) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_rsa_padding(ctx, RSA_PKCS1_PADDING) <= 0)
       /* Error */
```

```
if (EVP_PKEY_CTX_set_signature_md(ctx, EVP_sha256()) <= 0)
       /* Error */

/* Perform operation */
ret = EVP_PKEY_verify(ctx, sig, siglen, md, mdlen);

/* ret == 1 indicates success, 0 verify failure and < 0 for some
 * other error.
 */
```

SEE ALSO

EVP_PKEY_CTX_new(3), EVP_PKEY_encrypt(3), EVP_PKEY_decrypt(3), EVP_PKEY_sign(3), EVP_PKEY_verify_recover(3), EVP_PKEY_derive(3)

HISTORY

These functions were first added to OpenSSL 1.0.0.

Name

EVP_PKEY_verify_recover_init and EVP_PKEY_verify_recover — recover signature using a public key algorithm

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_PKEY_verify_recover_init(EVP_PKEY_CTX *ctx);
int EVP_PKEY_verify_recover(EVP_PKEY_CTX *ctx,
                        unsigned char *rout, size_t *routlen,
                        const unsigned char *sig, size_t siglen);
```

DESCRIPTION

The EVP_PKEY_verify_recover_init() function initializes a public key algorithm context using key **pkey** for a verify recover operation.

The EVP_PKEY_verify_recover() function recovers signed data using **ctx**. The signature is specified using the **sig** and **siglen** parameters. If **rout** is **NULL** then the maximum size of the output buffer is written to the **routlen** parameter. If **rout** is not **NULL** then before the call the **routlen** parameter should contain the length of the **rout** buffer, if the call is successful recovered data is written to **rout** and the amount of data written to **routlen**.

NOTES

Normally an application is only interested in whether a signature verification operation is successful in those cases the EVP_verify() function should be used.

Sometimes however it is useful to obtain the data originally signed using a signing operation. Only certain public key algorithms can recover a signature in this way (for example RSA in PKCS padding mode).

After the call to EVP_PKEY_verify_recover_init() algorithm specific control operations can be performed to set any appropriate parameters for the operation.

The function EVP_PKEY_verify_recover() can be called more than once on the same context if several operations are performed using the same parameters.

RETURN VALUES

EVP_PKEY_verify_recover_init() and EVP_PKEY_verify_recover() return 1 for success and 0 or a negative value for failure. In particular a return value of -2 indicates the operation is not supported by the public key algorithm.

EXAMPLE

Recover digest originally signed using PKCS#1 and SHA256 digest:

```
#include <openssl/evp.h>
#include <openssl/rsa.h>

EVP_PKEY_CTX *ctx;
unsigned char *rout, *sig;
size_t routlen, siglen;
EVP_PKEY *verify_key;
/* NB: assumes verify_key, sig and siglen are already set up
 * and that verify_key is an RSA public key
 */
ctx = EVP_PKEY_CTX_new(verify_key);
if (!ctx)
```

```
       /* Error occurred */
if (EVP_PKEY_verify_recover_init(ctx) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_rsa_padding(ctx, RSA_PKCS1_PADDING) <= 0)
       /* Error */
if (EVP_PKEY_CTX_set_signature_md(ctx, EVP_sha256()) <= 0)
       /* Error */

/* Determine buffer length */
if (EVP_PKEY_verify_recover(ctx, NULL, &routlen, sig, siglen) <= 0)

Name

EVP_SealInit, EVP_SealUpdate and EVP_SealFinal — EVP envelope encryption

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_SealInit(EVP_CIPHER_CTX *ctx, const EVP_CIPHER *type,
                 unsigned char **ek, int *ekl, unsigned char *iv,
                 EVP_PKEY **pubk, int npubk);
int EVP_SealUpdate(EVP_CIPHER_CTX *ctx, unsigned char *out,
        int *outl, unsigned char *in, int inl);
int EVP_SealFinal(EVP_CIPHER_CTX *ctx, unsigned char *out,
        int *outl);
```

DESCRIPTION

The EVP envelope routines are a high level interface to envelope encryption. They generate a random key and IV (if required) then "envelope" it by using public key encryption. Data can then be encrypted using this key.

EVP_SealInit() initializes a cipher context **ctx** for encryption with cipher **type** using a random secret key and IV. **type** is normally supplied by a function such as EVP_des_cbc(). The secret key is encrypted using one or more public keys, this allows the same encrypted data to be decrypted using any of the corresponding private keys. **ek** is an array of buffers where the public key encrypted secret key will be written, each buffer must contain enough room for the corresponding encrypted key: that is **ek[i]** must have room for **EVP_PKEY_size(pubk[i])** bytes. The actual size of each encrypted secret key is written to the array **ekl**. **pubk** is an array of **npubk** public keys.

The **iv** parameter is a buffer where the generated IV is written to. It must contain enough room for the corresponding cipher's IV, as determined by (for example) EVP_CIPHER_iv_length(type).

If the cipher does not require an IV then the **iv** parameter is ignored and can be **NULL**.

EVP_SealUpdate() and EVP_SealFinal() have exactly the same properties as the EVP_EncryptUpdate() and EVP_EncryptFinal() routines, as documented on the EVP_EncryptInit(3) manual page.

RETURN VALUES

EVP_SealInit() returns 0 on error or **npubk** if successful.

EVP_SealUpdate() and EVP_SealFinal() return 1 for success and 0 for failure.

NOTES

Because a random secret key is generated the random number generator must be seeded before calling EVP_SealInit().

The public key must be RSA because it is the only OpenSSL public key algorithm that supports key transport.

Envelope encryption is the usual method of using public key encryption on large amounts of data, this is because public key encryption is slow but symmetric encryption is fast. So symmetric encryption is used for bulk encryption and the small random symmetric key used is transferred using public key encryption.

It is possible to call EVP_SealInit() twice in the same way as EVP_EncryptInit(). The first call should have **npubk** set to 0 and (after setting any cipher parameters) it should be called again with **type** set to NULL.

HISTORY

EVP_SealFinal() did not return a value before OpenSSL 0.9.7.

Name

EVP_SignInit, EVP_SignInit_ex, EVP_SignUpdate and EVP_SignFinal — EVP signing functions

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_SignInit_ex(EVP_MD_CTX *ctx, const EVP_MD *type, ENGINE *impl);
int EVP_SignUpdate(EVP_MD_CTX *ctx, const void *d, unsigned int cnt);
int EVP_SignFinal(EVP_MD_CTX *ctx,unsigned char *sig,unsigned int *s, EVP_PKEY *pkey);
```

```
void EVP_SignInit(EVP_MD_CTX *ctx, const EVP_MD *type);
```

```
int EVP_PKEY_size(EVP_PKEY *pkey);
```

DESCRIPTION

The EVP signature routines are a high level interface to digital signatures.

EVP_SignInit_ex() sets up signing context **ctx** to use digest **type** from ENGINE **impl**. **ctx** must be initialized with EVP_MD_CTX_init() before calling this function.

EVP_SignUpdate() hashes **cnt** bytes of data at **d** into the signature context **ctx**. This function can be called several times on the same **ctx** to include additional data.

EVP_SignFinal() signs the data in **ctx** using the private key **pkey** and places the signature in **sig**. **sig** must be at least EVP_PKEY_size(pkey) bytes in size. **s** is an OUT paramter, and not used as an IN parameter. The number of bytes of data written (i.e. the length of the signature) will be written to the integer at **s**, at most EVP_PKEY_size(pkey) bytes will be written.

EVP_SignInit() initializes a signing context **ctx** to use the default implementation of digest **type**.

EVP_PKEY_size() returns the maximum size of a signature in bytes. The actual signature returned by EVP_SignFinal() may be smaller.

RETURN VALUES

EVP_SignInit_ex(), EVP_SignUpdate() and EVP_SignFinal() return 1 for success and 0 for failure.

EVP_PKEY_size() returns the maximum size of a signature in bytes.

The error codes can be obtained by ERR_get_error(3).

NOTES

The **EVP** interface to digital signatures should almost always be used in preference to the low level interfaces. This is because the code then becomes transparent to the algorithm used and much more flexible.

Due to the link between message digests and public key algorithms the correct digest algorithm must be used with the correct public key type. A list of algorithms and associated public key algorithms appears in EVP_DigestInit(3).

When signing with DSA private keys the random number generator must be seeded or the operation will fail. The random number generator does not need to be seeded for RSA signatures.

The call to EVP_SignFinal() internally finalizes a copy of the digest context. This means that calls to EVP_SignUpdate() and EVP_SignFinal() can be called later to digest and sign additional data.

Since only a copy of the digest context is ever finalized the context must be cleaned up after use by calling EVP_MD_CTX_cleanup() or a memory leak will occur.

BUGS

Older versions of this documentation wrongly stated that calls to EVP_SignUpdate() could not be made after calling EVP_SignFinal().

Since the private key is passed in the call to EVP_SignFinal() any error relating to the private key (for example an unsuitable key and digest combination) will not be indicated until after potentially large amounts of data have been passed through EVP_SignUpdate().

It is not possible to change the signing parameters using these function.

The previous two bugs are fixed in the newer EVP_SignDigest*() function.

HISTORY

EVP_SignInit(), EVP_SignUpdate() and EVP_SignFinal() are available in all versions of SSLeay and OpenSSL.

EVP_SignInit_ex() was added in OpenSSL 0.9.7.

Name

EVP_VerifyInit, EVP_VerifyUpdate and EVP_VerifyFinal — EVP signature verification functions

Synopsis

```
#include  <openssl/evp.h>
```

```
int EVP_VerifyInit_ex(EVP_MD_CTX *ctx, const EVP_MD *type, ENGINE *impl);
int EVP_VerifyUpdate(EVP_MD_CTX *ctx, const void *d, unsigned int cnt);
int EVP_VerifyFinal(EVP_MD_CTX *ctx,unsigned char *sigbuf, unsigned int siglen,EVP_PKEY *pkey);
```

```
int EVP_VerifyInit(EVP_MD_CTX *ctx, const EVP_MD *type);
```

DESCRIPTION

The EVP signature verification routines are a high level interface to digital signatures.

EVP_VerifyInit_ex() sets up verification context **ctx** to use digest **type** from ENGINE **impl**. **ctx** must be initialized by calling EVP_MD_CTX_init() before calling this function.

EVP_VerifyUpdate() hashes **cnt** bytes of data at **d** into the verification context **ctx**. This function can be called several times on the same **ctx** to include additional data.

EVP_VerifyFinal() verifies the data in **ctx** using the public key **pkey** and against the **siglen** bytes at **sigbuf**.

EVP_VerifyInit() initializes verification context **ctx** to use the default implementation of digest **type**.

RETURN VALUES

EVP_VerifyInit_ex() and EVP_VerifyUpdate() return 1 for success and 0 for failure.

EVP_VerifyFinal() returns 1 for a correct signature, 0 for failure and -1 if some other error occurred.

The error codes can be obtained by ERR_get_error(3).

NOTES

The **EVP** interface to digital signatures should almost always be used in preference to the low level interfaces. This is because the code then becomes transparent to the algorithm used and much more flexible.

Due to the link between message digests and public key algorithms the correct digest algorithm must be used with the correct public key type. A list of algorithms and associated public key algorithms appears in EVP_DigestInit(3).

The call to EVP_VerifyFinal() internally finalizes a copy of the digest context. This means that calls to EVP_VerifyUpdate() and EVP_VerifyFinal() can be called later to digest and verify additional data.

Since only a copy of the digest context is ever finalized the context must be cleaned up after use by calling EVP_MD_CTX_cleanup() or a memory leak will occur.

BUGS

Older versions of this documentation wrongly stated that calls to EVP_VerifyUpdate() could not be made after calling EVP_VerifyFinal().

Since the public key is passed in the call to EVP_SignFinal() any error relating to the private key (for example an unsuitable key and digest combination) will not be indicated until after potentially large amounts of data have been passed through EVP_SignUpdate().

It is not possible to change the signing parameters using these function.

The previous two bugs are fixed in the newer EVP_VerifyDigest*() function.

Name

HMAC, HMAC_Init, HMAC_Update, HMAC_Final and HMAC_cleanup — HMAC message authentication code

Synopsis

```
#include  <openssl/hmac.h>
```

```
unsigned char *HMAC(const EVP_MD *evp_md, const void *key,
              int key_len, const unsigned char *d, int n,
              unsigned char *md, unsigned int *md_len);
```

```
void HMAC_CTX_init(HMAC_CTX *ctx);
```

```
int HMAC_Init(HMAC_CTX *ctx, const void *key, int key_len,
              const EVP_MD *md);
int HMAC_Init_ex(HMAC_CTX *ctx, const void *key, int key_len,
                  const EVP_MD *md, ENGINE *impl);
int HMAC_Update(HMAC_CTX *ctx, const unsigned char *data, int len);
int HMAC_Final(HMAC_CTX *ctx, unsigned char *md, unsigned int *len);
```

```
void HMAC_CTX_cleanup(HMAC_CTX *ctx);
void HMAC_cleanup(HMAC_CTX *ctx);
```

DESCRIPTION

HMAC is a MAC (message authentication code), i.e. a keyed hash function used for message authentication, which is based on a hash function.

HMAC() computes the message authentication code of the **n** bytes at **d** using the hash function **evp_md** and the key **key** which is **key_len** bytes long.

It places the result in **md** (which must have space for the output of the hash function, which is no more than **EVP_MAX_MD_SIZE** bytes). If **md** is NULL, the digest is placed in a static array. The size of the output is placed in **md_len**, unless it is **NULL**.

evp_md can be EVP_sha1(), EVP_ripemd160() etc.

HMAC_CTX_init() initialises a **HMAC_CTX** before first use. It must be called.

HMAC_CTX_cleanup() erases the key and other data from the **HMAC_CTX** and releases any associated resources. It must be called when an **HMAC_CTX** is no longer required.

HMAC_cleanup() is an alias for HMAC_CTX_cleanup() included for back compatibility with 0.9.6b, it is deprecated.

The following functions may be used if the message is not completely stored in memory:

HMAC_Init() initializes a **HMAC_CTX** structure to use the hash function **evp_md** and the key **key** which is **key_len** bytes long. It is deprecated and only included for backward compatibility with OpenSSL 0.9.6b.

HMAC_Init_ex() initializes or reuses a **HMAC_CTX** structure to use the function **evp_md** and key **key**. Either can be NULL, in which case the existing one will be reused. HMAC_CTX_init() must have been called before the first use of an **HMAC_CTX** in this function. **N.B. HMAC_Init() had this undocumented behaviour in previous versions of OpenSSL - failure to switch to HMAC_Init_ex() in programs that expect it will cause them to stop working**.

HMAC_Update() can be called repeatedly with chunks of the message to be authenticated (**len** bytes at **data**).

HMAC_Final() places the message authentication code in **md**, which must have space for the hash function output.

RETURN VALUES

HMAC() returns a pointer to the message authentication code or NULL if an error occurred.

HMAC_Init_ex(), HMAC_Update() and HMAC_Final() return 1 for success or 0 if an error occurred.

HMAC_CTX_init() and HMAC_CTX_cleanup() do not return values.

CONFORMING TO

RFC 2104

SEE ALSO

sha(3), evp(3)

HISTORY

HMAC(), HMAC_Init(), HMAC_Update(), HMAC_Final() and HMAC_cleanup() are available since SSLeay 0.9.0.

HMAC_CTX_init(), HMAC_Init_ex() and HMAC_CTX_cleanup() are available since OpenSSL 0.9.7.

HMAC_Init_ex(), HMAC_Update() and HMAC_Final() did not return values in versions of OpenSSL before 1.0.0.

Name

i2d_CMS_bio_stream — output CMS_ContentInfo structure in BER format.

Synopsis

```
#include  <openssl/cms.h>
```

```
int i2d_CMS_bio_stream(BIO *out, CMS_ContentInfo *cms, BIO *data, int flags);
```

DESCRIPTION

i2d_CMS_bio_stream() outputs a CMS_ContentInfo structure in BER format.

It is otherwise identical to the function SMIME_write_CMS().

NOTES

This function is effectively a version of the i2d_CMS_bio() supporting streaming.

BUGS

The prefix "i2d" is arguably wrong because the function outputs BER format.

RETURN VALUES

i2d_CMS_bio_stream() returns 1 for success or 0 for failure.

```

DESCRIPTION

This library implements type-checked dynamic hash tables. The hash table entries can be arbitrary structures. Usually they consist of key and value fields.

lh_<type>_new() creates a new **LHASH_OF(type)** structure to store arbitrary data entries, and provides the 'hash' and 'compare' callbacks to be used in organising the table's entries. The **hash** callback takes a pointer to a table entry as its argument and returns an unsigned long hash value for its key field. The hash value is normally truncated to a power of 2, so make sure that your hash function returns well mixed low order bits. The **compare** callback takes two arguments (pointers to two hash table entries), and returns 0 if their keys are equal, non-zero otherwise. If your hash table will contain items of some particular type and the **hash** and **compare** callbacks hash/compare these types, then the **DECLARE_LHASH_HASH_FN** and **IMPLEMENT_LHASH_COMP_FN** macros can be used to create callback wrappers of the prototypes required by lh_<type>_new(). These provide per-variable casts before calling the type-specific callbacks written by the application author. These macros, as well as those used for the "doall" callbacks, are defined as;

```
#define DECLARE_LHASH_HASH_FN(name, o_type) \
        unsigned long name##_LHASH_HASH(const void *);
#define IMPLEMENT_LHASH_HASH_FN(name, o_type) \
        unsigned long name##_LHASH_HASH(const void *arg) { \
                const o_type *a = arg; \
                return name##_hash(a); }
#define LHASH_HASH_FN(name) name##_LHASH_HASH

#define DECLARE_LHASH_COMP_FN(name, o_type) \
        int name##_LHASH_COMP(const void *, const void *);
#define IMPLEMENT_LHASH_COMP_FN(name, o_type) \
        int name##_LHASH_COMP(const void *arg1, const void *arg2) { \
                const o_type *a = arg1;                     \
                const o_type *b = arg2; \
                return name##_cmp(a,b); }
#define LHASH_COMP_FN(name) name##_LHASH_COMP

#define DECLARE_LHASH_DOALL_FN(name, o_type) \
        void name##_LHASH_DOALL(void *);
#define IMPLEMENT_LHASH_DOALL_FN(name, o_type) \
        void name##_LHASH_DOALL(void *arg) { \
                o_type *a = arg; \
                name##_doall(a); }
#define LHASH_DOALL_FN(name) name##_LHASH_DOALL

#define DECLARE_LHASH_DOALL_ARG_FN(name, o_type, a_type) \
        void name##_LHASH_DOALL_ARG(void *, void *);
#define IMPLEMENT_LHASH_DOALL_ARG_FN(name, o_type, a_type) \
        void name##_LHASH_DOALL_ARG(void *arg1, void *arg2) { \
                o_type *a = arg1; \
                a_type *b = arg2; \
                name##_doall_arg(a, b); }
#define LHASH_DOALL_ARG_FN(name) name##_LHASH_DOALL_ARG

An example of a hash table storing (pointers to) structures of type 'STUFF'
could be defined as follows;

/* Calculates the hash value of 'tohash' (implemented elsewhere) */
unsigned long STUFF_hash(const STUFF *tohash);
/* Orders 'arg1' and 'arg2' (implemented elsewhere) */
int stuff_cmp(const STUFF *arg1, const STUFF *arg2);
/* Create the type-safe wrapper functions for use in the LHASH internals */
static IMPLEMENT_LHASH_HASH_FN(stuff, STUFF);
static IMPLEMENT_LHASH_COMP_FN(stuff, STUFF);
/* … */
int main(int argc, char *argv[]) {
        /* Create the new hash table using the hash/compare wrappers */
        LHASH_OF(STUFF) *hashtable = lh_STUFF_new(LHASH_HASH_FN(STUFF_hash),
                                  LHASH_COMP_FN(STUFF_cmp));
        /* … */
}
```

lh_<type>_free() frees the **LHASH_OF(type)** structure **table**. Allocated hash table entries will not be freed; consider using lh_<type>_doall() to deallocate any remaining entries in the hash table (see below).

lh_<type>_insert() inserts the structure pointed to by **data** into **table**. If there already is an entry with the same key, the old value is replaced. Note that lh_<type>_insert() stores pointers, the data are not copied.

lh_<type>_delete() deletes an entry from **table**.

lh_<type>_retrieve() looks up an entry in **table**. Normally, **data** is a structure with the key field(s) set; the function will return a pointer to a fully populated structure.

lh_<type>_doall() will, for every entry in the hash table, call **func** with the data item as its parameter. For lh_<type>_doall() and lh_<type>_doall_arg(), function pointer casting should be avoided in the callbacks (see **NOTE**) - instead use the declare/ implement macros to create type-checked wrappers that cast variables prior to calling your type-specific callbacks. An example of this is illustrated here where the callback is used to cleanup resources for items in the hash table prior to the hashtable itself being deallocated:

```
/* Cleans up resources belonging to 'a' (this is implemented elsewhere) */
void STUFF_cleanup_doall(STUFF *a);
/* Implement a prototype-compatible wrapper for "STUFF_cleanup" */
IMPLEMENT_LHASH_DOALL_FN(STUFF_cleanup, STUFF)
        /* … then later in the code … */
/* So to run "STUFF_cleanup" against all items in a hash table … */
lh_STUFF_doall(hashtable, LHASH_DOALL_FN(STUFF_cleanup));
/* Then the hash table itself can be deallocated */
lh_STUFF_free(hashtable);
```

When doing this, be careful if you delete entries from the hash table in your callbacks: the table may decrease in size, moving the item that you are currently on down lower in the hash table - this could cause some entries to be skipped during the iteration. The second best solution to this problem is to set hash->down_load=0 before you start (which will stop the hash table ever decreasing in size). The best solution is probably to avoid deleting items from the hash table inside a "doall" callback!

lh_<type>_doall_arg() is the same as lh_<type>_doall() except that **func** will be called with **arg** as the second argument and **func** should be of type **LHASH_DOALL_ARG_FN_TYPE** (a callback prototype that is passed both the table entry and an extra argument). As with lh_doall(), you can instead choose to declare your callback with a prototype matching the types you are dealing with and use the declare/implement macros to create compatible wrappers that cast variables before calling your type-specific callbacks. An example of this is demonstrated here (printing all hash table entries to a BIO that is provided by the caller):

```
/* Prints item 'a' to 'output_bio' (this is implemented elsewhere) */
void STUFF_print_doall_arg(const STUFF *a, BIO *output_bio);
/* Implement a prototype-compatible wrapper for "STUFF_print" */
static IMPLEMENT_LHASH_DOALL_ARG_FN(STUFF, const STUFF, BIO)
        /* … then later in the code … */
/* Print out the entire hashtable to a particular BIO */
lh_STUFF_doall_arg(hashtable, LHASH_DOALL_ARG_FN(STUFF_print), BIO,
                   logging_bio);
```

lh_<type>_error() can be used to determine if an error occurred in the last operation. lh_<type>_error() is a macro.

RETURN VALUES

lh_<type>_new() returns **NULL** on error, otherwise a pointer to the new **LHASH** structure.

When a hash table entry is replaced, lh_<type>_insert() returns the value being replaced. **NULL** is returned on normal operation and on error.

lh_<type>_delete() returns the entry being deleted. **NULL** is returned if there is no such value in the hash table.

lh_<type>_retrieve() returns the hash table entry if it has been found, **NULL** otherwise.

lh_<type>_error() returns 1 if an error occurred in the last operation, 0 otherwise.

lh_<type>_free(), lh_<type>_doall() and lh_<type>_doall_arg() return no values.

NOTE

The various LHASH macros and callback types exist to make it possible to write type-checked code without resorting to function-prototype casting - an evil that makes application code much harder to audit/verify and also opens the window of opportunity for stack corruption and other hard-to-find bugs. It also, apparently, violates ANSI-C.

The LHASH code regards table entries as constant data. As such, it internally represents lh_insert()'d items with a "const void *" pointer type. This is why callbacks such as those used by lh_doall() and lh_doall_arg() declare their prototypes with "const", even for the parameters that pass back the table items' data pointers - for consistency, user-provided data is "const" at all times as far as the LHASH code is concerned. However, as callers are themselves providing these pointers, they can choose whether they too should be treating all such parameters as constant.

As an example, a hash table may be maintained by code that, for reasons of encapsulation, has only "const" access to the data being indexed in the hash table (ie. it is returned as "const" from elsewhere in their code) - in this case the LHASH prototypes are appropriate as-is. Conversely, if the caller is responsible for the life-time of the data in question, then they may well wish to make modifications to table item passed back in the lh_doall() or lh_doall_arg() callbacks (see the "STUFF_cleanup" example above). If so, the caller can either cast the "const" away (if they're providing the raw callbacks themselves) or use the macros to declare/implement the wrapper functions without "const" types.

Callers that only have "const" access to data they're indexing in a table, yet declare callbacks without constant types (or cast the "const" away themselves), are therefore creating their own risks/bugs without being encouraged to do so by the API. On a related note, those auditing code should pay special attention to any instances of DECLARE/IMPLEMENT_LHASH_DOALL_[ARG_]_FN macros that provide types without any "const" qualifiers.

BUGS

lh_<type>_insert() returns **NULL** both for success and error.

INTERNALS

The following description is based on the SSLeay documentation:

The **lhash** library implements a hash table described in the *Communications of the ACM* in 1991. What makes this hash table different is that as the table fills, the hash table is increased (or decreased) in size via OPENSSL_realloc(). When a 'resize' is done, instead of all hashes being redistributed over twice as many 'buckets', one bucket is split. So when an 'expand' is done, there is only a minimal cost to redistribute some values. Subsequent inserts will cause more single 'bucket' redistributions but there will never be a sudden large cost due to redistributing all the 'buckets'.

The state for a particular hash table is kept in the **LHASH** structure. The decision to increase or decrease the hash table size is made depending on the 'load' of the hash table. The load is the number of items in the hash table divided by the size of the hash table. The default values are as follows. If (hash->up_load < load) => expand. if (hash->down_load > load) => contract. The **up_load** has a default value of 1 and **down_load** has a default value of 2. These numbers can be modified by the application by just playing with the **up_load** and **down_load** variables. The 'load' is kept in a form which is multiplied by 256. So hash->up_load=8*256; will cause a load of 8 to be set.

If you are interested in performance the field to watch is num_comp_calls. The hash library keeps track of the 'hash' value for each item so when a lookup is done, the 'hashes' are compared, if there is a match, then a full compare is done, and hash->num_comp_calls is incremented. If num_comp_calls is not equal to num_delete plus num_retrieve it means that your hash function is generating hashes that are the same for different values. It is probably worth changing your hash function if this is the case because even if your hash table has 10 items in a 'bucket', it can be searched with 10 **unsigned long** compares and 10 linked list traverses. This will be much less expensive that 10 calls to your compare function.

lh_strhash() is a demo string hashing function:

```
unsigned long lh_strhash(const char *c);
```

Since the **LHASH** routines would normally be passed structures, this routine would not normally be passed to lh_<type>_new(), rather it would be used in the function passed to lh_<type>_new().

SEE ALSO

lh_stats(3)

HISTORY

The **lhash** library is available in all versions of SSLeay and OpenSSL. lh_error() was added in SSLeay 0.9.1b.

This manpage is derived from the SSLeay documentation.

In OpenSSL 0.9.7, all lhash functions that were passed function pointers were changed for better type safety, and the function types LHASH_COMP_FN_TYPE, LHASH_HASH_FN_TYPE, LHASH_DOALL_FN_TYPE and LHASH_DOALL_ARG_FN_TYPE became available.

In OpenSSL 1.0.0, the lhash interface was revamped for even better type checking.

Name

lh_stats, lh_node_stats, lh_node_usage_stats, lh_stats_bio, lh_node_stats_bio and lh_node_usage_stats_bio — LHASH statistics

Synopsis

```
#include  <openssl/lhash.h>
```

```
void lh_stats(LHASH *table, FILE *out);
void lh_node_stats(LHASH *table, FILE *out);
void lh_node_usage_stats(LHASH *table, FILE *out);
```

```
void lh_stats_bio(LHASH *table, BIO *out);
void lh_node_stats_bio(LHASH *table, BIO *out);
void lh_node_usage_stats_bio(LHASH *table, BIO *out);
```

DESCRIPTION

The **LHASH** structure records statistics about most aspects of accessing the hash table. This is mostly a legacy of Eric Young writing this library for the reasons of implementing what looked like a nice algorithm rather than for a particular software product.

lh_stats() prints out statistics on the size of the hash table, how many entries are in it, and the number and result of calls to the routines in this library.

lh_node_stats() prints the number of entries for each 'bucket' in the hash table.

lh_node_usage_stats() prints out a short summary of the state of the hash table. It prints the 'load' and the 'actual load'. The load is the average number of data items per 'bucket' in the hash table. The 'actual load' is the average number of items per 'bucket', but only for buckets which contain entries. So the 'actual load' is the average number of searches that will need to find an item in the hash table, while the 'load' is the average number that will be done to record a miss.

lh_stats_bio(), lh_node_stats_bio() and lh_node_usage_stats_bio() are the same as the above, except that the output goes to a **BIO**.

RETURN VALUES

These functions do not return values.

int MD5_Update(MD5_CTX *c, const void *data,
                 unsigned long len);
int MD5_Final(unsigned char *md, MD5_CTX *c);
```

DESCRIPTION

MD2, MD4, and MD5 are cryptographic hash functions with a 128 bit output.

MD2(), MD4(), and MD5() compute the MD2, MD4, and MD5 message digest of the **n** bytes at **d** and place it in **md** (which must have space for MD2_DIGEST_LENGTH == MD4_DIGEST_LENGTH == MD5_DIGEST_LENGTH == 16 bytes of output). If **md** is NULL, the digest is placed in a static array.

The following functions may be used if the message is not completely stored in memory:

MD2_Init() initializes a **MD2_CTX** structure.

MD2_Update() can be called repeatedly with chunks of the message to be hashed (**len** bytes at **data**).

MD2_Final() places the message digest in **md**, which must have space for MD2_DIGEST_LENGTH == 16 bytes of output, and erases the **MD2_CTX**.

MD4_Init(), MD4_Update(), MD4_Final(), MD5_Init(), MD5_Update(), and MD5_Final() are analogous using an **MD4_CTX** and **MD5_CTX** structure.

Applications should use the higher level functions EVP_DigestInit(3) etc. instead of calling the hash functions directly.

NOTE

MD2, MD4, and MD5 are recommended only for compatibility with existing applications. In new applications, SHA-1 or RIPEMD-160 should be preferred.

RETURN VALUES

MD2(), MD4(), and MD5() return pointers to the hash value.

MD2_Init(), MD2_Update(), MD2_Final(), MD4_Init(), MD4_Update(), MD4_Final(), MD5_Init(), MD5_Update(), and MD5_Final() return 1 for success, 0 otherwise.

CONFORMING TO

RFC 1319, RFC 1320, RFC 1321

SEE ALSO

sha(3), ripemd(3), EVP_DigestInit(3)

HISTORY

MD2(), MD2_Init(), MD2_Update() MD2_Final(), MD5(), MD5_Init(), MD5_Update() and MD5_Final() are available in all versions of SSLeay and OpenSSL.

MD4(), MD4_Init(), and MD4_Update() are available in OpenSSL 0.9.6 and above.

Name

MDC2, MDC2_Init, MDC2_Update and MDC2_Final — MDC2 hash function

Synopsis

```
#include  <openssl/mdc2.h>
```

```
unsigned char *MDC2(const unsigned char *d, unsigned long n,
                 unsigned char *md);
```

```
int MDC2_Init(MDC2_CTX *c);
int MDC2_Update(MDC2_CTX *c, const unsigned char *data,
                 unsigned long len);
int MDC2_Final(unsigned char *md, MDC2_CTX *c);
```

DESCRIPTION

MDC2 is a method to construct hash functions with 128 bit output from block ciphers. These functions are an implementation of MDC2 with DES.

MDC2() computes the MDC2 message digest of the **n** bytes at **d** and places it in **md** (which must have space for MDC2_DIGEST_LENGTH == 16 bytes of output). If **md** is NULL, the digest is placed in a static array.

The following functions may be used if the message is not completely stored in memory:

MDC2_Init() initializes a **MDC2_CTX** structure.

MDC2_Update() can be called repeatedly with chunks of the message to be hashed (**len** bytes at **data**).

MDC2_Final() places the message digest in **md**, which must have space for MDC2_DIGEST_LENGTH == 16 bytes of output, and erases the **MDC2_CTX**.

Applications should use the higher level functions EVP_DigestInit(3) etc. instead of calling the hash functions directly.

RETURN VALUES

MDC2() returns a pointer to the hash value.

MDC2_Init(), MDC2_Update() and MDC2_Final() return 1 for success, 0 otherwise.

CONFORMING TO

ISO/IEC 10118-2, with DES

SEE ALSO

sha(3), EVP_DigestInit(3)

HISTORY

MDC2(), MDC2_Init(), MDC2_Update() and MDC2_Final() are available since SSLeay 0.8.

int OBJ_obj2txt(char *buf, int buf_len, const ASN1_OBJECT *a, int no_name);
```

```
int OBJ_cmp(const ASN1_OBJECT *a,const ASN1_OBJECT *b);
ASN1_OBJECT * OBJ_dup(const ASN1_OBJECT *o);
```

```
int OBJ_create(const char *oid,const char *sn,const char *ln);
void OBJ_cleanup(void);
```

DESCRIPTION

The ASN1 object utility functions process ASN1_OBJECT structures which are a representation of the ASN1 OBJECT IDENTIFIER (OID) type.

OBJ_nid2obj(), OBJ_nid2ln() and OBJ_nid2sn() convert the NID **n** to an ASN1_OBJECT structure, its long name and its short name respectively, or **NULL** is an error occurred.

OBJ_obj2nid(), OBJ_ln2nid(), OBJ_sn2nid() return the corresponding NID for the object **o**, the long name <ln> or the short name <sn> respectively or NID_undef if an error occurred.

OBJ_txt2nid() returns NID corresponding to text string <s>. **s** can be a long name, a short name or the numerical respresentation of an object.

OBJ_txt2obj() converts the text string **s** into an ASN1_OBJECT structure. If **no_name** is 0 then long names and short names will be interpreted as well as numerical forms. If **no_name** is 1 only the numerical form is acceptable.

OBJ_obj2txt() converts the **ASN1_OBJECT a** into a textual representation. The representation is written as a null terminated string to **buf** at most **buf_len** bytes are written, truncating the result if necessary. The total amount of space required is returned. If **no_name** is 0 then if the object has a long or short name then that will be used, otherwise the numerical form will be used. If **no_name** is 1 then the numerical form will always be used.

OBJ_cmp() compares **a** to **b**. If the two are identical 0 is returned.

OBJ_dup() returns a copy of **o**.

OBJ_create() adds a new object to the internal table. **oid** is the numerical form of the object, **sn** the short name and **ln** the long name. A new NID is returned for the created object.

OBJ_cleanup() cleans up OpenSSLs internal object table: this should be called before an application exits if any new objects were added using OBJ_create().

NOTES

Objects in OpenSSL can have a short name, a long name and a numerical identifier (NID) associated with them. A standard set of objects is represented in an internal table. The appropriate values are defined in the header file **objects.h**.

For example the OID for commonName has the following definitions:

```
#define SN_commonName                   "CN"
#define LN_commonName                   "commonName"
#define NID_commonName                  13
```

New objects can be added by calling OBJ_create().

Table objects have certain advantages over other objects: for example their NIDs can be used in a C language switch statement. They are also static constant structures which are shared: that is there is only a single constant structure for each table object.

Objects which are not in the table have the NID value NID_undef.

Objects do not need to be in the internal tables to be processed, the functions OBJ_txt2obj() and OBJ_obj2txt() can process the numerical form of an OID.

EXAMPLES

Create an object for **commonName**:

```
ASN1_OBJECT *o;
o = OBJ_nid2obj(NID_commonName);
```

Check if an object is **commonName**

```
if (OBJ_obj2nid(obj) == NID_commonName)
       /* Do something */
```

Create a new NID and initialize an object from it:

```
int new_nid;
ASN1_OBJECT *obj;
new_nid = OBJ_create("1.2.3.4", "NewOID", "New Object Identifier");

obj = OBJ_nid2obj(new_nid);
```

Create a new object directly:

```
obj = OBJ_txt2obj("1.2.3.4", 1);
```

BUGS

OBJ_obj2txt() is awkward and messy to use: it doesn't follow the convention of other OpenSSL functions where the buffer can be set to **NULL** to determine the amount of data that should be written. Instead **buf** must point to a valid buffer and **buf_len** should be set to a positive value. A buffer length of 80 should be more than enough to handle any OID encountered in practice.

RETURN VALUES

OBJ_nid2obj() returns an **ASN1_OBJECT** structure or **NULL** is an error occurred.

OBJ_nid2ln() and OBJ_nid2sn() returns a valid string or **NULL** on error.

OBJ_obj2nid(), OBJ_ln2nid(), OBJ_sn2nid() and OBJ_txt2nid() return a NID or **NID_undef** on error.

Name

OpenSSL_add_all_algorithms, OpenSSL_add_all_ciphers and OpenSSL_add_all_digests — add algorithms to internal table

Synopsis

```
#include  <openssl/evp.h>
```

```
void OpenSSL_add_all_algorithms(void);
void OpenSSL_add_all_ciphers(void);
void OpenSSL_add_all_digests(void);
```

```
void EVP_cleanup(void);
```

DESCRIPTION

OpenSSL keeps an internal table of digest algorithms and ciphers. It uses this table to lookup ciphers via functions such as EVP_get_cipher_byname().

OpenSSL_add_all_digests() adds all digest algorithms to the table.

OpenSSL_add_all_algorithms() adds all algorithms to the table (digests and ciphers).

OpenSSL_add_all_ciphers() adds all encryption algorithms to the table including password based encryption algorithms.

EVP_cleanup() removes all ciphers and digests from the table.

RETURN VALUES

None of the functions return a value.

NOTES

A typical application will call OpenSSL_add_all_algorithms() initially and EVP_cleanup() before exiting.

An application does not need to add algorithms to use them explicitly, for example by EVP_sha1(). It just needs to add them if it (or any of the functions it calls) needs to lookup algorithms.

The cipher and digest lookup functions are used in many parts of the library. If the table is not initialized several functions will misbehave and complain they cannot find algorithms. This includes the PEM, PKCS#12, SSL and S/MIME libraries. This is a common query in the OpenSSL mailing lists.

Calling OpenSSL_add_all_algorithms() links in all algorithms: as a result a statically linked executable can be quite large. If this is important it is possible to just add the required ciphers and digests.

BUGS

Although the functions do not return error codes it is possible for them to fail. This will only happen as a result of a memory allocation failure so this is not too much of a problem in practice.

Name

OPENSSL_Applink — glue between OpenSSL BIO and Win32 compiler run-time

Synopsis

```
__declspec(dllexport) void **OPENSSL_Applink();
```

DESCRIPTION

OPENSSL_Applink is application-side interface which provides a glue between OpenSSL BIO layer and Win32 compiler run-time environment. Even though it appears at application side, it's essentially OpenSSL private interface. For this reason application developers are not expected to implement it, but to compile provided module with compiler of their choice and link it into the target application. The referred module is available as <openssl>/ms/applink.c.

Name

OPENSSL_config and OPENSSL_no_config — simple OpenSSL configuration functions

Synopsis

```
#include  <openssl/conf.h>
```

```
void OPENSSL_config(const char *config_name);
void OPENSSL_no_config(void);
```

DESCRIPTION

OPENSSL_config() configures OpenSSL using the standard **openssl.cnf** configuration file name using **config_name**. If **config_name** is NULL then the file specified in the environment variable **OPENSSL_CONF** will be used, and if that is not set then a system default location is used. Errors are silently ignored. Multiple calls have no effect.

OPENSSL_no_config() disables configuration. If called before OPENSSL_config() no configuration takes place.

NOTES

The OPENSSL_config() function is designed to be a very simple "call it and forget it" function. It is however **much** better than nothing. Applications which need finer control over their configuration functionality should use the configuration functions such as CONF_modules_load() directly. This function is deprecated and its use should be avoided. Applications should instead call CONF_modules_load() during initialization (that is before starting any threads).

There are several reasons why calling the OpenSSL configuration routines is advisable. For example new ENGINE functionality was added to OpenSSL 0.9.7. In OpenSSL 0.9.7 control functions can be supported by ENGINEs, this can be used (among other things) to load dynamic ENGINEs from shared libraries (DSOs). However very few applications currently support the control interface and so very few can load and use dynamic ENGINEs. Equally in future more sophisticated ENGINEs will require certain control operations to customize them. If an application calls OPENSSL_config() it doesn't need to know or care about ENGINE control operations because they can be performed by editing a configuration file.

Applications should free up configuration at application closedown by calling CONF_modules_free().

RESTRICTIONS

The OPENSSL_config() function is designed to be a very simple "call it and forget it" function. As a result its behaviour is somewhat limited. It ignores all errors silently and it can only load from the standard configuration file location for example.

It is however **much** better than nothing. Applications which need finer control over their configuration functionality should use the configuration functions such as CONF_load_modules() directly.

RETURN VALUES

Neither OPENSSL_config() nor OPENSSL_no_config() return a value.

SEE ALSO

conf(5), CONF_load_modules_file(3), CONF_modules_free(3)

HISTORY

OPENSSL_config() and OPENSSL_no_config() first appeared in OpenSSL 0.9.7

Name

OPENSSL_ia32cap — finding the IA-32 processor capabilities

Synopsis

```
unsigned long *OPENSSL_ia32cap_loc(void);
#define OPENSSL_ia32cap (*(OPENSSL_ia32cap_loc()))
```

DESCRIPTION

Value returned by OPENSSL_ia32cap_loc() is address of a variable containing IA-32 processor capabilities bit vector as it appears in EDX register after executing CPUID instruction with EAX=1 input value (see Intel Application Note #241618). Naturally it's meaningful on IA-32[E] platforms only. The variable is normally set up automatically upon toolkit initialization, but can be manipulated afterwards to modify crypto library behaviour. For the moment of this writing six bits are significant, namely:

1. bit #28 denoting Hyperthreading, which is used to distiguish cores with shared cache; 2. bit #26 denoting SSE2 support; 3. bit #25 denoting SSE support; 4. bit #23 denoting MMX support; 5. bit #20, reserved by Intel, is used to choose between RC4 code pathes; 6. bit #4 denoting presence of Time-Stamp Counter.

For example, clearing bit #26 at run-time disables high-performance SSE2 code present in the crypto library. You might have to do this if target OpenSSL application is executed on SSE2 capable CPU, but under control of OS which does not support SSE2 extentions. Even though you can manipulate the value programmatically, you most likely will find it more appropriate to set up an environment variable with the same name prior starting target application, e.g. on Intel P4 processor 'env OPENSSL_ia32cap=0x12900010 apps/openssl', to achieve same effect without modifying the application source code. Alternatively you can reconfigure the toolkit with no-sse2 option and recompile.

Name

OPENSSL_load_builtin_modules — add standard configuration modules

Synopsis

```
#include  <openssl/conf.h>
```

```
void OPENSSL_load_builtin_modules(void);
void ASN1_add_oid_module(void);
ENGINE_add_conf_module();
```

DESCRIPTION

The function OPENSSL_load_builtin_modules() adds all the standard OpenSSL configuration modules to the internal list. They can then be used by the OpenSSL configuration code.

ASN1_add_oid_module() adds just the ASN1 OBJECT module.

ENGINE_add_conf_module() adds just the ENGINE configuration module.

NOTES

If the simple configuration function OPENSSL_config() is called then OPENSSL_load_builtin_modules() is called automatically.

Applications which use the configuration functions directly will need to call OPENSSL_load_builtin_modules() themselves *before* any other configuration code.

Applications should call OPENSSL_load_builtin_modules() to load all configuration modules instead of adding modules selectively: otherwise functionality may be missing from the application if an when new modules are added.

RETURN VALUE

None of the functions return a value.

SEE ALSO

conf(3), OPENSSL_config(3)

HISTORY

These functions first appeared in OpenSSL 0.9.7.

Name

OPENSSL_VERSION_NUMBER, SSLeay and SSLeay_version — get OpenSSL version number

Synopsis

```
#include  <openssl/opensslv.h>
#define OPENSSL_VERSION_NUMBER 0xnnnnnnnnnL
```

```
#include  <openssl/crypto.h>
long SSLeay(void);
const char *SSLeay_version(int t);
```

DESCRIPTION

OPENSSL_VERSION_NUMBER is a numeric release version identifier:

```
MMNNFFPPS: major minor fix patch status
```

The status nibble has one of the values 0 for development, 1 to e for betas 1 to 14, and f for release.

for example

```
0x000906000 == 0.9.6 dev
0x000906023 == 0.9.6b beta 3
0x00090605f == 0.9.6e release
```

Versions prior to 0.9.3 have identifiers < 0x0930. Versions between 0.9.3 and 0.9.5 had a version identifier with this interpretation:

```
MMNNFFRBB major minor fix final beta/patch
```

for example

```
0x000904100 == 0.9.4 release
0x000905000 == 0.9.5 dev
```

Version 0.9.5a had an interim interpretation that is like the current one, except the patch level got the highest bit set, to keep continuity. The number was therefore 0x0090581f.

For backward compatibility, SSLEAY_VERSION_NUMBER is also defined.

SSLeay() returns this number. The return value can be compared to the macro to make sure that the correct version of the library has been loaded, especially when using DLLs on Windows systems.

SSLeay_version() returns different strings depending on **t**:

SSLEAY_VERSION

The text variant of the version number and the release date. For example, "OpenSSL 0.9.5a 1 Apr 2000".

SSLEAY_CFLAGS

The compiler flags set for the compilation process in the form "compiler: …" if available or "compiler: information not available" otherwise.

SSLEAY_BUILT_ON

The date of the build process in the form "built on: …" if available or "built on: date not available" otherwise.

SSLEAY_PLATFORM

The "Configure" target of the library build in the form "platform: …" if available or "platform: information not available" otherwise.

SSLEAY_DIR

> The "OPENSSLDIR" setting of the library build in the form "OPENSSLDIR: "..."" if available or "OPENSSLDIR: N/A" otherwise.

For an unknown **t**, the text "not available" is returned.

RETURN VALUE

The version number.

SEE ALSO

crypto(3)

HISTORY

SSLeay() and SSLEAY_VERSION_NUMBER are available in all versions of SSLeay and OpenSSL. OPENSSL_VERSION_NUMBER is available in all versions of OpenSSL. **SSLEAY_DIR** was added in OpenSSL 0.9.7.

DESCRIPTION

The PEM functions read or write structures in PEM format. In this sense PEM format is simply base64 encoded data surrounded by header lines.

For more details about the meaning of arguments see the **PEM FUNCTION ARGUMENTS** section.

Each operation has four functions associated with it. For clarity the term "**foobar** functions" will be used to collectively refer to the PEM_read_bio_foobar(), PEM_read_foobar(), PEM_write_bio_foobar() and PEM_write_foobar() functions.

The **PrivateKey** functions read or write a private key in PEM format using an EVP_PKEY structure. The write routines use "traditional" private key format and can handle both RSA and DSA private keys. The read functions can additionally transparently handle PKCS#8 format encrypted and unencrypted keys too.

PEM_write_bio_PKCS8PrivateKey() and PEM_write_PKCS8PrivateKey() write a private key in an EVP_PKEY structure in PKCS#8 EncryptedPrivateKeyInfo format using PKCS#5 v2.0 password based encryption algorithms. The **cipher** argument specifies the encryption algorithm to use: unlike all other PEM routines the encryption is applied at the PKCS#8 level and not in the PEM headers. If **cipher** is NULL then no encryption is used and a PKCS#8 PrivateKeyInfo structure is used instead.

PEM_write_bio_PKCS8PrivateKey_nid() and PEM_write_PKCS8PrivateKey_nid() also write out a private key as a PKCS#8 EncryptedPrivateKeyInfo however it uses PKCS#5 v1.5 or PKCS#12 encryption algorithms instead. The algorithm to use is specified in the **nid** parameter and should be the NID of the corresponding OBJECT IDENTIFIER (see NOTES section).

The **PUBKEY** functions process a public key using an EVP_PKEY structure. The public key is encoded as a SubjectPublicKeyInfo structure.

The **RSAPrivateKey** functions process an RSA private key using an RSA structure. It handles the same formats as the **PrivateKey** functions but an error occurs if the private key is not RSA.

The **RSAPublicKey** functions process an RSA public key using an RSA structure. The public key is encoded using a PKCS#1 RSAPublicKey structure.

The **RSA_PUBKEY** functions also process an RSA public key using an RSA structure. However the public key is encoded using a SubjectPublicKeyInfo structure and an error occurs if the public key is not RSA.

The **DSAPrivateKey** functions process a DSA private key using a DSA structure. It handles the same formats as the **PrivateKey** functions but an error occurs if the private key is not DSA.

The **DSA_PUBKEY** functions process a DSA public key using a DSA structure. The public key is encoded using a SubjectPublicKeyInfo structure and an error occurs if the public key is not DSA.

The **DSAparams** functions process DSA parameters using a DSA structure. The parameters are encoded using a Dss-Parms structure as defined in RFC2459.

The **DHparams** functions process DH parameters using a DH structure. The parameters are encoded using a PKCS#3 DHparameter structure.

The **X509** functions process an X509 certificate using an X509 structure. They will also process a trusted X509 certificate but any trust settings are discarded.

The **X509_AUX** functions process a trusted X509 certificate using an X509 structure.

The **X509_REQ** and **X509_REQ_NEW** functions process a PKCS#10 certificate request using an X509_REQ structure. The **X509_REQ** write functions use **CERTIFICATE REQUEST** in the header whereas the **X509_REQ_NEW** functions use **NEW CERTIFICATE REQUEST** (as required by some CAs). The **X509_REQ** read functions will handle either form so there are no **X509_REQ_NEW** read functions.

The **X509_CRL** functions process an X509 CRL using an X509_CRL structure.

The **PKCS7** functions process a PKCS#7 ContentInfo using a PKCS7 structure.

The **NETSCAPE_CERT_SEQUENCE** functions process a Netscape Certificate Sequence using a NETSCAPE_CERT_SEQUENCE structure.

PEM FUNCTION ARGUMENTS

The PEM functions have many common arguments.

The **bp** BIO parameter (if present) specifies the BIO to read from or write to.

The **fp** FILE parameter (if present) specifies the FILE pointer to read from or write to.

The PEM read functions all take an argument **TYPE **x** and return a **TYPE *** pointer. Where **TYPE** is whatever structure the function uses. If **x** is NULL then the parameter is ignored. If **x** is not NULL but ***x** is NULL then the structure returned will be written to ***x**. If neither **x** nor ***x** is NULL then an attempt is made to reuse the structure at ***x** (but see BUGS and EXAMPLES sections). Irrespective of the value of **x** a pointer to the structure is always returned (or NULL if an error occurred).

The PEM functions which write private keys take an **enc** parameter which specifies the encryption algorithm to use, encryption is done at the PEM level. If this parameter is set to NULL then the private key is written in unencrypted form.

The **cb** argument is the callback to use when querying for the pass phrase used for encrypted PEM structures (normally only private keys).

For the PEM write routines if the **kstr** parameter is not NULL then **klen** bytes at **kstr** are used as the passphrase and **cb** is ignored.

If the **cb** parameters is set to NULL and the **u** parameter is not NULL then the **u** parameter is interpreted as a null terminated string to use as the passphrase. If both **cb** and **u** are NULL then the default callback routine is used which will typically prompt for the passphrase on the current terminal with echoing turned off.

The default passphrase callback is sometimes inappropriate (for example in a GUI application) so an alternative can be supplied. The callback routine has the following form:

```
int cb(char *buf, int size, int rwflag, void *u);
```

buf is the buffer to write the passphrase to. **size** is the maximum length of the passphrase (i.e. the size of buf). **rwflag** is a flag which is set to 0 when reading and 1 when writing. A typical routine will ask the user to verify the passphrase (for example by prompting for it twice) if **rwflag** is 1. The **u** parameter has the same value as the **u** parameter passed to the PEM routine. It allows arbitrary data to be passed to the callback by the application (for example a window handle in a GUI application). The callback **must** return the number of characters in the passphrase or 0 if an error occurred.

EXAMPLES

Although the PEM routines take several arguments in almost all applications most of them are set to 0 or NULL.

Read a certificate in PEM format from a BIO:

```
X509 *x;
x = PEM_read_bio_X509(bp, NULL, 0, NULL);
if (x == NULL)
       {
       /* Error */
       }
```

Alternative method:

```
X509 *x = NULL;
if (!PEM_read_bio_X509(bp, &x, 0, NULL))
       {
       /* Error */
       }
```

Write a certificate to a BIO:

```
if (!PEM_write_bio_X509(bp, x))
       {
       /* Error */
       }
```

Write an unencrypted private key to a FILE pointer:

```
if (!PEM_write_PrivateKey(fp, key, NULL, NULL, 0, 0, NULL))
       {
       /* Error */
       }
```

Write a private key (using traditional format) to a BIO using triple DES encryption, the pass phrase is prompted for:

```
if (!PEM_write_bio_PrivateKey(bp, key, EVP_des_ede3_cbc(), NULL, 0, 0, NULL))
       {
       /* Error */
       }
```

Write a private key (using PKCS#8 format) to a BIO using triple DES encryption, using the pass phrase "hello":

```
if (!PEM_write_bio_PKCS8PrivateKey(bp, key, EVP_des_ede3_cbc(), NULL, 0, 0, "hello"))
       {
       /* Error */
       }
```

Read a private key from a BIO using the pass phrase "hello":

```
key = PEM_read_bio_PrivateKey(bp, NULL, 0, "hello");
if (key == NULL)
       {
       /* Error */
       }
```

Read a private key from a BIO using a pass phrase callback:

```
key = PEM_read_bio_PrivateKey(bp, NULL, pass_cb, "My Private Key");
if (key == NULL)
       {
       /* Error */
       }
```

Skeleton pass phrase callback:

```
int pass_cb(char *buf, int size, int rwflag, void *u);
       {
       int len;
       char *tmp;
       /* We'd probably do something else if 'rwflag' is 1 */
       printf("Enter pass phrase for \"%s\"\n", u);

/* get pass phrase, length 'len' into 'tmp' */
tmp = "hello";
len = strlen(tmp);

if (len <= 0) return 0;
/* if too long, truncate */
if (len > size) len = size;
memcpy(buf, tmp, len);
return len;
}
```

NOTES

The old **PrivateKey** write routines are retained for compatibility. New applications should write private keys using the PEM_write_bio_PKCS8PrivateKey() or PEM_write_PKCS8PrivateKey() routines because they are more secure (they use an iteration count of 2048 whereas the traditional routines use a count of 1) unless compatibility with older versions of OpenSSL is important.

The **PrivateKey** read routines can be used in all applications because they handle all formats transparently.

A frequent cause of problems is attempting to use the PEM routines like this:

```
X509 *x;
PEM_read_bio_X509(bp, &x, 0, NULL);
```

this is a bug because an attempt will be made to reuse the data at **x** which is an uninitialised pointer.

PEM ENCRYPTION FORMAT

This old **PrivateKey** routines use a non standard technique for encryption.

The private key (or other data) takes the following form:

```
-----BEGIN RSA PRIVATE KEY-----
Proc-Type: 4,ENCRYPTED
DEK-Info: DES-EDE3-CBC,3F17F5316E2BAC89

…base64 encoded data…
-----END RSA PRIVATE KEY-----
```

The line beginning DEK-Info contains two comma separated pieces of information: the encryption algorithm name as used by EVP_get_cipherbyname() and an 8 byte **salt** encoded as a set of hexadecimal digits.

After this is the base64 encoded encrypted data.

The encryption key is determined using EVP_BytesToKey(), using **salt** and an iteration count of 1. The IV used is the value of **salt** and *not* the IV returned by EVP_BytesToKey().

BUGS

The PEM read routines in some versions of OpenSSL will not correctly reuse an existing structure. Therefore the following:

```
PEM_read_bio_X509(bp, &x, 0, NULL);
```

where **x** already contains a valid certificate, may not work, whereas:

```
X509_free(x);
x = PEM_read_bio_X509(bp, NULL, 0, NULL);
```

is guaranteed to work.

RETURN CODES

The read routines return either a pointer to the structure read or NULL if an error occurred.

The write routines return 1 for success or 0 for failure.

SEE ALSO

HISTORY

PEM_write_bio_CMS_stream() was added to OpenSSL 1.0.0

Name

PEM_write_bio_PKCS7_stream — output PKCS7 structure in PEM format.

Synopsis

```
#include  <openssl/pkcs7.h>
#include  <openssl/pem.h>
```

```
int PEM_write_bio_PKCS7_stream(BIO *out, PKCS7 *p7, BIO *data, int flags);
```

DESCRIPTION

PEM_write_bio_PKCS7_stream() outputs a PKCS7 structure in PEM format.

It is otherwise identical to the function SMIME_write_PKCS7().

NOTES

This function is effectively a version of the PEM_write_bio_PKCS7() supporting streaming.

RETURN VALUES

PEM_write_bio_PKCS7_stream() returns 1 for success or 0 for failure.

SEE ALSO

ERR_get_error(3), PKCS7_sign(3), PKCS7_verify(3), PKCS7_encrypt(3), PKCS7_decrypt(3), SMIME_write_PKCS7(3), i2d_PKCS7_bio_stream(3)

HISTORY

PEM_write_bio_PKCS7_stream() was added to OpenSSL 1.0.0

Name

PKCS12_create — create a PKCS#12 structure

Synopsis

```
#include  <openssl/pkcs12.h>
```

```
PKCS12 *PKCS12_create(char *pass, char *name, EVP_PKEY *pkey, X509 *cert, STACK_OF(X509) *ca,
                               int nid_key, int nid_cert, int iter, int mac_iter, int keytype);
```

DESCRIPTION

PKCS12_create() creates a PKCS#12 structure.

pass is the passphrase to use. **name** is the **friendlyName** to use for the supplied certifictate and key. **pkey** is the private key to include in the structure and **cert** its corresponding certificates. **ca**, if not **NULL** is an optional set of certificates to also include in the structure.

nid_key and **nid_cert** are the encryption algorithms that should be used for the key and certificate respectively. **iter** is the encryption algorithm iteration count to use and **mac_iter** is the MAC iteration count to use. **keytype** is the type of key.

NOTES

The parameters **nid_key**, **nid_cert**, **iter**, **mac_iter** and **keytype** can all be set to zero and sensible defaults will be used.

These defaults are: 40 bit RC2 encryption for certificates, triple DES encryption for private keys, a key iteration count of PKCS12_DEFAULT_ITER (currently 2048) and a MAC iteration count of 1.

The default MAC iteration count is 1 in order to retain compatibility with old software which did not interpret MAC iteration counts. If such compatibility is not required then **mac_iter** should be set to PKCS12_DEFAULT_ITER.

keytype adds a flag to the store private key. This is a non standard extension that is only currently interpreted by MSIE. If set to zero the flag is omitted, if set to **KEY_SIG** the key can be used for signing only, if set to **KEY_EX** it can be used for signing and encryption. This option was useful for old export grade software which could use signing only keys of arbitrary size but had restrictions on the permissible sizes of keys which could be used for encryption.

NEW FUNCTIONALITY IN OPENSSL 0.9.8

Some additional functionality was added to PKCS12_create() in OpenSSL 0.9.8. These extensions are detailed below.

If a certificate contains an **alias** or **keyid** then this will be used for the corresponding **friendlyName** or **localKeyID** in the PKCS12 structure.

Either **pkey**, **cert** or both can be **NULL** to indicate that no key or certficate is required. In previous versions both had to be present or a fatal error is returned.

nid_key or **nid_cert** can be set to -1 indicating that no encryption should be used.

mac_iter can be set to -1 and the MAC will then be omitted entirely.

SEE ALSO

d2i_PKCS12(3)

HISTORY

PKCS12_create was added in OpenSSL 0.9.3

Name

PKCS12_parse — parse a PKCS#12 structure

Synopsis

```
#include  <openssl/pkcs12.h>
```

```
int PKCS12_parse(PKCS12 *p12, const char *pass, EVP_PKEY **pkey, X509 **cert, STACK_OF(X509) **ca);
```

DESCRIPTION

PKCS12_parse() parses a PKCS12 structure.

p12 is the **PKCS12** structure to parse. **pass** is the passphrase to use. If successful the private key will be written to ***pkey**, the corresponding certificate to ***cert** and any additional certificates to ***ca**.

NOTES

The parameters **pkey** and **cert** cannot be **NULL**. **ca** can be <NULL> in which case additional certificates will be discarded. ***ca** can also be a valid STACK in which case additional certificates are appended to ***ca**. If ***ca** is **NULL** a new STACK will be allocated.

The **friendlyName** and **localKeyID** attributes (if present) on each certificate will be stored in the **alias** and **keyid** attributes of the **X509** structure.

RETURN VALUES

PKCS12_parse() returns 1 for success and zero if an error occurred.

The error can be obtained from ERR_get_error(3)

BUGS

Only a single private key and corresponding certificate is returned by this function. More complex PKCS#12 files with multiple private keys will only return the first match.

Only **friendlyName** and **localKeyID** attributes are currently stored in certificates. Other attributes are discarded.

Attributes currently cannot be stored in the private key **EVP_PKEY** structure.

SEE ALSO

d2i_PKCS12(3)

HISTORY

PKCS12_parse was added in OpenSSL 0.9.3

Name

PKCS7_decrypt — decrypt content from a PKCS#7 envelopedData structure

Synopsis

```
#include  <openssl/pkcs7.h>
```

```
int PKCS7_decrypt(PKCS7 *p7, EVP_PKEY *pkey, X509 *cert, BIO *data, int flags);
```

DESCRIPTION

PKCS7_decrypt() extracts and decrypts the content from a PKCS#7 envelopedData structure. **pkey** is the private key of the recipient, **cert** is the recipients certificate, **data** is a BIO to write the content to and **flags** is an optional set of flags.

NOTES

OpenSSL_add_all_algorithms() (or equivalent) should be called before using this function or errors about unknown algorithms will occur.

Although the recipients certificate is not needed to decrypt the data it is needed to locate the appropriate (of possible several) recipients in the PKCS#7 structure.

The following flags can be passed in the **flags** parameter.

If the **PKCS7_TEXT** flag is set MIME headers for type **text/plain** are deleted from the content. If the content is not of type **text/plain** then an error is returned.

RETURN VALUES

PKCS7_decrypt() returns either 1 for success or 0 for failure. The error can be obtained from ERR_get_error(3)

BUGS

PKCS7_decrypt() must be passed the correct recipient key and certificate. It would be better if it could look up the correct key and certificate from a database.

The lack of single pass processing and need to hold all data in memory as mentioned in PKCS7_sign() also applies to PKCS7_verify().

SEE ALSO

ERR_get_error(3), PKCS7_encrypt(3)

HISTORY

PKCS7_decrypt() was added to OpenSSL 0.9.5

Name

PKCS7_encrypt — create a PKCS#7 envelopedData structure

Synopsis

```
#include  <openssl/pkcs7.h>
```

```
PKCS7 *PKCS7_encrypt(STACK_OF(X509) *certs, BIO *in, const EVP_CIPHER *cipher, int flags);
```

DESCRIPTION

PKCS7_encrypt() creates and returns a PKCS#7 envelopedData structure. **certs** is a list of recipient certificates. **in** is the content to be encrypted. **cipher** is the symmetric cipher to use. **flags** is an optional set of flags.

NOTES

Only RSA keys are supported in PKCS#7 and envelopedData so the recipient certificates supplied to this function must all contain RSA public keys, though they do not have to be signed using the RSA algorithm.

EVP_des_ede3_cbc() (triple DES) is the algorithm of choice for S/MIME use because most clients will support it.

Some old "export grade" clients may only support weak encryption using 40 or 64 bit RC2. These can be used by passing EVP_rc2_40_cbc() and EVP_rc2_64_cbc() respectively.

The algorithm passed in the **cipher** parameter must support ASN1 encoding of its parameters.

Many browsers implement a "sign and encrypt" option which is simply an S/MIME envelopedData containing an S/MIME signed message. This can be readily produced by storing the S/MIME signed message in a memory BIO and passing it to PKCS7_encrypt().

The following flags can be passed in the **flags** parameter.

If the **PKCS7_TEXT** flag is set MIME headers for type **text/plain** are prepended to the data.

Normally the supplied content is translated into MIME canonical format (as required by the S/MIME specifications) if **PKCS7_BINARY** is set no translation occurs. This option should be used if the supplied data is in binary format otherwise the translation will corrupt it. If **PKCS7_BINARY** is set then **PKCS7_TEXT** is ignored.

If the **PKCS7_STREAM** flag is set a partial **PKCS7** structure is output suitable for streaming I/O: no data is read from the BIO **in**.

NOTES

If the flag **PKCS7_STREAM** is set the returned **PKCS7** structure is **not** complete and outputting its contents via a function that does not properly finalize the **PKCS7** structure will give unpredictable results.

Several functions including SMIME_write_PKCS7(), i2d_PKCS7_bio_stream(), PEM_write_bio_PKCS7_stream() finalize the structure. Alternatively finalization can be performed by obtaining the streaming ASN1 **BIO** directly using BIO_new_PKCS7().

RETURN VALUES

PKCS7_encrypt() returns either a PKCS7 structure or NULL if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), PKCS7_decrypt(3)

HISTORY

PKCS7_decrypt() was added to OpenSSL 0.9.5 The **PKCS7_STREAM** flag was first supported in OpenSSL 1.0.0.

Name

PKCS7_sign_add_signer — add a signer PKCS7 signed data structure.

Synopsis

```
#include  <openssl/pkcs7.h>
```

```
PKCS7_SIGNER_INFO *PKCS7_sign_add_signer(PKCS7 *p7, X509 *signcert, EVP_PKEY *pkey,
    const EVP_MD *md, int flags);
```

DESCRIPTION

PKCS7_sign_add_signer() adds a signer with certificate **signcert** and private key **pkey** using message digest **md** to a PKCS7 signed data structure **p7**.

The PKCS7 structure should be obtained from an initial call to PKCS7_sign() with the flag **PKCS7_PARTIAL** set or in the case or re-signing a valid PKCS7 signed data structure.

If the **md** parameter is **NULL** then the default digest for the public key algorithm will be used.

Unless the **PKCS7_REUSE_DIGEST** flag is set the returned PKCS7 structure is not complete and must be finalized either by streaming (if applicable) or a call to PKCS7_final().

NOTES

The main purpose of this function is to provide finer control over a PKCS#7 signed data structure where the simpler PKCS7_sign() function defaults are not appropriate. For example if multiple signers or non default digest algorithms are needed.

Any of the following flags (ored together) can be passed in the **flags** parameter.

If **PKCS7_REUSE_DIGEST** is set then an attempt is made to copy the content digest value from the PKCS7 struture: to add a signer to an existing structure. An error occurs if a matching digest value cannot be found to copy. The returned PKCS7 structure will be valid and finalized when this flag is set.

If **PKCS7_PARTIAL** is set in addition to **PKCS7_REUSE_DIGEST** then the **PKCS7_SIGNER_INO** structure will not be finalized so additional attributes can be added. In this case an explicit call to PKCS7_SIGNER_INFO_sign() is needed to finalize it.

If **PKCS7_NOCERTS** is set the signer's certificate will not be included in the PKCS7 structure, the signer's certificate must still be supplied in the **signcert** parameter though. This can reduce the size of the signature if the signers certificate can be obtained by other means: for example a previously signed message.

The signedData structure includes several PKCS#7 autenticatedAttributes including the signing time, the PKCS#7 content type and the supported list of ciphers in an SMIMECapabilities attribute. If **PKCS7_NOATTR** is set then no authenticatedAttributes will be used. If **PKCS7_NOSMIMECAP** is set then just the SMIMECapabilities are omitted.

If present the SMIMECapabilities attribute indicates support for the following algorithms: triple DES, 128 bit RC2, 64 bit RC2, DES and 40 bit RC2. If any of these algorithms is disabled then it will not be included.

PKCS7_sign_add_signers() returns an internal pointer to the PKCS7_SIGNER_INFO structure just added, this can be used to set additional attributes before it is finalized.

RETURN VALUES

PKCS7_sign_add_signers() returns an internal pointer to the PKCS7_SIGNER_INFO structure just added or NULL if an error occurs.

SEE ALSO

ERR_get_error(3), PKCS7_sign(3), PKCS7_final(3),

HISTORY

PPKCS7_sign_add_signer() was added to OpenSSL 1.0.0

Name

PKCS7_sign — create a PKCS#7 signedData structure

Synopsis

```
#include  <openssl/pkcs7.h>
```

```
PKCS7 *PKCS7_sign(X509 *signcert, EVP_PKEY *pkey, STACK_OF(X509) *certs, BIO *data, int flags);
```

DESCRIPTION

PKCS7_sign() creates and returns a PKCS#7 signedData structure. **signcert** is the certificate to sign with, **pkey** is the corresponsding private key. **certs** is an optional additional set of certificates to include in the PKCS#7 structure (for example any intermediate CAs in the chain).

The data to be signed is read from BIO **data**.

flags is an optional set of flags.

NOTES

Any of the following flags (ored together) can be passed in the **flags** parameter.

Many S/MIME clients expect the signed content to include valid MIME headers. If the **PKCS7_TEXT** flag is set MIME headers for type **text/plain** are prepended to the data.

If **PKCS7_NOCERTS** is set the signer's certificate will not be included in the PKCS7 structure, the signer's certificate must still be supplied in the **signcert** parameter though. This can reduce the size of the signature if the signers certificate can be obtained by other means: for example a previously signed message.

The data being signed is included in the PKCS7 structure, unless **PKCS7_DETACHED** is set in which case it is omitted. This is used for PKCS7 detached signatures which are used in S/MIME plaintext signed messages for example.

Normally the supplied content is translated into MIME canonical format (as required by the S/MIME specifications) if **PKCS7_BINARY** is set no translation occurs. This option should be used if the supplied data is in binary format otherwise the translation will corrupt it.

The signedData structure includes several PKCS#7 autenticatedAttributes including the signing time, the PKCS#7 content type and the supported list of ciphers in an SMIMECapabilities attribute. If **PKCS7_NOATTR** is set then no authenticatedAttributes will be used. If **PKCS7_NOSMIMECAP** is set then just the SMIMECapabilities are omitted.

If present the SMIMECapabilities attribute indicates support for the following algorithms: triple DES, 128 bit RC2, 64 bit RC2, DES and 40 bit RC2. If any of these algorithms is disabled then it will not be included.

If the flags **PKCS7_STREAM** is set then the returned **PKCS7** structure is just initialized ready to perform the signing operation. The signing is however **not** performed and the data to be signed is not read from the **data** parameter. Signing is deferred until after the data has been written. In this way data can be signed in a single pass.

If the **PKCS7_PARTIAL** flag is set a partial **PKCS7** structure is output to which additional signers and capabilities can be added before finalization.

NOTES

If the flag **PKCS7_STREAM** is set the returned **PKCS7** structure is **not** complete and outputting its contents via a function that does not properly finalize the **PKCS7** structure will give unpredictable results.

Several functions including SMIME_write_PKCS7(), i2d_PKCS7_bio_stream(), PEM_write_bio_PKCS7_stream() finalize the structure. Alternatively finalization can be performed by obtaining the streaming ASN1 **BIO** directly using BIO_new_PKCS7().

If a signer is specified it will use the default digest for the signing algorithm. This is **SHA1** for both RSA and DSA keys.

In OpenSSL 1.0.0 the **certs**, **signcert** and **pkey** parameters can all be **NULL** if the **PKCS7_PARTIAL** flag is set. One or more signers can be added using the function **PKCS7_sign_add_signer()**. **PKCS7_final()** must also be called to finalize the structure if streaming is not enabled. Alternative signing digests can also be specified using this method.

In OpenSSL 1.0.0 if **signcert** and **pkey** are NULL then a certificates only PKCS#7 structure is output.

In versions of OpenSSL before 1.0.0 the **signcert** and **pkey** parameters must **NOT** be NULL.

BUGS

Some advanced attributes such as counter signatures are not supported.

RETURN VALUES

PKCS7_sign() returns either a valid PKCS7 structure or NULL if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), PKCS7_verify(3)

HISTORY

PKCS7_sign() was added to OpenSSL 0.9.5

The **PKCS7_PARTIAL** flag was added in OpenSSL 1.0.0

The **PKCS7_STREAM** flag was added in OpenSSL 1.0.0

Name

PKCS7_verify — verify a PKCS#7 signedData structure

Synopsis

```
#include  <openssl/pkcs7.h>
```

```
int PKCS7_verify(PKCS7 *p7, STACK_OF(X509) *certs, X509_STORE *store, BIO *indata, BIO *out, int flags);
```

```
STACK_OF(X509) *PKCS7_get0_signers(PKCS7 *p7, STACK_OF(X509) *certs, int flags);
```

DESCRIPTION

PKCS7_verify() verifies a PKCS#7 signedData structure. **p7** is the PKCS7 structure to verify. **certs** is a set of certificates in which to search for the signer's certificate. **store** is a trusted certficate store (used for chain verification). **indata** is the signed data if the content is not present in **p7** (that is it is detached). The content is written to **out** if it is not NULL.

flags is an optional set of flags, which can be used to modify the verify operation.

PKCS7_get0_signers() retrieves the signer's certificates from **p7**, it does **not** check their validity or whether any signatures are valid. The **certs** and **flags** parameters have the same meanings as in PKCS7_verify().

VERIFY PROCESS

Normally the verify process proceeds as follows.

Initially some sanity checks are performed on **p7**. The type of **p7** must be signedData. There must be at least one signature on the data and if the content is detached **indata** cannot be **NULL**.

An attempt is made to locate all the signer's certificates, first looking in the **certs** parameter (if it is not **NULL**) and then looking in any certificates contained in the **p7** structure itself. If any signer's certificates cannot be located the operation fails.

Each signer's certificate is chain verified using the **smimesign** purpose and the supplied trusted certificate store. Any internal certificates in the message are used as untrusted CAs. If any chain verify fails an error code is returned.

Finally the signed content is read (and written to **out** is it is not NULL) and the signature's checked.

If all signature's verify correctly then the function is successful.

Any of the following flags (ored together) can be passed in the **flags** parameter to change the default verify behaviour. Only the flag **PKCS7_NOINTERN** is meaningful to PKCS7_get0_signers().

If **PKCS7_NOINTERN** is set the certificates in the message itself are not searched when locating the signer's certificate. This means that all the signers certificates must be in the **certs** parameter.

If the **PKCS7_TEXT** flag is set MIME headers for type **text/plain** are deleted from the content. If the content is not of type **text/plain** then an error is returned.

If **PKCS7_NOVERIFY** is set the signer's certificates are not chain verified.

If **PKCS7_NOCHAIN** is set then the certificates contained in the message are not used as untrusted CAs. This means that the whole verify chain (apart from the signer's certificate) must be contained in the trusted store.

If **PKCS7_NOSIGS** is set then the signatures on the data are not checked.

NOTES

One application of **PKCS7_NOINTERN** is to only accept messages signed by a small number of certificates. The acceptable certificates would be passed in the **certs** parameter. In this case if the signer is not one of the certificates supplied in **certs** then the verify will fail because the signer cannot be found.

Care should be taken when modifying the default verify behaviour, for example setting **PKCS7_NOVERIFY|PKCS7_NOSIGS** will totally disable all verification and any signed message will be considered valid. This combination is however useful if one merely wishes to write the content to **out** and its validity is not considered important.

Chain verification should arguably be performed using the signing time rather than the current time. However since the signing time is supplied by the signer it cannot be trusted without additional evidence (such as a trusted timestamp).

RETURN VALUES

PKCS7_verify() returns 1 for a successful verification and zero or a negative value if an error occurs.

PKCS7_get0_signers() returns all signers or **NULL** if an error occurred.

The error can be obtained from ERR_get_error(3)

BUGS

The trusted certificate store is not searched for the signers certificate, this is primarily due to the inadequacies of the current **X509_STORE** functionality.

The lack of single pass processing and need to hold all data in memory as mentioned in PKCS7_sign() also applies to PKCS7_verify().

```

DESCRIPTION

Since the introduction of the ENGINE API, the recommended way of controlling default implementations is by using the ENGINE API functions. The default **RAND_METHOD**, as set by RAND_set_rand_method() and returned by RAND_get_rand_method(), is only used if no ENGINE has been set as the default "rand" implementation. Hence, these two functions are no longer the recommened way to control defaults.

If an alternative **RAND_METHOD** implementation is being used (either set directly or as provided by an ENGINE module), then it is entirely responsible for the generation and management of a cryptographically secure PRNG stream. The mechanisms described below relate solely to the software PRNG implementation built in to OpenSSL and used by default.

These functions implement a cryptographically secure pseudo-random number generator (PRNG). It is used by other library functions for example to generate random keys, and applications can use it when they need randomness.

A cryptographic PRNG must be seeded with unpredictable data such as mouse movements or keys pressed at random by the user. This is described in RAND_add(3). Its state can be saved in a seed file (see RAND_load_file(3)) to avoid having to go through the seeding process whenever the application is started.

RAND_bytes(3) describes how to obtain random data from the PRNG.

INTERNALS

The RAND_SSLeay() method implements a PRNG based on a cryptographic hash function.

The following description of its design is based on the SSLeay documentation:

First up I will state the things I believe I need for a good RNG.

1. A good hashing algorithm to mix things up and to convert the RNG 'state' to random numbers.

2. An initial source of random 'state'.

3. The state should be very large. If the RNG is being used to generate 4096 bit RSA keys, 2 2048 bit random strings are required (at a minimum). If your RNG state only has 128 bits, you are obviously limiting the search space to 128 bits, not 2048. I'm probably getting a little carried away on this last point but it does indicate that it may not be a bad idea to keep quite a lot of RNG state. It should be easier to break a cipher than guess the RNG seed data.

4. Any RNG seed data should influence all subsequent random numbers generated. This implies that any random seed data entered will have an influence on all subsequent random numbers generated.

5. When using data to seed the RNG state, the data used should not be extractable from the RNG state. I believe this should be a requirement because one possible source of 'secret' semi random data would be a private key or a password. This data must not be disclosed by either subsequent random numbers or a 'core' dump left by a program crash.

6. Given the same initial 'state', 2 systems should deviate in their RNG state (and hence the random numbers generated) over time if at all possible.

7. Given the random number output stream, it should not be possible to determine the RNG state or the next random number.

The algorithm is as follows.

There is global state made up of a 1023 byte buffer (the 'state'), a working hash value ('md'), and a counter ('count').

Whenever seed data is added, it is inserted into the 'state' as follows.

The input is chopped up into units of 20 bytes (or less for the last block). Each of these blocks is run through the hash function as follows: The data passed to the hash function is the current 'md', the same number of bytes from the 'state' (the location determined by in incremented looping index) as the current 'block', the new key data 'block', and 'count' (which is incremented after each use). The result of this is kept in 'md' and also xored into the 'state' at the same locations that were used as input into the hash function. I believe this system addresses points 1 (hash function; currently SHA-1), 3 (the 'state'), 4 (via the 'md'), 5 (by the use of a hash function and xor).

When bytes are extracted from the RNG, the following process is used. For each group of 10 bytes (or less), we do the following:

Input into the hash function the local 'md' (which is initialized from the global 'md' before any bytes are generated), the bytes that are to be overwritten by the random bytes, and bytes from the 'state' (incrementing looping index). From this digest output (which is kept in 'md'), the top (up to) 10 bytes are returned to the caller and the bottom 10 bytes are xored into the 'state'.

Finally, after we have finished 'num' random bytes for the caller, 'count' (which is incremented) and the local and global 'md' are fed into the hash function and the results are kept in the global 'md'.

I believe the above addressed points 1 (use of SHA-1), 6 (by hashing into the 'state' the 'old' data from the caller that is about to be overwritten) and 7 (by not using the 10 bytes given to the caller to update the 'state', but they are used to update 'md').

So of the points raised, only 2 is not addressed (but see RAND_add(3)).

SEE ALSO

BN_rand(3), RAND_add(3), RAND_load_file(3), RAND_egd(3), RAND_bytes(3), RAND_set_rand_method(3), RAND_cleanup(3)

Name

RAND_add, RAND_seed, RAND_status, RAND_event and RAND_screen — add entropy to the PRNG

Synopsis

```
#include  <openssl/rand.h>

void RAND_seed(const void *buf, int num);

void RAND_add(const void *buf, int num, double entropy);

int  RAND_status(void);

int  RAND_event(UINT iMsg, WPARAM wParam, LPARAM lParam);
void RAND_screen(void);
```

DESCRIPTION

RAND_add() mixes the **num** bytes at **buf** into the PRNG state. Thus, if the data at **buf** are unpredictable to an adversary, this increases the uncertainty about the state and makes the PRNG output less predictable. Suitable input comes from user interaction (random key presses, mouse movements) and certain hardware events. The **entropy** argument is (the lower bound of) an estimate of how much randomness is contained in **buf**, measured in bytes. Details about sources of randomness and how to estimate their entropy can be found in the literature, e.g. RFC 1750.

RAND_add() may be called with sensitive data such as user entered passwords. The seed values cannot be recovered from the PRNG output.

OpenSSL makes sure that the PRNG state is unique for each thread. On systems that provide `/dev/urandom`, the randomness device is used to seed the PRNG transparently. However, on all other systems, the application is responsible for seeding the PRNG by calling RAND_add(), RAND_egd(3) or RAND_load_file(3).

RAND_seed() is equivalent to RAND_add() when **num == entropy**.

RAND_event() collects the entropy from Windows events such as mouse movements and other user interaction. It should be called with the **iMsg**, **wParam** and **lParam** arguments of *all* messages sent to the window procedure. It will estimate the entropy contained in the event message (if any), and add it to the PRNG. The program can then process the messages as usual.

The RAND_screen() function is available for the convenience of Windows programmers. It adds the current contents of the screen to the PRNG. For applications that can catch Windows events, seeding the PRNG by calling RAND_event() is a significantly better source of randomness. It should be noted that both methods cannot be used on servers that run without user interaction.

RETURN VALUES

RAND_status() and RAND_event() return 1 if the PRNG has been seeded with enough data, 0 otherwise.

The other functions do not return values.

SEE ALSO

rand(3), RAND_egd(3), RAND_load_file(3), RAND_cleanup(3)

HISTORY

RAND_seed() and RAND_screen() are available in all versions of SSLeay and OpenSSL. RAND_add() and RAND_status() have been added in OpenSSL 0.9.5, RAND_event() in OpenSSL 0.9.5a.

Name

RAND_bytes and RAND_pseudo_bytes — generate random data

Synopsis

```
#include  <openssl/rand.h>
```

```
int RAND_bytes(unsigned char *buf, int num);
```

```
int RAND_pseudo_bytes(unsigned char *buf, int num);
```

DESCRIPTION

RAND_bytes() puts **num** cryptographically strong pseudo-random bytes into **buf**. An error occurs if the PRNG has not been seeded with enough randomness to ensure an unpredictable byte sequence.

RAND_pseudo_bytes() puts **num** pseudo-random bytes into **buf**. Pseudo-random byte sequences generated by RAND_pseudo_bytes() will be unique if they are of sufficient length, but are not necessarily unpredictable. They can be used for non-cryptographic purposes and for certain purposes in cryptographic protocols, but usually not for key generation etc.

The contents of **buf** is mixed into the entropy pool before retrieving the new pseudo-random bytes unless disabled at compile time (see FAQ).

RETURN VALUES

RAND_bytes() returns 1 on success, 0 otherwise. The error code can be obtained by ERR_get_error(3). RAND_pseudo_bytes() returns 1 if the bytes generated are cryptographically strong, 0 otherwise. Both functions return -1 if they are not supported by the current RAND method.

SEE ALSO

rand(3), ERR_get_error(3), RAND_add(3)

HISTORY

RAND_bytes() is available in all versions of SSLeay and OpenSSL. It has a return value since OpenSSL 0.9.5. RAND_pseudo_bytes() was added in OpenSSL 0.9.5.

Name

RAND_cleanup — erase the PRNG state

Synopsis

```
#include  <openssl/rand.h>
```

```
void RAND_cleanup(void);
```

DESCRIPTION

RAND_cleanup() erases the memory used by the PRNG.

RETURN VALUE

RAND_cleanup() returns no value.

SEE ALSO

rand(3)

HISTORY

RAND_cleanup() is available in all versions of SSLeay and OpenSSL.

Name

RAND_egd — query entropy gathering daemon

Synopsis

```
#include  <openssl/rand.h>

int RAND_egd(const char *path);
int RAND_egd_bytes(const char *path, int bytes);

int RAND_query_egd_bytes(const char *path, unsigned char *buf, int bytes);
```

DESCRIPTION

RAND_egd() queries the entropy gathering daemon EGD on socket **path**. It queries 255 bytes and uses RAND_add(3) to seed the OpenSSL built-in PRNG. RAND_egd(path) is a wrapper for RAND_egd_bytes(path, 255);

RAND_egd_bytes() queries the entropy gathering daemon EGD on socket **path**. It queries **bytes** bytes and uses RAND_add(3) to seed the OpenSSL built-in PRNG. This function is more flexible than RAND_egd(). When only one secret key must be generated, it is not necessary to request the full amount 255 bytes from the EGD socket. This can be advantageous, since the amount of entropy that can be retrieved from EGD over time is limited.

RAND_query_egd_bytes() performs the actual query of the EGD daemon on socket **path**. If **buf** is given, **bytes** bytes are queried and written into **buf**. If **buf** is NULL, **bytes** bytes are queried and used to seed the OpenSSL built-in PRNG using RAND_add(3).

NOTES

On systems without /dev/*random devices providing entropy from the kernel, the EGD entropy gathering daemon can be used to collect entropy. It provides a socket interface through which entropy can be gathered in chunks up to 255 bytes. Several chunks can be queried during one connection.

EGD is available from http://www.lothar.com/tech/crypto/ (`perl Makefile.PL; make; make install` to install). It is run as **egd** *path*, where *path* is an absolute path designating a socket. When RAND_egd() is called with that path as an argument, it tries to read random bytes that EGD has collected. RAND_egd() retrieves entropy from the daemon using the daemon's "non-blocking read" command which shall be answered immediately by the daemon without waiting for additional entropy to be collected. The write and read socket operations in the communication are blocking.

Alternatively, the EGD-interface compatible daemon PRNGD can be used. It is available from http://prngd.sourceforge.net/ . PRNGD does employ an internal PRNG itself and can therefore never run out of entropy.

OpenSSL automatically queries EGD when entropy is requested via RAND_bytes() or the status is checked via RAND_status() for the first time, if the socket is located at /var/run/egd-pool, /dev/egd-pool or /etc/egd-pool.

RETURN VALUE

RAND_egd() and RAND_egd_bytes() return the number of bytes read from the daemon on success, and -1 if the connection failed or the daemon did not return enough data to fully seed the PRNG.

RAND_query_egd_bytes() returns the number of bytes read from the daemon on success, and -1 if the connection failed. The PRNG state is not considered.

SEE ALSO

rand(3), RAND_add(3), RAND_cleanup(3)

HISTORY

RAND_egd() is available since OpenSSL 0.9.5.

RAND_egd_bytes() is available since OpenSSL 0.9.6.

RAND_query_egd_bytes() is available since OpenSSL 0.9.7.

The automatic query of /var/run/egd-pool et al was added in OpenSSL 0.9.7.

Name

RAND_load_file, RAND_write_file and RAND_file_name — PRNG seed file

Synopsis

```
#include  <openssl/rand.h>
```

```
const char *RAND_file_name(char *buf, size_t num);
```

```
int RAND_load_file(const char *filename, long max_bytes);
```

```
int RAND_write_file(const char *filename);
```

DESCRIPTION

RAND_file_name() generates a default path for the random seed file. **buf** points to a buffer of size **num** in which to store the filename. The seed file is $RANDFILE if that environment variable is set, $HOME/.rnd otherwise. If $HOME is not set either, or **num** is too small for the path name, an error occurs.

RAND_load_file() reads a number of bytes from file **filename** and adds them to the PRNG. If **max_bytes** is non-negative, up to to **max_bytes** are read; starting with OpenSSL 0.9.5, if **max_bytes** is -1, the complete file is read.

RAND_write_file() writes a number of random bytes (currently 1024) to file **filename** which can be used to initialize the PRNG by calling RAND_load_file() in a later session.

RETURN VALUES

RAND_load_file() returns the number of bytes read.

RAND_write_file() returns the number of bytes written, and -1 if the bytes written were generated without appropriate seed.

RAND_file_name() returns a pointer to **buf** on success, and NULL on error.

SEE ALSO

rand(3), RAND_add(3), RAND_cleanup(3)

HISTORY

RAND_load_file(), RAND_write_file() and RAND_file_name() are available in all versions of SSLeay and OpenSSL.

Name

RAND_set_rand_method, RAND_get_rand_method and RAND_SSLeay — select RAND method

Synopsis

```
#include  <openssl/rand.h>
```

```
void RAND_set_rand_method(const RAND_METHOD *meth);
```

```
const RAND_METHOD *RAND_get_rand_method(void);
```

```
RAND_METHOD *RAND_SSLeay(void);
```

DESCRIPTION

A **RAND_METHOD** specifies the functions that OpenSSL uses for random number generation. By modifying the method, alternative implementations such as hardware RNGs may be used. IMPORTANT: See the NOTES section for important information about how these RAND API functions are affected by the use of **ENGINE** API calls.

Initially, the default RAND_METHOD is the OpenSSL internal implementation, as returned by RAND_SSLeay().

RAND_set_default_method() makes **meth** the method for PRNG use. **NB**: This is true only whilst no ENGINE has been set as a default for RAND, so this function is no longer recommended.

RAND_get_default_method() returns a pointer to the current RAND_METHOD. However, the meaningfulness of this result is dependent on whether the ENGINE API is being used, so this function is no longer recommended.

THE RAND_METHOD STRUCTURE

```
typedef struct rand_meth_st
{
       void (*seed)(const void *buf, int num);
       int (*bytes)(unsigned char *buf, int num);
       void (*cleanup)(void);
       void (*add)(const void *buf, int num, int entropy);
       int (*pseudorand)(unsigned char *buf, int num);
       int (*status)(void);
} RAND_METHOD;
```

The components point to the implementation of RAND_seed(), RAND_bytes(), RAND_cleanup(), RAND_add(), RAND_pseudo_rand() and RAND_status(). Each component may be NULL if the function is not implemented.

RETURN VALUES

RAND_set_rand_method() returns no value. RAND_get_rand_method() and RAND_SSLeay() return pointers to the respective methods.

NOTES

As of version 0.9.7, RAND_METHOD implementations are grouped together with other algorithmic APIs (eg. RSA_METHOD, EVP_CIPHER, etc) in **ENGINE** modules. If a default ENGINE is specified for RAND functionality using an ENGINE API function, that will override any RAND defaults set using the RAND API (ie. RAND_set_rand_method()). For this reason, the ENGINE API is the recommended way to control default implementations for use in RAND and other cryptographic algorithms.

SEE ALSO

rand(3), engine(3)

HISTORY

RAND_set_rand_method(), RAND_get_rand_method() and RAND_SSLeay() are available in all versions of OpenSSL.

In the engine version of version 0.9.6, RAND_set_rand_method() was altered to take an ENGINE pointer as its argument. As of version 0.9.7, that has been reverted as the ENGINE API transparently overrides RAND defaults if used, otherwise RAND API functions work as before. RAND_set_rand_engine() was also introduced in version 0.9.7.

Name

RC4_set_key and RC4 — RC4 encryption

Synopsis

```
#include  <openssl/rc4.h>
```

```
void RC4_set_key(RC4_KEY *key, int len, const unsigned char *data);
```

```
void RC4(RC4_KEY *key, unsigned long len, const unsigned char *indata,
         unsigned char *outdata);
```

DESCRIPTION

This library implements the Alleged RC4 cipher, which is described for example in *Applied Cryptography*. It is believed to be compatible with RC4[TM], a proprietary cipher of RSA Security Inc.

RC4 is a stream cipher with variable key length. Typically, 128 bit (16 byte) keys are used for strong encryption, but shorter insecure key sizes have been widely used due to export restrictions.

RC4 consists of a key setup phase and the actual encryption or decryption phase.

RC4_set_key() sets up the **RC4_KEY key** using the **len** bytes long key at **data**.

RC4() encrypts or decrypts the **len** bytes of data at **indata** using **key** and places the result at **outdata**. Repeated RC4() calls with the same **key** yield a continuous key stream.

Since RC4 is a stream cipher (the input is XORed with a pseudo-random key stream to produce the output), decryption uses the same function calls as encryption.

Applications should use the higher level functions EVP_EncryptInit(3) etc. instead of calling the RC4 functions directly.

RETURN VALUES

RC4_set_key() and RC4() do not return values.

NOTE

Certain conditions have to be observed to securely use stream ciphers. It is not permissible to perform multiple encryptions using the same key stream.

SEE ALSO

blowfish(3), des(3), rc2(3)

HISTORY

RC4_set_key() and RC4() are available in all versions of SSLeay and OpenSSL.

Name

RIPEMD160, RIPEMD160_Init, RIPEMD160_Update and RIPEMD160_Final — RIPEMD-160 hash function

Synopsis

```
#include  <openssl/ripemd.h>
```

```
unsigned char *RIPEMD160(const unsigned char *d, unsigned long n,
                 unsigned char *md);
```

```
int RIPEMD160_Init(RIPEMD160_CTX *c);
int RIPEMD160_Update(RIPEMD_CTX *c, const void *data,
                 unsigned long len);
int RIPEMD160_Final(unsigned char *md, RIPEMD160_CTX *c);
```

DESCRIPTION

RIPEMD-160 is a cryptographic hash function with a 160 bit output.

RIPEMD160() computes the RIPEMD-160 message digest of the **n** bytes at **d** and places it in **md** (which must have space for RIPEMD160_DIGEST_LENGTH == 20 bytes of output). If **md** is NULL, the digest is placed in a static array.

The following functions may be used if the message is not completely stored in memory:

RIPEMD160_Init() initializes a **RIPEMD160_CTX** structure.

RIPEMD160_Update() can be called repeatedly with chunks of the message to be hashed (**len** bytes at **data**).

RIPEMD160_Final() places the message digest in **md**, which must have space for RIPEMD160_DIGEST_LENGTH == 20 bytes of output, and erases the **RIPEMD160_CTX**.

Applications should use the higher level functions EVP_DigestInit(3) etc. instead of calling the hash functions directly.

RETURN VALUES

RIPEMD160() returns a pointer to the hash value.

RIPEMD160_Init(), RIPEMD160_Update() and RIPEMD160_Final() return 1 for success, 0 otherwise.

CONFORMING TO

ISO/IEC 10118-3 (draft) (??)

   RSA *rsa);
int RSA_verify_ASN1_OCTET_STRING(int dummy, unsigned char *m,
   unsigned int m_len, unsigned char *sigbuf, unsigned int siglen,
   RSA *rsa);
```

DESCRIPTION

These functions implement RSA public key encryption and signatures as defined in PKCS #1 v2.0 [RFC 2437].

The **RSA** structure consists of several BIGNUM components. It can contain public as well as private RSA keys:

```
struct
```

```
       {
       BIGNUM *n;              // public modulus
       BIGNUM *e;              // public exponent
       BIGNUM *d;              // private exponent
       BIGNUM *p;              // secret prime factor
       BIGNUM *q;              // secret prime factor
       BIGNUM *dmp1;           // d mod (p-1)
       BIGNUM *dmq1;           // d mod (q-1)
       BIGNUM *iqmp;           // q^-1 mod p
       // ...
       };
RSA
```

In public keys, the private exponent and the related secret values are **NULL**.

p, **q**, **dmp1**, **dmq1** and **iqmp** may be **NULL** in private keys, but the RSA operations are much faster when these values are available.

Note that RSA keys may use non-standard **RSA_METHOD** implementations, either directly or by the use of **ENGINE** modules. In some cases (eg. an ENGINE providing support for hardware-embedded keys), these BIGNUM values will not be used by the implementation or may be used for alternative data storage. For this reason, applications should generally avoid using RSA structure elements directly and instead use API functions to query or modify keys.

CONFORMING TO

SSL, PKCS #1 v2.0

PATENTS

RSA was covered by a US patent which expired in September 2000.

Name

RSA_blinding_on and RSA_blinding_off — protect the RSA operation from timing attacks

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_blinding_on(RSA *rsa, BN_CTX *ctx);
```

```
void RSA_blinding_off(RSA *rsa);
```

DESCRIPTION

RSA is vulnerable to timing attacks. In a setup where attackers can measure the time of RSA decryption or signature operations, blinding must be used to protect the RSA operation from that attack.

RSA_blinding_on() turns blinding on for key **rsa** and generates a random blinding factor. **ctx** is **NULL** or a pre-allocated and initialized **BN_CTX**. The random number generator must be seeded prior to calling RSA_blinding_on().

RSA_blinding_off() turns blinding off and frees the memory used for the blinding factor.

RETURN VALUES

RSA_blinding_on() returns 1 on success, and 0 if an error occurred.

RSA_blinding_off() returns no value.

SEE ALSO

rsa(3), rand(3)

HISTORY

RSA_blinding_on() and RSA_blinding_off() appeared in SSLeay 0.9.0.

Name

RSA_check_key — validate private RSA keys

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_check_key(RSA *rsa);
```

DESCRIPTION

This function validates RSA keys. It checks that **p** and **q** are in fact prime, and that **n = p*q**.

It also checks that **d*e = 1 mod (p-1*q-1)**, and that **dmp1**, **dmq1** and **iqmp** are set correctly or are **NULL**.

As such, this function can not be used with any arbitrary RSA key object, even if it is otherwise fit for regular RSA operation. See **NOTES** for more information.

RETURN VALUE

RSA_check_key() returns 1 if **rsa** is a valid RSA key, and 0 otherwise. -1 is returned if an error occurs while checking the key.

If the key is invalid or an error occurred, the reason code can be obtained using ERR_get_error(3).

NOTES

This function does not work on RSA public keys that have only the modulus and public exponent elements populated. It performs integrity checks on all the RSA key material, so the RSA key structure must contain all the private key data too.

Unlike most other RSA functions, this function does **not** work transparently with any underlying ENGINE implementation because it uses the key data in the RSA structure directly. An ENGINE implementation can override the way key data is stored and handled, and can even provide support for HSM keys - in which case the RSA structure may contain **no** key data at all! If the ENGINE in question is only being used for acceleration or analysis purposes, then in all likelihood the RSA key data is complete and untouched, but this can't be assumed in the general case.

BUGS

A method of verifying the RSA key using opaque RSA API functions might need to be considered. Right now RSA_check_key() simply uses the RSA structure elements directly, bypassing the RSA_METHOD table altogether (and completely violating encapsulation and object-orientation in the process). The best fix will probably be to introduce a "check_key()" handler to the RSA_METHOD function table so that alternative implementations can also provide their own verifiers.

SEE ALSO

rsa(3), ERR_get_error(3)

HISTORY

RSA_check_key() appeared in OpenSSL 0.9.4.

Name

RSA_generate_key — generate RSA key pair

Synopsis

```
#include  <openssl/rsa.h>
```

```
RSA *RSA_generate_key(int num, unsigned long e,
   void (*callback)(int,int,void *), void *cb_arg);
```

DESCRIPTION

RSA_generate_key() generates a key pair and returns it in a newly allocated **RSA** structure. The pseudo-random number generator must be seeded prior to calling RSA_generate_key().

The modulus size will be **num** bits, and the public exponent will be **e**. Key sizes with **num** < 1024 should be considered insecure. The exponent is an odd number, typically 3, 17 or 65537.

A callback function may be used to provide feedback about the progress of the key generation. If **callback** is not **NULL**, it will be called as follows:

- While a random prime number is generated, it is called as described in BN_generate_prime(3).
- When the n-th randomly generated prime is rejected as not suitable for the key, **callback(2, n, cb_arg)** is called.
- When a random p has been found with p-1 relatively prime to **e**, it is called as **callback(3, 0, cb_arg)**.

The process is then repeated for prime q with **callback(3, 1, cb_arg)**.

RETURN VALUE

If key generation fails, RSA_generate_key() returns **NULL**; the error codes can be obtained by ERR_get_error(3).

BUGS

callback(2, x, cb_arg) is used with two different meanings.

RSA_generate_key() goes into an infinite loop for illegal input values.

SEE ALSO

ERR_get_error(3), rand(3), rsa(3), RSA_free(3)

HISTORY

The **cb_arg** argument was added in SSLeay 0.9.0.

Name

```

```
typedef int CRYPTO_EX_new(void *parent, void *ptr, CRYPTO_EX_DATA *ad,
                          int idx, long argl, void *argp);
typedef void CRYPTO_EX_free(void *parent, void *ptr, CRYPTO_EX_DATA *ad,
                            int idx, long argl, void *argp);
typedef int CRYPTO_EX_dup(CRYPTO_EX_DATA *to, CRYPTO_EX_DATA *from, void *from_d,
                          int idx, long argl, void *argp);
```

DESCRIPTION

Several OpenSSL structures can have application specific data attached to them. This has several potential uses, it can be used to cache data associated with a structure (for example the hash of some part of the structure) or some additional data (for example a handle to the data in an external library).

Since the application data can be anything at all it is passed and retrieved as a **void *** type.

The **RSA_get_ex_new_index()** function is initially called to "register" some new application specific data. It takes three optional function pointers which are called when the parent structure (in this case an RSA structure) is initially created, when it is copied and when it is freed up. If any or all of these function pointer arguments are not used they should be set to NULL. The precise manner in which these function pointers are called is described in more detail below. **RSA_get_ex_new_index()** also takes additional long and pointer parameters which will be passed to the supplied functions but which otherwise have no special meaning. It returns an **index** which should be stored (typically in a static variable) and passed used in the **idx** parameter in the remaining functions. Each successful call to **RSA_get_ex_new_index()** will return an index greater than any previously returned, this is important because the optional functions are called in order of increasing index value.

RSA_set_ex_data() is used to set application specific data, the data is supplied in the **arg** parameter and its precise meaning is up to the application.

RSA_get_ex_data() is used to retrieve application specific data. The data is returned to the application, this will be the same value as supplied to a previous **RSA_set_ex_data()** call.

new_func() is called when a structure is initially allocated (for example with **RSA_new()**. The parent structure members will not have any meaningful values at this point. This function will typically be used to allocate any application specific structure.

free_func() is called when a structure is being freed up. The dynamic parent structure members should not be accessed because they will be freed up when this function is called.

new_func() and **free_func()** take the same parameters. **parent** is a pointer to the parent RSA structure. **ptr** is a the application specific data (this wont be of much use in **new_func()**. **ad** is a pointer to the **CRYPTO_EX_DATA** structure from the parent RSA structure: the functions **CRYPTO_get_ex_data()** and **CRYPTO_set_ex_data()** can be called to manipulate it. The **idx** parameter is the index: this will be the same value returned by **RSA_get_ex_new_index()** when the functions were initially registered. Finally the **argl** and **argp** parameters are the values originally passed to the same corresponding parameters when **RSA_get_ex_new_index()** was called.

dup_func() is called when a structure is being copied. Pointers to the destination and source **CRYPTO_EX_DATA** structures are passed in the **to** and **from** parameters respectively. The **from_d** parameter is passed a pointer to the source application data when the function is called, when the function returns the value is copied to the destination: the application can thus modify the data pointed to by **from_d** and have different values in the source and destination. The **idx**, **argl** and **argp** parameters are the same as those in **new_func()** and **free_func()**.

RETURN VALUES

RSA_get_ex_new_index() returns a new index or -1 on failure (note 0 is a valid index value).

RSA_set_ex_data() returns 1 on success or 0 on failure.

RSA_get_ex_data() returns the application data or 0 on failure. 0 may also be valid application data but currently it can only fail if given an invalid **idx** parameter.

new_func() and **dup_func()** should return 0 for failure and 1 for success.

On failure an error code can be obtained from ERR_get_error(3).

BUGS

dup_func() is currently never called.

The return value of **new_func()** is ignored.

The **new_func()** function isn't very useful because no meaningful values are present in the parent RSA structure when it is called.

SEE ALSO

rsa(3), CRYPTO_set_ex_data(3)

HISTORY

RSA_get_ex_new_index(), RSA_set_ex_data() and RSA_get_ex_data() are available since SSLeay 0.9.0.

Name

RSA_new and RSA_free — allocate and free RSA objects

Synopsis

```
#include  <openssl/rsa.h>
```

```
RSA * RSA_new(void);
```

```
void RSA_free(RSA *rsa);
```

DESCRIPTION

RSA_new() allocates and initializes an **RSA** structure. It is equivalent to calling RSA_new_method(NULL).

RSA_free() frees the **RSA** structure and its components. The key is erased before the memory is returned to the system.

RETURN VALUES

If the allocation fails, RSA_new() returns **NULL** and sets an error code that can be obtained by ERR_get_error(3). Otherwise it returns a pointer to the newly allocated structure.

RSA_free() returns no value.

SEE ALSO

ERR_get_error(3), rsa(3), RSA_generate_key(3), RSA_new_method(3)

HISTORY

RSA_new() and RSA_free() are available in all versions of SSLeay and OpenSSL.

Name

Synopsis

```
#include  <openssl/rsa.h>

int RSA_padding_add_PKCS1_type_1(unsigned char *to, int tlen,
   unsigned char *f, int fl);

int RSA_padding_check_PKCS1_type_1(unsigned char *to, int tlen,
   unsigned char *f, int fl, int rsa_len);

int RSA_padding_add_PKCS1_type_2(unsigned char *to, int tlen,
   unsigned char *f, int fl);

int RSA_padding_check_PKCS1_type_2(unsigned char *to, int tlen,
   unsigned char *f, int fl, int rsa_len);

int RSA_padding_add_PKCS1_OAEP(unsigned char *to, int tlen,
   unsigned char *f, int fl, unsigned char *p, int pl);

int RSA_padding_check_PKCS1_OAEP(unsigned char *to, int tlen,
   unsigned char *f, int fl, int rsa_len, unsigned char *p, int pl);

int RSA_padding_add_SSLv23(unsigned char *to, int tlen,
   unsigned char *f, int fl);

int RSA_padding_check_SSLv23(unsigned char *to, int tlen,
   unsigned char *f, int fl, int rsa_len);

int RSA_padding_add_none(unsigned char *to, int tlen,
   unsigned char *f, int fl);

int RSA_padding_check_none(unsigned char *to, int tlen,
   unsigned char *f, int fl, int rsa_len);
```

DESCRIPTION

The RSA_padding_xxx_xxx() functions are called from the RSA encrypt, decrypt, sign and verify functions. Normally they should not be called from application programs.

However, they can also be called directly to implement padding for other asymmetric ciphers. RSA_padding_add_PKCS1_OAEP() and RSA_padding_check_PKCS1_OAEP() may be used in an application combined with **RSA_NO_PADDING** in order to implement OAEP with an encoding parameter.

RSA_padding_add_xxx() encodes **fl** bytes from **f** so as to fit into **tlen** bytes and stores the result at **to**. An error occurs if **fl** does not meet the size requirements of the encoding method.

The following encoding methods are implemented:

PKCS1_type_1	PKCS #1 v2.0 EMSA-PKCS1-v1_5 (PKCS #1 v1.5 block type 1); used for signatures
PKCS1_type_2	PKCS #1 v2.0 EME-PKCS1-v1_5 (PKCS #1 v1.5 block type 2)
PKCS1_OAEP	PKCS #1 v2.0 EME-OAEP
SSLv23	PKCS #1 EME-PKCS1-v1_5 with SSL-specific modification

none simply copy the data

The random number generator must be seeded prior to calling RSA_padding_add_xxx().

RSA_padding_check_xxx() verifies that the **fl** bytes at **f** contain a valid encoding for a **rsa_len** byte RSA key in the respective encoding method and stores the recovered data of at most **tlen** bytes (for **RSA_NO_PADDING**: of size **tlen**) at **to**.

For RSA_padding_xxx_OAEP(), **p** points to the encoding parameter of length **pl**. **p** may be **NULL** if **pl** is 0.

RETURN VALUES

The RSA_padding_add_xxx() functions return 1 on success, 0 on error. The RSA_padding_check_xxx() functions return the length of the recovered data, -1 on error. Error codes can be obtained by calling ERR_get_error(3).

SEE ALSO

RSA_public_encrypt(3), RSA_private_decrypt(3), RSA_sign(3), RSA_verify(3)

HISTORY

RSA_padding_add_PKCS1_type_1(), RSA_padding_check_PKCS1_type_1(), RSA_padding_add_PKCS1_type_2(), RSA_padding_check_PKCS1_type_2(), RSA_padding_add_SSLv23(), RSA_padding_check_SSLv23(), RSA_padding_add_none() and RSA_padding_check_none() appeared in SSLeay 0.9.0.

RSA_padding_add_PKCS1_OAEP() and RSA_padding_check_PKCS1_OAEP() were added in OpenSSL 0.9.2b.

Name

RSA_print, RSA_print_fp, DSAparams_print, DSAparams_print_fp, DSA_print, DSA_print_fp, DHparams_print and DHparams_print_fp — print cryptographic parameters

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_print(BIO *bp, RSA *x, int offset);
int RSA_print_fp(FILE *fp, RSA *x, int offset);
```

```
#include  <openssl/dsa.h>
```

```
int DSAparams_print(BIO *bp, DSA *x);
int DSAparams_print_fp(FILE *fp, DSA *x);
int DSA_print(BIO *bp, DSA *x, int offset);
int DSA_print_fp(FILE *fp, DSA *x, int offset);
```

```
#include  <openssl/dh.h>
```

```
int DHparams_print(BIO *bp, DH *x);
int DHparams_print_fp(FILE *fp, DH *x);
```

DESCRIPTION

A human-readable hexadecimal output of the components of the RSA key, DSA parameters or key or DH parameters is printed to **bp** or **fp**.

The output lines are indented by **offset** spaces.

RETURN VALUES

These functions return 1 on success, 0 on error.

SEE ALSO

dh(3), dsa(3), rsa(3), BN_bn2bin(3)

HISTORY

RSA_print(), RSA_print_fp(), DSA_print(), DSA_print_fp(), DH_print(), DH_print_fp() are available in all versions of SSLeay and OpenSSL. DSAparams_print() and DSAparams_print_fp() were added in SSLeay 0.8.

Name

RSA_private_encrypt and RSA_public_decrypt — low level signature operations

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_private_encrypt(int flen, unsigned char *from,
   unsigned char *to, RSA *rsa, int padding);
```

```
int RSA_public_decrypt(int flen, unsigned char *from,
   unsigned char *to, RSA *rsa, int padding);
```

DESCRIPTION

These functions handle RSA signatures at a low level.

RSA_private_encrypt() signs the **flen** bytes at **from** (usually a message digest with an algorithm identifier) using the private key **rsa** and stores the signature in **to**. **to** must point to **RSA_size(rsa)** bytes of memory.

padding denotes one of the following modes:

RSA_PKCS1_PADDING

> PKCS #1 v1.5 padding. This function does not handle the **algorithmIdentifier** specified in PKCS #1. When generating or verifying PKCS #1 signatures, RSA_sign(3) and RSA_verify(3) should be used.

RSA_NO_PADDING

> Raw RSA signature. This mode should *only* be used to implement cryptographically sound padding modes in the application code. Signing user data directly with RSA is insecure.

RSA_public_decrypt() recovers the message digest from the **flen** bytes long signature at **from** using the signer's public key **rsa**. **to** must point to a memory section large enough to hold the message digest (which is smaller than **RSA_size(rsa) - 11**). **padding** is the padding mode that was used to sign the data.

RETURN VALUES

RSA_private_encrypt() returns the size of the signature (i.e., RSA_size(rsa)). RSA_public_decrypt() returns the size of the recovered message digest.

On error, -1 is returned; the error codes can be obtained by ERR_get_error(3).

SEE ALSO

ERR_get_error(3), rsa(3), RSA_sign(3), RSA_verify(3)

HISTORY

The **padding** argument was added in SSLeay 0.8. RSA_NO_PADDING is available since SSLeay 0.9.0.

Name

RSA_public_encrypt and RSA_private_decrypt — RSA public key cryptography

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_public_encrypt(int flen, unsigned char *from,
   unsigned char *to, RSA *rsa, int padding);
```

```
int RSA_private_decrypt(int flen, unsigned char *from,
    unsigned char *to, RSA *rsa, int padding);
```

DESCRIPTION

RSA_public_encrypt() encrypts the **flen** bytes at **from** (usually a session key) using the public key **rsa** and stores the ciphertext in **to**. **to** must point to RSA_size(**rsa**) bytes of memory.

padding denotes one of the following modes:

RSA_PKCS1_PADDING

> PKCS #1 v1.5 padding. This currently is the most widely used mode.

RSA_PKCS1_OAEP_PADDING

> EME-OAEP as defined in PKCS #1 v2.0 with SHA-1, MGF1 and an empty encoding parameter. This mode is recommended for all new applications.

RSA_SSLV23_PADDING

> PKCS #1 v1.5 padding with an SSL-specific modification that denotes that the server is SSL3 capable.

RSA_NO_PADDING

> Raw RSA encryption. This mode should *only* be used to implement cryptographically sound padding modes in the application code. Encrypting user data directly with RSA is insecure.

flen must be less than RSA_size(**rsa**) - 11 for the PKCS #1 v1.5 based padding modes, less than RSA_size(**rsa**) - 41 for RSA_PKCS1_OAEP_PADDING and exactly RSA_size(**rsa**) for RSA_NO_PADDING. The random number generator must be seeded prior to calling RSA_public_encrypt().

RSA_private_decrypt() decrypts the **flen** bytes at **from** using the private key **rsa** and stores the plaintext in **to**. **to** must point to a memory section large enough to hold the decrypted data (which is smaller than RSA_size(**rsa**)). **padding** is the padding mode that was used to encrypt the data.

RETURN VALUES

RSA_public_encrypt() returns the size of the encrypted data (i.e., RSA_size(**rsa**)). RSA_private_decrypt() returns the size of the recovered plaintext.

On error, -1 is returned; the error codes can be obtained by ERR_get_error(3).

CONFORMING TO

SSL, PKCS #1 v2.0

SEE ALSO

ERR_get_error(3), rand(3), rsa(3), RSA_size(3)

HISTORY

The **padding** argument was added in SSLeay 0.8. RSA_NO_PADDING is available since SSLeay 0.9.0, OAEP was added in OpenSSL 0.9.2b.

Name

RSA_set_default_method, RSA_get_default_method, RSA_set_method, RSA_get_method, RSA_PKCS1_SSLeay, RSA_null_method, RSA_flags and RSA_new_method — select RSA method

Synopsis

```
#include  <openssl/rsa.h>
```

```
void RSA_set_default_method(const RSA_METHOD *meth);
```

```
RSA_METHOD *RSA_get_default_method(void);
```

```
int RSA_set_method(RSA *rsa, const RSA_METHOD *meth);
```

```
RSA_METHOD *RSA_get_method(const RSA *rsa);
```

```
RSA_METHOD *RSA_PKCS1_SSLeay(void);
```

```
RSA_METHOD *RSA_null_method(void);
```

```
int RSA_flags(const RSA *rsa);
```

```
RSA *RSA_new_method(RSA_METHOD *method);
```

DESCRIPTION

An **RSA_METHOD** specifies the functions that OpenSSL uses for RSA operations. By modifying the method, alternative implementations such as hardware accelerators may be used. IMPORTANT: See the NOTES section for important information about how these RSA API functions are affected by the use of **ENGINE** API calls.

Initially, the default RSA_METHOD is the OpenSSL internal implementation, as returned by RSA_PKCS1_SSLeay().

RSA_set_default_method() makes **meth** the default method for all RSA structures created later. **NB**: This is true only whilst no ENGINE has been set as a default for RSA, so this function is no longer recommended.

RSA_get_default_method() returns a pointer to the current default RSA_METHOD. However, the meaningfulness of this result is dependent on whether the ENGINE API is being used, so this function is no longer recommended.

RSA_set_method() selects **meth** to perform all operations using the key **rsa**. This will replace the RSA_METHOD used by the RSA key and if the previous method was supplied by an ENGINE, the handle to that ENGINE will be released during the change. It is possible to have RSA keys that only work with certain RSA_METHOD implementations (eg. from an ENGINE module that supports embedded hardware-protected keys), and in such cases attempting to change the RSA_METHOD for the key can have unexpected results.

RSA_get_method() returns a pointer to the RSA_METHOD being used by **rsa**. This method may or may not be supplied by an ENGINE implementation, but if it is, the return value can only be guaranteed to be valid as long as the RSA key itself is valid and does not have its implementation changed by RSA_set_method().

RSA_flags() returns the **flags** that are set for **rsa**'s current RSA_METHOD. See the BUGS section.

RSA_new_method() allocates and initializes an RSA structure so that **engine** will be used for the RSA operations. If **engine** is NULL, the default ENGINE for RSA operations is used, and if no default ENGINE is set, the RSA_METHOD controlled by RSA_set_default_method() is used.

RSA_flags() returns the **flags** that are set for **rsa**'s current method.

RSA_new_method() allocates and initializes an **RSA** structure so that **method** will be used for the RSA operations. If **method** is **NULL**, the default method is used.

THE RSA_METHOD STRUCTURE

```
typedef struct rsa_meth_st
```

```
{
    /* name of the implementation */
       const char *name;

/* encrypt */
   int (*rsa_pub_enc)(int flen, unsigned char *from,
     unsigned char *to, RSA *rsa, int padding);

/* verify arbitrary data */
   int (*rsa_pub_dec)(int flen, unsigned char *from,
     unsigned char *to, RSA *rsa, int padding);

/* sign arbitrary data */
   int (*rsa_priv_enc)(int flen, unsigned char *from,
     unsigned char *to, RSA *rsa, int padding);

/* decrypt */
   int (*rsa_priv_dec)(int flen, unsigned char *from,
     unsigned char *to, RSA *rsa, int padding);

/* compute r0 = r0 ^ I mod rsa->n (May be NULL for some
                                   implementations) */
   int (*rsa_mod_exp)(BIGNUM *r0, BIGNUM *I, RSA *rsa);

/* compute r = a ^ p mod m (May be NULL for some implementations) */
   int (*bn_mod_exp)(BIGNUM *r, BIGNUM *a, const BIGNUM *p,
     const BIGNUM *m, BN_CTX *ctx, BN_MONT_CTX *m_ctx);

/* called at RSA_new */
   int (*init)(RSA *rsa);

/* called at RSA_free */
   int (*finish)(RSA *rsa);

/* RSA_FLAG_EXT_PKEY        - rsa_mod_exp is called for private key
 *                            operations, even if p,q,dmp1,dmq1,iqmp
 *                            are NULL
 * RSA_FLAG_SIGN_VER        - enable rsa_sign and rsa_verify
 * RSA_METHOD_FLAG_NO_CHECK - don't check pub/private match
 */
   int flags;

char *app_data; /* ?? */

/* sign. For backward compatibility, this is used only
 * if (flags & RSA_FLAG_SIGN_VER)
 */
   int (*rsa_sign)(int type,
           const unsigned char *m, unsigned int m_length,
           unsigned char *sigret, unsigned int *siglen, const RSA *rsa);
/* verify. For backward compatibility, this is used only
 * if (flags & RSA_FLAG_SIGN_VER)
 */
   int (*rsa_verify)(int dtype,
           const unsigned char *m, unsigned int m_length,
           const unsigned char *sigbuf, unsigned int siglen,
                                                           const RSA *rsa);
/* keygen. If NULL builtin RSA key generation will be used */
   int (*rsa_keygen)(RSA *rsa, int bits, BIGNUM *e, BN_GENCB *cb);

} RSA_METHOD;
```

RETURN VALUES

RSA_PKCS1_SSLeay(), RSA_PKCS1_null_method(), RSA_get_default_method() and RSA_get_method() return pointers to the respective RSA_METHODs.

RSA_set_default_method() returns no value.

RSA_set_method() returns a pointer to the old RSA_METHOD implementation that was replaced. However, this return value should probably be ignored because if it was supplied by an ENGINE, the pointer could be invalidated at any time if the ENGINE is unloaded (in fact it could be unloaded as a result of the RSA_set_method() function releasing its handle to the ENGINE). For this reason, the return type may be replaced with a **void** declaration in a future release.

RSA_new_method() returns NULL and sets an error code that can be obtained by ERR_get_error(3) if the allocation fails. Otherwise it returns a pointer to the newly allocated structure.

NOTES

As of version 0.9.7, RSA_METHOD implementations are grouped together with other algorithmic APIs (eg. DSA_METHOD, EVP_CIPHER, etc) into **ENGINE** modules. If a default ENGINE is specified for RSA functionality using an ENGINE API function, that will override any RSA defaults set using the RSA API (ie. RSA_set_default_method()). For this reason, the ENGINE API is the recommended way to control default implementations for use in RSA and other cryptographic algorithms.

BUGS

The behaviour of RSA_flags() is a mis-feature that is left as-is for now to avoid creating compatibility problems. RSA functionality, such as the encryption functions, are controlled by the **flags** value in the RSA key itself, not by the **flags** value in the RSA_METHOD attached to the RSA key (which is what this function returns). If the flags element of an RSA key is changed, the changes will be honoured by RSA functionality but will not be reflected in the return value of the RSA_flags() function - in effect RSA_flags() behaves more like an RSA_default_flags() function (which does not currently exist).

SEE ALSO

rsa(3), RSA_new(3)

HISTORY

RSA_new_method() and RSA_set_default_method() appeared in SSLeay 0.8. RSA_get_default_method(), RSA_set_method() and RSA_get_method() as well as the rsa_sign and rsa_verify components of RSA_METHOD were added in OpenSSL 0.9.4.

RSA_set_default_openssl_method() and RSA_get_default_openssl_method() replaced RSA_set_default_method() and RSA_get_default_method() respectively, and RSA_set_method() and RSA_new_method() were altered to use **ENGINE**s rather than **RSA_METHOD**s during development of the engine version of OpenSSL 0.9.6. For 0.9.7, the handling of defaults in the ENGINE API was restructured so that this change was reversed, and behaviour of the other functions resembled more closely the previous behaviour. The behaviour of defaults in the ENGINE API now transparently overrides the behaviour of defaults in the RSA API without requiring changing these function prototypes.

Name

RSA_sign_ASN1_OCTET_STRING and RSA_verify_ASN1_OCTET_STRING — RSA signatures

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_sign_ASN1_OCTET_STRING(int dummy, unsigned char *m,
   unsigned int m_len, unsigned char *sigret, unsigned int *siglen,
   RSA *rsa);
```

```
int RSA_verify_ASN1_OCTET_STRING(int dummy, unsigned char *m,
   unsigned int m_len, unsigned char *sigbuf, unsigned int siglen,
   RSA *rsa);
```

DESCRIPTION

RSA_sign_ASN1_OCTET_STRING() signs the octet string **m** of size **m_len** using the private key **rsa** represented in DER using PKCS #1 padding. It stores the signature in **sigret** and the signature size in **siglen**. **sigret** must point to **RSA_size(rsa)** bytes of memory.

dummy is ignored.

The random number generator must be seeded prior to calling RSA_sign_ASN1_OCTET_STRING().

RSA_verify_ASN1_OCTET_STRING() verifies that the signature **sigbuf** of size **siglen** is the DER representation of a given octet string **m** of size **m_len**. **dummy** is ignored. **rsa** is the signer's public key.

RETURN VALUES

RSA_sign_ASN1_OCTET_STRING() returns 1 on success, 0 otherwise. RSA_verify_ASN1_OCTET_STRING() returns 1 on successful verification, 0 otherwise.

The error codes can be obtained by ERR_get_error(3).

BUGS

These functions serve no recognizable purpose.

SEE ALSO

ERR_get_error(3), objects(3), rand(3), rsa(3), RSA_sign(3), RSA_verify(3)

HISTORY

RSA_sign_ASN1_OCTET_STRING() and RSA_verify_ASN1_OCTET_STRING() were added in SSLeay 0.8.

Name

RSA_sign and RSA_verify — RSA signatures

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_sign(int type, const unsigned char *m, unsigned int m_len,
   unsigned char *sigret, unsigned int *siglen, RSA *rsa);
```

```
int RSA_verify(int type, const unsigned char *m, unsigned int m_len,
   unsigned char *sigbuf, unsigned int siglen, RSA *rsa);
```

DESCRIPTION

RSA_sign() signs the message digest **m** of size **m_len** using the private key **rsa** as specified in PKCS #1 v2.0. It stores the signature in **sigret** and the signature size in **siglen**. **sigret** must point to RSA_size(**rsa**) bytes of memory. Note that PKCS #1 adds meta-data, placing limits on the size of the key that can be used. See RSA_private_encrypt(3) for lower-level operations.

type denotes the message digest algorithm that was used to generate **m**. It usually is one of **NID_sha1**, **NID_ripemd160** and **NID_md5**; see objects(3) for details. If **type** is **NID_md5_sha1**, an SSL signature (MD5 and SHA1 message digests with PKCS #1 padding and no algorithm identifier) is created.

RSA_verify() verifies that the signature **sigbuf** of size **siglen** matches a given message digest **m** of size **m_len**. **type** denotes the message digest algorithm that was used to generate the signature. **rsa** is the signer's public key.

RETURN VALUES

RSA_sign() returns 1 on success, 0 otherwise. RSA_verify() returns 1 on successful verification, 0 otherwise.

The error codes can be obtained by ERR_get_error(3).

BUGS

Certain signatures with an improper algorithm identifier are accepted for compatibility with SSLeay 0.4.5 :-)

CONFORMING TO

SSL, PKCS #1 v2.0

SEE ALSO

Name

RSA_size — get RSA modulus size

Synopsis

```
#include  <openssl/rsa.h>
```

```
int RSA_size(const RSA *rsa);
```

DESCRIPTION

This function returns the RSA modulus size in bytes. It can be used to determine how much memory must be allocated for an RSA encrypted value.

rsa->n must not be **NULL**.

RETURN VALUE

The size in bytes.

SEE ALSO

rsa(3)

HISTORY

RSA_size() is available in all versions of SSLeay and OpenSSL.

Name

SHA1, SHA1_Init, SHA1_Update and SHA1_Final — Secure Hash Algorithm

Synopsis

```
#include  <openssl/sha.h>
```

```
unsigned char *SHA1(const unsigned char *d, unsigned long n,
                 unsigned char *md);
```

```
int SHA1_Init(SHA_CTX *c);
int SHA1_Update(SHA_CTX *c, const void *data,
                 unsigned long len);
int SHA1_Final(unsigned char *md, SHA_CTX *c);
```

DESCRIPTION

SHA-1 (Secure Hash Algorithm) is a cryptographic hash function with a 160 bit output.

SHA1() computes the SHA-1 message digest of the **n** bytes at **d** and places it in **md** (which must have space for SHA_DIGEST_LENGTH == 20 bytes of output). If **md** is NULL, the digest is placed in a static array.

The following functions may be used if the message is not completely stored in memory:

SHA1_Init() initializes a **SHA_CTX** structure.

SHA1_Update() can be called repeatedly with chunks of the message to be hashed (**len** bytes at **data**).

SHA1_Final() places the message digest in **md**, which must have space for SHA_DIGEST_LENGTH == 20 bytes of output, and erases the **SHA_CTX**.

Applications should use the higher level functions EVP_DigestInit(3) etc. instead of calling the hash functions directly.

The predecessor of SHA-1, SHA, is also implemented, but it should be used only when backward compatibility is required.

RETURN VALUES

SHA1() returns a pointer to the hash value.

SHA1_Init(), SHA1_Update() and SHA1_Final() return 1 for success, 0 otherwise.

CONFORMING TO

SHA: US Federal Information Processing Standard FIPS PUB 180 (Secure Hash Standard), SHA-1: US Federal Information Processing Standard FIPS PUB 180-1 (Secure Hash Standard), ANSI X9.30

SEE ALSO

ripemd(3), hmac(3), EVP_DigestInit(3)

HISTORY

SHA1(), SHA1_Init(), SHA1_Update() and SHA1_Final() are available in all versions of SSLeay and OpenSSL.

Name

SMIME_read_CMS — parse S/MIME message.

Synopsis

```
#include  <openssl/cms.h>
```

```
CMS_ContentInfo *SMIME_read_CMS(BIO *in, BIO **bcont);
```

DESCRIPTION

SMIME_read_CMS() parses a message in S/MIME format.

in is a BIO to read the message from.

If cleartext signing is used then the content is saved in a memory bio which is written to ***bcont**, otherwise ***bcont** is set to NULL.

The parsed CMS_ContentInfo structure is returned or NULL if an error occurred.

NOTES

If ***bcont** is not NULL then the message is clear text signed. ***bcont** can then be passed to CMS_verify() with the **CMS_DETACHED** flag set.

Otherwise the type of the returned structure can be determined using CMS_get0_type().

To support future functionality if **bcont** is not NULL ***bcont** should be initialized to NULL. For example:

```
BIO *cont = NULL;
CMS_ContentInfo *cms;

cms = SMIME_read_CMS(in, &cont);
```

BUGS

The MIME parser used by SMIME_read_CMS() is somewhat primitive. While it will handle most S/MIME messages more complex compound formats may not work.

The parser assumes that the CMS_ContentInfo structure is always base64 encoded and will not handle the case where it is in binary format or uses quoted printable format.

The use of a memory BIO to hold the signed content limits the size of message which can be processed due to memory restraints: a streaming single pass option should be available.

RETURN VALUES

SMIME_read_CMS() returns a valid **CMS_ContentInfo** structure or **NULL** if an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), CMS_type(3), SMIME_read_CMS(3), CMS_sign(3), CMS_verify(3), CMS_encrypt(3), CMS_decrypt(3)

HISTORY

SMIME_read_CMS() was added to OpenSSL 0.9.8

Name

SMIME_read_PKCS7 — parse S/MIME message.

Synopsis

```
#include  <openssl/pkcs7.h>
```

```
PKCS7 *SMIME_read_PKCS7(BIO *in, BIO **bcont);
```

DESCRIPTION

SMIME_read_PKCS7() parses a message in S/MIME format.

in is a BIO to read the message from.

If cleartext signing is used then the content is saved in a memory bio which is written to ***bcont**, otherwise ***bcont** is set to **NULL**.

The parsed PKCS#7 structure is returned or **NULL** if an error occurred.

NOTES

If ***bcont** is not **NULL** then the message is clear text signed. ***bcont** can then be passed to PKCS7_verify() with the **PKCS7_DETACHED** flag set.

Otherwise the type of the returned structure can be determined using PKCS7_type().

To support future functionality if **bcont** is not **NULL** ***bcont** should be initialized to **NULL**. For example:

```
BIO *cont = NULL;
PKCS7 *p7;

p7 = SMIME_read_PKCS7(in, &cont);
```

BUGS

The MIME parser used by SMIME_read_PKCS7() is somewhat primitive. While it will handle most S/MIME messages more complex compound formats may not work.

The parser assumes that the PKCS7 structure is always base64 encoded and will not handle the case where it is in binary format or uses quoted printable format.

The use of a memory BIO to hold the signed content limits the size of message which can be processed due to memory restraints: a streaming single pass option should be available.

RETURN VALUES

SMIME_read_PKCS7() returns a valid **PKCS7** structure or **NULL** is an error occurred. The error can be obtained from ERR_get_error(3).

SEE ALSO

ERR_get_error(3), PKCS7_type(3), SMIME_read_PKCS7(3), PKCS7_sign(3), PKCS7_verify(3), PKCS7_encrypt(3), PKCS7_decrypt(3)

HISTORY

SMIME_read_PKCS7() was added to OpenSSL 0.9.5

Name

SMIME_write_CMS — convert CMS structure to S/MIME format.

Synopsis

```
#include  <openssl/cms.h>
```

```
int SMIME_write_CMS(BIO *out, CMS_ContentInfo *cms, BIO *data, int flags);
```

DESCRIPTION

SMIME_write_CMS() adds the appropriate MIME headers to a CMS structure to produce an S/MIME message.

out is the BIO to write the data to. **cms** is the appropriate **CMS_ContentInfo** structure. If streaming is enabled then the content must be supplied in the **data** argument. **flags** is an optional set of flags.

NOTES

The following flags can be passed in the **flags** parameter.

If **CMS_DETACHED** is set then cleartext signing will be used, this option only makes sense for SignedData where **CMS_DETACHED** is also set when CMS_sign() is called.

If the **CMS_TEXT** flag is set MIME headers for type **text/plain** are added to the content, this only makes sense if **CMS_DETACHED** is also set.

If the **CMS_STREAM** flag is set streaming is performed. This flag should only be set if **CMS_STREAM** was also set in the previous call to a CMS_ContentInfo creation function.

If cleartext signing is being used and **CMS_STREAM** not set then the data must be read twice: once to compute the signature in CMS_sign() and once to output the S/MIME message.

If streaming is performed the content is output in BER format using indefinite length constructed encoding except in the case of signed data with detached content where the content is absent and DER format is used.

BUGS

SMIME_write_CMS() always base64 encodes CMS structures, there should be an option to disable this.

RETURN VALUES

SMIME_write_CMS() returns 1 for success or 0 for failure.

SEE ALSO

ERR_get_error(3), CMS_sign(3), CMS_verify(3), CMS_encrypt(3), CMS_decrypt(3)

HISTORY

SMIME_write_CMS() was added to OpenSSL 0.9.8

Name

SMIME_write_PKCS7 — convert PKCS#7 structure to S/MIME format.

Synopsis

```
#include  <openssl/pkcs7.h>
```

```
int SMIME_write_PKCS7(BIO *out, PKCS7 *p7, BIO *data, int flags);
```

DESCRIPTION

SMIME_write_PKCS7() adds the appropriate MIME headers to a PKCS#7 structure to produce an S/MIME message.

out is the BIO to write the data to. **p7** is the appropriate **PKCS7** structure. If streaming is enabled then the content must be supplied in the **data** argument. **flags** is an optional set of flags.

NOTES

The following flags can be passed in the **flags** parameter.

If **PKCS7_DETACHED** is set then cleartext signing will be used, this option only makes sense for signedData where **PKCS7_DETACHED** is also set when PKCS7_sign() is also called.

If the **PKCS7_TEXT** flag is set MIME headers for type **text/plain** are added to the content, this only makes sense if **PKCS7_DETACHED** is also set.

If the **PKCS7_STREAM** flag is set streaming is performed. This flag should only be set if **PKCS7_STREAM** was also set in the previous call to PKCS7_sign() or **PKCS7_encrypt()**.

If cleartext signing is being used and **PKCS7_STREAM** not set then the data must be read twice: once to compute the signature in PKCS7_sign() and once to output the S/MIME message.

If streaming is performed the content is output in BER format using indefinite length constructuted encoding except in the case of signed data with detached content where the content is absent and DER format is used.

BUGS

SMIME_write_PKCS7() always base64 encodes PKCS#7 structures, there should be an option to disable this.

RETURN VALUES

SMIME_write_PKCS7() returns 1 for success or 0 for failure.

```

DESCRIPTION

OpenSSL can safely be used in multi-threaded applications provided that at least two callback functions are set, locking_function and threadid_func.

locking_function(int mode, int n, const char *file, int line) is needed to perform locking on shared data structures. (Note that OpenSSL uses a number of global data structures that will be implicitly shared whenever multiple threads use OpenSSL.) Multi-threaded applications will crash at random if it is not set.

locking_function() must be able to handle up to CRYPTO_num_locks() different mutex locks. It sets the **n**-th lock if **mode** & **CRYPTO_LOCK**, and releases it otherwise.

file and **line** are the file number of the function setting the lock. They can be useful for debugging.

threadid_func(CRYPTO_THREADID *id) is needed to record the currently-executing thread's identifier into **id**. The implementation of this callback should not fill in **id** directly, but should use CRYPTO_THREADID_set_numeric() if thread IDs are numeric, or CRYPTO_THREADID_set_pointer() if they are pointer-based. If the application does not register such a callback using CRYPTO_THREADID_set_callback(), then a default implementation is used - on Windows and BeOS this uses the system's default thread identifying APIs, and on all other platforms it uses the address of **errno**. The latter is satisfactory for thread-safety if and only if the platform has a thread-local error number facility.

Once threadid_func() is registered, or if the built-in default implementation is to be used;

- CRYPTO_THREADID_current() records the currently-executing thread ID into the given **id** object.
- CRYPTO_THREADID_cmp() compares two thread IDs (returning zero for equality, ie. the same semantics as memcmp()).
- CRYPTO_THREADID_cpy() duplicates a thread ID value,
- CRYPTO_THREADID_hash() returns a numeric value usable as a hash-table key. This is usually the exact numeric or pointer-based thread ID used internally, however this also handles the unusual case where pointers are larger than 'long' variables and the platform's thread IDs are pointer-based - in this case, mixing is done to attempt to produce a unique numeric value even though it is not as wide as the platform's true thread IDs.

Additionally, OpenSSL supports dynamic locks, and sometimes, some parts of OpenSSL need it for better performance. To enable this, the following is required:

- Three additional callback function, dyn_create_function, dyn_lock_function and dyn_destroy_function.
- A structure defined with the data that each lock needs to handle.

struct CRYPTO_dynlock_value has to be defined to contain whatever structure is needed to handle locks.

dyn_create_function(const char *file, int line) is needed to create a lock. Multi-threaded applications might crash at random if it is not set.

dyn_lock_function(int mode, CRYPTO_dynlock *l, const char *file, int line) is needed to perform locking off dynamic lock numbered n. Multi-threaded applications might crash at random if it is not set.

dyn_destroy_function(CRYPTO_dynlock *l, const char *file, int line) is needed to destroy the lock l. Multi-threaded applications might crash at random if it is not set.

CRYPTO_get_new_dynlockid() is used to create locks. It will call dyn_create_function for the actual creation.

CRYPTO_destroy_dynlockid() is used to destroy locks. It will call dyn_destroy_function for the actual destruction.

CRYPTO_lock() is used to lock and unlock the locks. mode is a bitfield describing what should be done with the lock. n is the number of the lock as returned from CRYPTO_get_new_dynlockid(). mode can be combined from the following values. These values are pairwise exclusive, with undefined behaviour if misused (for example, CRYPTO_READ and CRYPTO_WRITE should not be used together):

```
CRYPTO_LOCK     0x01
CRYPTO_UNLOCK   0x02
```

```
CRYPTO_READ     0x04
CRYPTO_WRITE    0x08
```

RETURN VALUES

CRYPTO_num_locks() returns the required number of locks.

CRYPTO_get_new_dynlockid() returns the index to the newly created lock.

The other functions return no values.

NOTES

You can find out if OpenSSL was configured with thread support:

```
#define OPENSSL_THREAD_DEFINES
#include <openssl/opensslconf.h>
#if defined(OPENSSL_THREADS)
  // thread support enabled
#else
  // no thread support
#endif
```

Also, dynamic locks are currently not used internally by OpenSSL, but may do so in the future.

EXAMPLES

crypto/threads/mttest.c shows examples of the callback functions on Solaris, Irix and Win32.

HISTORY

CRYPTO_set_locking_callback() is available in all versions of SSLeay and OpenSSL. CRYPTO_num_locks() was added in OpenSSL 0.9.4. All functions dealing with dynamic locks were added in OpenSSL 0.9.5b-dev. **CRYPTO_THREADID** and associated functions were introduced in OpenSSL 1.0.0 to replace (actually, deprecate) the previous CRYPTO_set_id_callback(), CRYPTO_get_id_callback(), and CRYPTO_thread_id() functions which assumed thread IDs to always be represented by 'unsigned long'.

SEE ALSO

Name

des_read_password, des_read_2passwords, des_read_pw_string and des_read_pw — Compatibility user interface functions

Synopsis

```
#include  <openssl/des_old.h>
```

```
int des_read_password(DES_cblock *key,const char *prompt,int verify);
int des_read_2passwords(DES_cblock *key1,DES_cblock *key2,
       const char *prompt,int verify);
```

```
int des_read_pw_string(char *buf,int length,const char *prompt,int verify);
int des_read_pw(char *buf,char *buff,int size,const char *prompt,int verify);
```

DESCRIPTION

The DES library contained a few routines to prompt for passwords. These aren't necessarely dependent on DES, and have therefore become part of the UI compatibility library.

des_read_pw() writes the string specified by *prompt* to standard output turns echo off and reads an input string from the terminal. The string is returned in *buf*, which must have spac for at least *size* bytes. If *verify* is set, the user is asked for the password twice and unless the two copies match, an error is returned. The second password is stored in *buff*, which must therefore also be at least *size* bytes. A return code of -1 indicates a system error, 1 failure due to use interaction, and 0 is success. All other functions described here use des_read_pw() to do the work.

des_read_pw_string() is a variant of des_read_pw() that provides a buffer for you if *verify* is set.

des_read_password() calls des_read_pw() and converts the password to a DES key by calling DES_string_to_key(); des_read_2password() operates in the same way as des_read_password() except that it generates two keys by using the DES_string_to_2key() function.

NOTES

des_read_pw_string() is available in the MIT Kerberos library as well, and is also available under the name EVP_read_pw_string().

DESCRIPTION

UI stands for User Interface, and is general purpose set of routines to prompt the user for text-based information. Through user-written methods (see ui_create(3)), prompting can be done in any way imaginable, be it plain text prompting, through dialog boxes or from a cell phone.

All the functions work through a context of the type UI. This context contains all the information needed to prompt correctly as well as a reference to a UI_METHOD, which is an ordered vector of functions that carry out the actual prompting.

The first thing to do is to create a UI with UI_new() or UI_new_method(), then add information to it with the UI_add or UI_dup functions. Also, user-defined random data can be passed down to the underlying method through calls to UI_add_user_data. The default UI method doesn't care about these data, but other methods might. Finally, use UI_process() to actually perform the prompting and UI_get0_result() to find the result to the prompt.

A UI can contain more than one prompt, which are performed in the given sequence. Each prompt gets an index number which is returned by the UI_add and UI_dup functions, and has to be used to get the corresponding result with UI_get0_result().

The functions are as follows:

UI_new() creates a new UI using the default UI method. When done with this UI, it should be freed using UI_free().

UI_new_method() creates a new UI using the given UI method. When done with this UI, it should be freed using UI_free().

UI_OpenSSL() returns the built-in UI method (note: not the default one, since the default can be changed. See further on). This method is the most machine/OS dependent part of OpenSSL and normally generates the most problems when porting.

UI_free() removes a UI from memory, along with all other pieces of memory that's connected to it, like duplicated input strings, results and others.

UI_add_input_string() and UI_add_verify_string() add a prompt to the UI, as well as flags and a result buffer and the desired minimum and maximum sizes of the result. The given information is used to prompt for information, for example a password, and to verify a password (i.e. having the user enter it twice and check that the same string was entered twice). UI_add_verify_string() takes and extra argument that should be a pointer to the result buffer of the input string that it's supposed to verify, or verification will fail.

UI_add_input_boolean() adds a prompt to the UI that's supposed to be answered in a boolean way, with a single character for yes and a different character for no. A set of characters that can be used to cancel the prompt is given as well. The prompt itself is divided in two, one part being the descriptive text (given through the *prompt* argument) and one describing the possible answers (given through the *action_desc* argument).

UI_add_info_string() and UI_add_error_string() add strings that are shown at the same time as the prompt for extra information or to show an error string. The difference between the two is only conceptual. With the builtin method, there's no technical difference between them. Other methods may make a difference between them, however.

The flags currently supported are UI_INPUT_FLAG_ECHO, which is relevant for UI_add_input_string() and will have the users response be echoed (when prompting for a password, this flag should obviously not be used, and UI_INPUT_FLAG_DEFAULT_PWD, which means that a default password of some sort will be used (completely depending on the application and the UI method).

UI_dup_input_string(), UI_dup_verify_string(), UI_dup_input_boolean(), UI_dup_info_string() and UI_dup_error_string() are basically the same as their UI_add counterparts, except that they make their own copies of all strings.

UI_construct_prompt() is a helper function that can be used to create a prompt from two pieces of information: an description and a name. The default constructor (if there is none provided by the method used) creates a string "Enter *description* for *name*:". With the description "pass phrase" and the file name "foo.key", that becomes "Enter pass phrase for foo.key:". Other methods may create whatever string and may include encodings that will be processed by the other method functions.

UI_add_user_data() adds a piece of memory for the method to use at any time. The builtin UI method doesn't care about this info. Note that several calls to this function doesn't add data, it replaces the previous blob with the one given as argument.

UI_get0_user_data() retrieves the data that has last been given to the UI with UI_add_user_data().

UI_get0_result() returns a pointer to the result buffer associated with the information indexed by *i*.

UI_process() goes through the information given so far, does all the printing and prompting and returns.

UI_ctrl() adds extra control for the application author. For now, it understands two commands: UI_CTRL_PRINT_ERRORS, which makes UI_process() print the OpenSSL error stack as part of processing the UI, and UI_CTRL_IS_REDOABLE, which returns a flag saying if the used UI can be used again or not.

UI_set_default_method() changes the default UI method to the one given.

UI_get_default_method() returns a pointer to the current default UI method.

UI_get_method() returns the UI method associated with a given UI.

UI_set_method() changes the UI method associated with a given UI.

HISTORY

The UI section was first introduced in OpenSSL 0.9.7.

AUTHOR

Richard Levitte (richard@levitte.org) for the OpenSSL project (http://www.openssl.org).

Name

x509 — X.509 certificate handling

Synopsis

```
#include  <openssl/x509.h>
```

DESCRIPTION

A X.509 certificate is a structured grouping of information about an individual, a device, or anything one can imagine. A X.509 CRL (certificate revocation list) is a tool to help determine if a certificate is still valid. The exact definition of those can be found in the X.509 document from ITU-T, or in RFC3280 from PKIX. In OpenSSL, the type X509 is used to express such a certificate, and the type X509_CRL is used to express a CRL.

A related structure is a certificate request, defined in PKCS#10 from RSA Security, Inc, also reflected in RFC2896. In OpenSSL, the type X509_REQ is used to express such a certificate request.

To handle some complex parts of a certificate, there are the types X509_NAME (to express a certificate name), X509_ATTRIBUTE (to express a certificate attributes), X509_EXTENSION (to express a certificate extension) and a few more.

Finally, there's the supertype X509_INFO, which can contain a CRL, a certificate and a corresponding private key.

X509_..., **d2i_X509_**... and **i2d_X509_**... handle X.509 certificates, with some exceptions, shown below.

X509_CRL_..., **d2i_X509_CRL_**... and **i2d_X509_CRL_**... handle X.509 CRLs.

X509_REQ_..., **d2i_X509_REQ_**... and **i2d_X509_REQ_**... handle PKCS#10 certificate requests.

X509_NAME_... handle certificate names.

X509_ATTRIBUTE_... handle certificate attributes.

X509_EXTENSION_... handle certificate extensions.

Synopsis

```
#include  <openssl/x509.h>
```

```
int X509_NAME_add_entry_by_txt(X509_NAME *name, const char *field, int type, const unsigned char *bytes,
    int len, int loc, int set);
```

```
int X509_NAME_add_entry_by_OBJ(X509_NAME *name, ASN1_OBJECT *obj, int type, unsigned char *bytes,
    int len, int loc, int set);
```

```
int X509_NAME_add_entry_by_NID(X509_NAME *name, int nid, int type, unsigned char *bytes, int len,
    int loc, int set);
```

```
int X509_NAME_add_entry(X509_NAME *name,X509_NAME_ENTRY *ne, int loc, int set);
```

```
X509_NAME_ENTRY *X509_NAME_delete_entry(X509_NAME *name, int loc);
```

DESCRIPTION

X509_NAME_add_entry_by_txt(), X509_NAME_add_entry_by_OBJ() and X509_NAME_add_entry_by_NID() add a field whose name is defined by a string **field**, an object **obj** or a NID **nid** respectively. The field value to be added is in **bytes** of length **len**. If **len** is -1 then the field length is calculated internally using strlen(bytes).

The type of field is determined by **type** which can either be a definition of the type of **bytes** (such as **MBSTRING_ASC**) or a standard ASN1 type (such as **V_ASN1_IA5STRING**). The new entry is added to a position determined by **loc** and **set**.

X509_NAME_add_entry() adds a copy of **X509_NAME_ENTRY** structure **ne** to **name**. The new entry is added to a position determined by **loc** and **set**. Since a copy of **ne** is added **ne** must be freed up after the call.

X509_NAME_delete_entry() deletes an entry from **name** at position **loc**. The deleted entry is returned and must be freed up.

NOTES

The use of string types such as **MBSTRING_ASC** or **MBSTRING_UTF8** is strongly recommened for the **type** parameter. This allows the internal code to correctly determine the type of the field and to apply length checks according to the relevant standards. This is done using ASN1_STRING_set_by_NID().

If instead an ASN1 type is used no checks are performed and the supplied data in **bytes** is used directly.

In X509_NAME_add_entry_by_txt() the **field** string represents the field name using OBJ_txt2obj(field, 0).

The **loc** and **set** parameters determine where a new entry should be added. For almost all applications **loc** can be set to -1 and **set** to 0. This adds a new entry to the end of **name** as a single valued RelativeDistinguishedName (RDN).

loc actually determines the index where the new entry is inserted: if it is -1 it is appended.

set determines how the new type is added. If it is zero a new RDN is created.

If **set** is -1 or 1 it is added to the previous or next RDN structure respectively. This will then be a multivalued RDN: since multivalues RDNs are very seldom used **set** is almost always set to zero.

EXAMPLES

Create an **X509_NAME** structure:

"C=UK, O=Disorganized Organization, CN=Joe Bloggs"

```
X509_NAME *nm;
nm = X509_NAME_new();
if (nm == NULL)
       /* Some error */
if (!X509_NAME_add_entry_by_txt(nm, "C", MBSTRING_ASC,
                       "UK", -1, -1, 0))
       /* Error */
if (!X509_NAME_add_entry_by_txt(nm, "O", MBSTRING_ASC,
                       "Disorganized Organization", -1, -1, 0))
       /* Error */
if (!X509_NAME_add_entry_by_txt(nm, "CN", MBSTRING_ASC,
                       "Joe Bloggs", -1, -1, 0))
       /* Error */
```

RETURN VALUES

X509_NAME_add_entry_by_txt(), X509_NAME_add_entry_by_OBJ(), X509_NAME_add_entry_by_NID() and X509_NAME_add_entry() return 1 for success of 0 if an error occurred.

X509_NAME_delete_entry() returns either the deleted **X509_NAME_ENTRY** structure of **NULL** if an error occurred.

BUGS

type can still be set to **V_ASN1_APP_CHOOSE** to use a different algorithm to determine field types. Since this form does not understand multicharacter types, performs no length checks and can result in invalid field types its use is strongly discouraged.

```
ASN1_OBJECT * X509_NAME_ENTRY_get_object(X509_NAME_ENTRY *ne);
ASN1_STRING * X509_NAME_ENTRY_get_data(X509_NAME_ENTRY *ne);
```

```
int X509_NAME_ENTRY_set_object(X509_NAME_ENTRY *ne, ASN1_OBJECT *obj);
int X509_NAME_ENTRY_set_data(X509_NAME_ENTRY *ne, int type, const unsigned char *bytes, int len);
```

```
X509_NAME_ENTRY *X509_NAME_ENTRY_create_by_txt(X509_NAME_ENTRY **ne, const char *field, int type,
    const unsigned char *bytes, int len);
X509_NAME_ENTRY *X509_NAME_ENTRY_create_by_NID(X509_NAME_ENTRY **ne, int nid, int type,
    unsigned char *bytes, int len);
X509_NAME_ENTRY *X509_NAME_ENTRY_create_by_OBJ(X509_NAME_ENTRY **ne, ASN1_OBJECT *obj,
    int type, const unsigned char *bytes, int len);
```

DESCRIPTION

X509_NAME_ENTRY_get_object() retrieves the field name of **ne** in and **ASN1_OBJECT** structure.

X509_NAME_ENTRY_get_data() retrieves the field value of **ne** in and **ASN1_STRING** structure.

X509_NAME_ENTRY_set_object() sets the field name of **ne** to **obj**.

X509_NAME_ENTRY_set_data() sets the field value of **ne** to string type **type** and value determined by **bytes** and **len**.

X509_NAME_ENTRY_create_by_txt(), X509_NAME_ENTRY_create_by_NID() and X509_NAME_ENTRY_create_by_OBJ() create and return an **X509_NAME_ENTRY** structure.

NOTES

X509_NAME_ENTRY_get_object() and X509_NAME_ENTRY_get_data() can be used to examine an **X509_NAME_ENTRY** function as returned by X509_NAME_get_entry() for example.

X509_NAME_ENTRY_create_by_txt(), X509_NAME_ENTRY_create_by_NID(), and X509_NAME_ENTRY_create_by_OBJ() create and return an

X509_NAME_ENTRY_create_by_txt(), X509_NAME_ENTRY_create_by_OBJ(), X509_NAME_ENTRY_create_by_NID() and X509_NAME_ENTRY_set_data() are seldom used in practice because **X509_NAME_ENTRY** structures are almost always part of **X509_NAME** structures and the corresponding **X509_NAME** functions are typically used to create and add new entries in a single operation.

The arguments of these functions support similar options to the similarly named ones of the corresponding **X509_NAME** functions such as X509_NAME_add_entry_by_txt(). So for example **type** can be set to **MBSTRING_ASC** but in the case of X509_set_data() the field name must be set first so the relevant field information can be looked up internally.

Synopsis

```
#include  <openssl/x509.h>
```

```
int X509_NAME_get_index_by_NID(X509_NAME *name,int nid,int lastpos);
int X509_NAME_get_index_by_OBJ(X509_NAME *name,ASN1_OBJECT *obj, int lastpos);
```

```
int X509_NAME_entry_count(X509_NAME *name);
X509_NAME_ENTRY *X509_NAME_get_entry(X509_NAME *name, int loc);
```

```
int X509_NAME_get_text_by_NID(X509_NAME *name, int nid, char *buf,int len);
int X509_NAME_get_text_by_OBJ(X509_NAME *name, ASN1_OBJECT *obj, char *buf,int len);
```

DESCRIPTION

These functions allow an **X509_NAME** structure to be examined. The **X509_NAME** structure is the same as the **Name** type defined in RFC2459 (and elsewhere) and used for example in certificate subject and issuer names.

X509_NAME_get_index_by_NID() and X509_NAME_get_index_by_OBJ() retrieve the next index matching **nid** or **obj** after **lastpos**. **lastpos** should initially be set to -1. If there are no more entries -1 is returned. If **nid** is invalid (doesn't correspond to a valid OID) then -2 is returned.

X509_NAME_entry_count() returns the total number of entries in **name**.

X509_NAME_get_entry() retrieves the **X509_NAME_ENTRY** from **name** corresponding to index **loc**. Acceptable values for **loc** run from 0 to (X509_NAME_entry_count(name) - 1). The value returned is an internal pointer which must not be freed.

X509_NAME_get_text_by_NID(), X509_NAME_get_text_by_OBJ() retrieve the "text" from the first entry in **name** which matches **nid** or **obj**, if no such entry exists -1 is returned. At most **len** bytes will be written and the text written to **buf** will be null terminated. The length of the output string written is returned excluding the terminating null. If **buf** is <NULL> then the amount of space needed in **buf** (excluding the final null) is returned.

NOTES

X509_NAME_get_text_by_NID() and X509_NAME_get_text_by_OBJ() are legacy functions which have various limitations which make them of minimal use in practice. They can only find the first matching entry and will copy the contents of the field verbatim: this can be highly confusing if the target is a muticharacter string type like a BMPString or a UTF8String.

For a more general solution X509_NAME_get_index_by_NID() or X509_NAME_get_index_by_OBJ() should be used followed by X509_NAME_get_entry() on any matching indices and then the various **X509_NAME_ENTRY** utility functions on the result.

The list of all relevant **NID_*** and **OBJ_* codes** can be found in the source code header files <openssl/obj_mac.h> and/or <openssl/objects.h>.

Applications which could pass invalid NIDs to X509_NAME_get_index_by_NID() should check for the return value of -2. Alternatively the NID validity can be determined first by checking OBJ_nid2obj(nid) is not NULL.

EXAMPLES

Process all entries:

```
int i;
X509_NAME_ENTRY *e;
```

```
for (i = 0; i < X509_NAME_entry_count(nm); i++)
       {
       e = X509_NAME_get_entry(nm, i);
       /* Do something with e */
       }
```

Process all commonName entries:

```
int loc;
X509_NAME_ENTRY *e;

loc = -1;
for (;;)
       {
       lastpos = X509_NAME_get_index_by_NID(nm, NID_commonName, lastpos);
       if (lastpos == -1)
               break;
       e = X509_NAME_get_entry(nm, lastpos);
       /* Do something with e */
       }
```

RETURN VALUES

X509_NAME_get_index_by_NID() and X509_NAME_get_index_by_OBJ() return the index of the next matching entry or -1 if not found. X509_NAME_get_index_by_NID() can also return -2 if the supplied NID is invalid.

X509_NAME_entry_count() returns the total number of entries.

X509_NAME_get_entry() returns an **X509_NAME** pointer to the requested entry or **NULL** if the index is invalid.

HISTORY

TBA

Name

X509_NAME_print_ex, X509_NAME_print_ex_fp, X509_NAME_print and X509_NAME_oneline — X509_NAME printing routines.

Synopsis

```
#include  <openssl/x509.h>
```

```
int X509_NAME_print_ex(BIO *out, X509_NAME *nm, int indent, unsigned long flags);
int X509_NAME_print_ex_fp(FILE *fp, X509_NAME *nm, int indent, unsigned long flags);
char * X509_NAME_oneline(X509_NAME *a,char *buf,int size);
int X509_NAME_print(BIO *bp, X509_NAME *name, int obase);
```

DESCRIPTION

X509_NAME_print_ex() prints a human readable version of **nm** to BIO **out**. Each line (for multiline formats) is indented by **indent** spaces. The output format can be extensively customised by use of the **flags** parameter.

X509_NAME_print_ex_fp() is identical to X509_NAME_print_ex() except the output is written to FILE pointer **fp**.

X509_NAME_oneline() prints an ASCII version of **a** to **buf**. At most **size** bytes will be written. If **buf** is **NULL** then a buffer is dynamically allocated and returned, otherwise **buf** is returned.

X509_NAME_print() prints out **name** to **bp** indenting each line by **obase** characters. Multiple lines are used if the output (including indent) exceeds 80 characters.

NOTES

The functions X509_NAME_oneline() and X509_NAME_print() are legacy functions which produce a non standard output form, they don't handle multi character fields and have various quirks and inconsistencies. Their use is strongly discouraged in new applications.

Although there are a large number of possible flags for most purposes **XN_FLAG_ONELINE**, **XN_FLAG_MULTILINE** or **XN_FLAG_RFC2253** will suffice. As noted on the ASN1_STRING_print_ex(3) manual page for UTF8 terminals the **ASN1_STRFLGS_ESC_MSB** should be unset: so for example **XN_FLAG_ONELINE & ~ASN1_STRFLGS_ESC_MSB** would be used.

The complete set of the flags supported by X509_NAME_print_ex() is listed below.

Several options can be ored together.

The options **XN_FLAG_SEP_COMMA_PLUS**, **XN_FLAG_SEP_CPLUS_SPC**, **XN_FLAG_SEP_SPLUS_SPC** and **XN_FLAG_SEP_MULTILINE** determine the field separators to use. Two distinct separators are used between distinct RelativeDistinguishedName components and separate values in the same RDN for a multi-valued RDN. Multi-valued RDNs are currently very rare so the second separator will hardly ever be used.

XN_FLAG_SEP_COMMA_PLUS uses comma and plus as separators. **XN_FLAG_SEP_CPLUS_SPC** uses comma and plus with spaces: this is more readable that plain comma and plus. **XN_FLAG_SEP_SPLUS_SPC** uses spaced semicolon and plus. **XN_FLAG_SEP_MULTILINE** uses spaced newline and plus respectively.

If **XN_FLAG_DN_REV** is set the whole DN is printed in reversed order.

The fields **XN_FLAG_FN_SN**, **XN_FLAG_FN_LN**, **XN_FLAG_FN_OID**, **XN_FLAG_FN_NONE** determine how a field name is displayed. It will use the short name (e.g. CN) the long name (e.g. commonName) always use OID numerical form (normally OIDs are only used if the field name is not recognised) and no field name respectively.

If **XN_FLAG_SPC_EQ** is set then spaces will be placed around the '=' character separating field names and values.

If **XN_FLAG_DUMP_UNKNOWN_FIELDS** is set then the encoding of unknown fields is printed instead of the values.

If **XN_FLAG_FN_ALIGN** is set then field names are padded to 20 characters: this is only of use for multiline format.

Additionally all the options supported by ASN1_STRING_print_ex() can be used to control how each field value is displayed.

In addition a number options can be set for commonly used formats.

XN_FLAG_RFC2253 sets options which produce an output compatible with RFC2253 it is equivalent to: **ASN1_STRFLGS_RFC2253 | XN_FLAG_SEP_COMMA_PLUS | XN_FLAG_DN_REV | XN_FLAG_FN_SN | XN_FLAG_DUMP_UNKNOWN_FIELDS**

XN_FLAG_ONELINE is a more readable one line format which is the same as: **ASN1_STRFLGS_RFC2253 | ASN1_STRFLGS_ESC_QUOTE | XN_FLAG_SEP_CPLUS_SPC | XN_FLAG_SPC_EQ | XN_FLAG_FN_SN**

XN_FLAG_MULTILINE is a multiline format which is the same as: **ASN1_STRFLGS_ESC_CTRL | ASN1_STRFLGS_ESC_MSB | XN_FLAG_SEP_MULTILINE | XN_FLAG_SPC_EQ | XN_FLAG_FN_LN | XN_FLAG_FN_ALIGN**

XN_FLAG_COMPAT uses a format identical to X509_NAME_print(): in fact it calls X509_NAME_print() internally.

Name

X509_new and X509_free — X509 certificate ASN1 allocation functions

Synopsis

```
#include  <openssl/x509.h>
```

```
X509 *X509_new(void);
void X509_free(X509 *a);
```

DESCRIPTION

The X509 ASN1 allocation routines, allocate and free an X509 structure, which represents an X509 certificate.

X509_new() allocates and initializes a X509 structure.

X509_free() frees up the **X509** structure **a**.

RETURN VALUES

If the allocation fails, X509_new() returns **NULL** and sets an error code that can be obtained by ERR_get_error(3). Otherwise it returns a pointer to the newly allocated structure.

X509_free() returns no value.

SEE ALSO

ERR_get_error(3), d2i_X509(3)

HISTORY

X509_new() and X509_free() are available in all versions of SSLeay and OpenSSL.

Name

X509_STORE_CTX_get_error, X509_STORE_CTX_set_error, X509_STORE_CTX_get_error_depth, X509_STORE_CTX_get_current_cert, X509_STORE_CTX_get1_chain and X509_verify_cert_error_string — get or set certificate verification status information

Synopsis

```
#include  <openssl/x509.h>
#include  <openssl/x509_vfy.h>
```

```
int    X509_STORE_CTX_get_error(X509_STORE_CTX *ctx);
void   X509_STORE_CTX_set_error(X509_STORE_CTX *ctx,int s);
int    X509_STORE_CTX_get_error_depth(X509_STORE_CTX *ctx);
X509 * X509_STORE_CTX_get_current_cert(X509_STORE_CTX *ctx);
```

```
STACK_OF(X509) *X509_STORE_CTX_get1_chain(X509_STORE_CTX *ctx);
```

```
const char *X509_verify_cert_error_string(long n);
```

DESCRIPTION

These functions are typically called after X509_verify_cert() has indicated an error or in a verification callback to determine the nature of an error.

X509_STORE_CTX_get_error() returns the error code of **ctx**, see the **ERROR CODES** section for a full description of all error codes.

X509_STORE_CTX_set_error() sets the error code of **ctx** to **s**. For example it might be used in a verification callback to set an error based on additional checks.

X509_STORE_CTX_get_error_depth() returns the **depth** of the error. This is a non-negative integer representing where in the certificate chain the error occurred. If it is zero it occured in the end entity certificate, one if it is the certificate which signed the end entity certificate and so on.

X509_STORE_CTX_get_current_cert() returns the certificate in **ctx** which caused the error or **NULL** if no certificate is relevant.

X509_STORE_CTX_get1_chain() returns a complete validate chain if a previous call to X509_verify_cert() is successful. If the call to X509_verify_cert() is **not** successful the returned chain may be incomplete or invalid. The returned chain persists after the **ctx** structure is freed, when it is no longer needed it should be free up using:

```
sk_X509_pop_free(chain, X509_free);
```

X509_verify_cert_error_string() returns a human readable error string for verification error **n**.

RETURN VALUES

X509_STORE_CTX_get_error() returns **X509_V_OK** or an error code.

X509_STORE_CTX_get_error_depth() returns a non-negative error depth.

X509_STORE_CTX_get_current_cert() returns the cerificate which caused the error or **NULL** if no certificate is relevant to the error.

X509_verify_cert_error_string() returns a human readable error string for verification error **n**.

ERROR CODES

A list of error codes and messages is shown below. Some of the error codes are defined but currently never returned: these are described as "unused".

X509_V_OK: ok

the operation was successful.

X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT: unable to get issuer certificate

the issuer certificate could not be found: this occurs if the issuer certificate of an untrusted certificate cannot be found.

X509_V_ERR_UNABLE_TO_GET_CRL: unable to get certificate CRL

the CRL of a certificate could not be found.

X509_V_ERR_UNABLE_TO_DECRYPT_CERT_SIGNATURE: unable to decrypt certificate's signature

the certificate signature could not be decrypted. This means that the actual signature value could not be determined rather than it not matching the expected value, this is only meaningful for RSA keys.

X509_V_ERR_UNABLE_TO_DECRYPT_CRL_SIGNATURE: unable to decrypt CRL's signature

the CRL signature could not be decrypted: this means that the actual signature value could not be determined rather than it not matching the expected value. Unused.

X509_V_ERR_UNABLE_TO_DECODE_ISSUER_PUBLIC_KEY: unable to decode issuer public key

the public key in the certificate SubjectPublicKeyInfo could not be read.

X509_V_ERR_CERT_SIGNATURE_FAILURE: certificate signature failure

the signature of the certificate is invalid.

X509_V_ERR_CRL_SIGNATURE_FAILURE: CRL signature failure

the signature of the certificate is invalid.

X509_V_ERR_CERT_NOT_YET_VALID: certificate is not yet valid

the certificate is not yet valid: the notBefore date is after the current time.

X509_V_ERR_CERT_HAS_EXPIRED: certificate has expired

the certificate has expired: that is the notAfter date is before the current time.

X509_V_ERR_CRL_NOT_YET_VALID: CRL is not yet valid

the CRL is not yet valid.

X509_V_ERR_CRL_HAS_EXPIRED: CRL has expired

the CRL has expired.

X509_V_ERR_ERROR_IN_CERT_NOT_BEFORE_FIELD: format error in certificate's notBefore field

the certificate notBefore field contains an invalid time.

X509_V_ERR_ERROR_IN_CERT_NOT_AFTER_FIELD: format error in certificate's notAfter field

the certificate notAfter field contains an invalid time.

X509_V_ERR_ERROR_IN_CRL_LAST_UPDATE_FIELD: format error in CRL's lastUpdate field

the CRL lastUpdate field contains an invalid time.

X509_V_ERR_ERROR_IN_CRL_NEXT_UPDATE_FIELD: format error in CRL's nextUpdate field

the CRL nextUpdate field contains an invalid time.

X509_V_ERR_OUT_OF_MEM: out of memory

an error occurred trying to allocate memory. This should never happen.

X509_V_ERR_DEPTH_ZERO_SELF_SIGNED_CERT: self signed certificate

the passed certificate is self signed and the same certificate cannot be found in the list of trusted certificates.

X509_V_ERR_SELF_SIGNED_CERT_IN_CHAIN: self signed certificate in certificate chain

the certificate chain could be built up using the untrusted certificates but the root could not be found locally.

X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT_LOCALLY: unable to get local issuer certificate

the issuer certificate of a locally looked up certificate could not be found. This normally means the list of trusted certificates is not complete.

X509_V_ERR_UNABLE_TO_VERIFY_LEAF_SIGNATURE: unable to verify the first certificate

no signatures could be verified because the chain contains only one certificate and it is not self signed.

X509_V_ERR_CERT_CHAIN_TOO_LONG: certificate chain too long

the certificate chain length is greater than the supplied maximum depth. Unused.

X509_V_ERR_CERT_REVOKED: certificate revoked

the certificate has been revoked.

X509_V_ERR_INVALID_CA: invalid CA certificate

a CA certificate is invalid. Either it is not a CA or its extensions are not consistent with the supplied purpose.

X509_V_ERR_PATH_LENGTH_EXCEEDED: path length constraint exceeded

the basicConstraints pathlength parameter has been exceeded.

X509_V_ERR_INVALID_PURPOSE: unsupported certificate purpose

the supplied certificate cannot be used for the specified purpose.

X509_V_ERR_CERT_UNTRUSTED: certificate not trusted

the root CA is not marked as trusted for the specified purpose.

X509_V_ERR_CERT_REJECTED: certificate rejected

the root CA is marked to reject the specified purpose.

X509_V_ERR_SUBJECT_ISSUER_MISMATCH: subject issuer mismatch

the current candidate issuer certificate was rejected because its subject name did not match the issuer name of the current certificate. This is only set if issuer check debugging is enabled it is used for status notification and is **not** in itself an error.

X509_V_ERR_AKID_SKID_MISMATCH: authority and subject key identifier mismatch

the current candidate issuer certificate was rejected because its subject key identifier was present and did not match the authority key identifier current certificate. This is only set if issuer check debugging is enabled it is used for status notification and is **not** in itself an error.

X509_V_ERR_AKID_ISSUER_SERIAL_MISMATCH: authority and issuer serial number mismatch

the current candidate issuer certificate was rejected because its issuer name and serial number was present and did not match the authority key identifier of the current certificate. This is only set if issuer check debugging is enabled it is used for status notification and is **not** in itself an error.

X509_V_ERR_KEYUSAGE_NO_CERTSIGN:key usage does not include certificate signing

the current candidate issuer certificate was rejected because its keyUsage extension does not permit certificate signing. This is only set if issuer check debugging is enabled it is used for status notification and is **not** in itself an error.

X509_V_ERR_INVALID_EXTENSION: invalid or inconsistent certificate extension

A certificate extension had an invalid value (for example an incorrect encoding) or some value inconsistent with other extensions.

X509_V_ERR_INVALID_POLICY_EXTENSION: invalid or inconsistent certificate policy extension

A certificate policies extension had an invalid value (for example an incorrect encoding) or some value inconsistent with other extensions. This error only occurs if policy processing is enabled.

X509_V_ERR_NO_EXPLICIT_POLICY: no explicit policy

The verification flags were set to require and explicit policy but none was present.

X509_V_ERR_DIFFERENT_CRL_SCOPE: Different CRL scope

The only CRLs that could be found did not match the scope of the certificate.

X509_V_ERR_UNSUPPORTED_EXTENSION_FEATURE: Unsupported extension feature

Some feature of a certificate extension is not supported. Unused.

X509_V_ERR_PERMITTED_VIOLATION: permitted subtree violation

A name constraint violation occured in the permitted subtrees.

X509_V_ERR_EXCLUDED_VIOLATION: excluded subtree violation

A name constraint violation occured in the excluded subtrees.

X509_V_ERR_SUBTREE_MINMAX: name constraints minimum and maximum not supported

A certificate name constraints extension included a minimum or maximum field: this is not supported.

X509_V_ERR_UNSUPPORTED_CONSTRAINT_TYPE: unsupported name constraint type

An unsupported name constraint type was encountered. OpenSSL currently only supports directory name, DNS name, email and URI types.

X509_V_ERR_UNSUPPORTED_CONSTRAINT_SYNTAX: unsupported or invalid name constraint syntax

The format of the name constraint is not recognised: for example an email address format of a form not mentioned in RFC3280. This could be caused by a garbage extension or some new feature not currently supported.

X509_V_ERR_CRL_PATH_VALIDATION_ERROR: CRL path validation error

An error occured when attempting to verify the CRL path. This error can only happen if extended CRL checking is enabled.

X509_V_ERR_APPLICATION_VERIFICATION: application verification failure

an application specific error. This will never be returned unless explicitly set by an application.

NOTES

The above functions should be used instead of directly referencing the fields in the **X509_VERIFY_CTX** structure.

In versions of OpenSSL before 1.0 the current certificate returned by X509_STORE_CTX_get_current_cert() was never **NULL**. Applications should check the return value before printing out any debugging information relating to the current certificate.

If an unrecognised error code is passed to X509_verify_cert_error_string() the numerical value of the unknown code is returned in a static buffer. This is not thread safe but will never happen unless an invalid code is passed.

Name

X509_STORE_CTX_get_ex_new_index, X509_STORE_CTX_set_ex_data and X509_STORE_CTX_get_ex_data — add application specific data to X509_STORE_CTX structures

Synopsis

```
#include  <openssl/x509_vfy.h>
```

```
int X509_STORE_CTX_get_ex_new_index(long argl, void *argp,
               CRYPTO_EX_new *new_func,
               CRYPTO_EX_dup *dup_func,
               CRYPTO_EX_free *free_func);
```

```
int X509_STORE_CTX_set_ex_data(X509_STORE_CTX *d, int idx, void *arg);
```

```
void *X509_STORE_CTX_get_ex_data(X509_STORE_CTX *d, int idx);
```

DESCRIPTION

These functions handle application specific data in X509_STORE_CTX structures. Their usage is identical to that of RSA_get_ex_new_index(), RSA_set_ex_data() and RSA_get_ex_data() as described in RSA_get_ex_new_index(3).

NOTES

This mechanism is used internally by the **ssl** library to store the **SSL** structure associated with a verification operation in an **X509_STORE_CTX** structure.

```
X509_VERIFY_PARAM *X509_STORE_CTX_get0_param(X509_STORE_CTX *ctx);
void X509_STORE_CTX_set0_param(X509_STORE_CTX *ctx, X509_VERIFY_PARAM *param);
int X509_STORE_CTX_set_default(X509_STORE_CTX *ctx, const char *name);
```

DESCRIPTION

These functions initialise an **X509_STORE_CTX** structure for subsequent use by X509_verify_cert().

X509_STORE_CTX_new() returns a newly initialised **X509_STORE_CTX** structure.

X509_STORE_CTX_cleanup() internally cleans up an **X509_STORE_CTX** structure. The context can then be reused with an new call to X509_STORE_CTX_init().

X509_STORE_CTX_free() completely frees up **ctx**. After this call **ctx** is no longer valid.

X509_STORE_CTX_init() sets up **ctx** for a subsequent verification operation. It must be called before each call to X509_verify_cert(), i.e. a **ctx** is only good for one call to X509_verify_cert(); if you want to verify a second certificate with the same **ctx** then you must call X509_XTORE_CTX_cleanup() and then X509_STORE_CTX_init() again before the second call to X509_verify_cert(). The trusted certificate store is set to **store**, the end entity certificate to be verified is set to **x509** and a set of additional certificates (which will be untrusted but may be used to build the chain) in **chain**. Any or all of the **store**, **x509** and **chain** parameters can be **NULL**.

X509_STORE_CTX_trusted_stack() sets the set of trusted certificates of **ctx** to **sk**. This is an alternative way of specifying trusted certificates instead of using an **X509_STORE**.

X509_STORE_CTX_set_cert() sets the certificate to be vertified in **ctx** to **x**.

X509_STORE_CTX_set_chain() sets the additional certificate chain used by **ctx** to **sk**.

X509_STORE_CTX_set0_crls() sets a set of CRLs to use to aid certificate verification to **sk**. These CRLs will only be used if CRL verification is enabled in the associated **X509_VERIFY_PARAM** structure. This might be used where additional "useful" CRLs are supplied as part of a protocol, for example in a PKCS#7 structure.

X509_VERIFY_PARAM *X509_STORE_CTX_get0_param() retrieves an intenal pointer to the verification parameters associated with **ctx**.

X509_STORE_CTX_set0_param() sets the intenal verification parameter pointer to **param**. After this call **param** should not be used.

X509_STORE_CTX_set_default() looks up and sets the default verification method to **name**. This uses the function X509_VERIFY_PARAM_lookup() to find an appropriate set of parameters from **name**.

NOTES

The certificates and CRLs in a store are used internally and should **not** be freed up until after the associated **X509_STORE_CTX** is freed. Legacy applications might implicitly use an **X509_STORE_CTX** like this:

```
X509_STORE_CTX ctx;
X509_STORE_CTX_init(&ctx, store, cert, chain);
```

this is **not** recommended in new applications they should instead do:

```
X509_STORE_CTX *ctx;
ctx = X509_STORE_CTX_new();
if (ctx == NULL)
      /* Bad error */
X509_STORE_CTX_init(ctx, store, cert, chain);
```

BUGS

The certificates and CRLs in a context are used internally and should **not** be freed up until after the associated **X509_STORE_CTX** is freed. Copies should be made or reference counts increased instead.

RETURN VALUES

X509_STORE_CTX_new() returns an newly allocates context or **NULL** is an error occurred.

X509_STORE_CTX_init() returns 1 for success or 0 if an error occurred.

X509_STORE_CTX_get0_param() returns a pointer to an **X509_VERIFY_PARAM** structure or **NULL** if an error occurred.

X509_STORE_CTX_cleanup(), X509_STORE_CTX_free(), X509_STORE_CTX_trusted_stack(), X509_STORE_CTX_set_cert(), X509_STORE_CTX_set_chain(), X509_STORE_CTX_set0_crls() and X509_STORE_CTX_set0_param() do not return values.

X509_STORE_CTX_set_default() returns 1 for success or 0 if an error occurred.

X509_verify_cert(3) X509_VERIFY_PARAM_set_flags(3)

HISTORY

X509_STORE_CTX_set0_crls() was first added to OpenSSL 1.0.0

Name

X509_STORE_CTX_set_verify_cb — set verification callback

Synopsis

```
#include  <openssl/x509_vfy.h>
```

```
void X509_STORE_CTX_set_verify_cb(X509_STORE_CTX *ctx,
                               int (*verify_cb)(int ok, X509_STORE_CTX *ctx));
```

DESCRIPTION

X509_STORE_CTX_set_verify_cb() sets the verification callback of **ctx** to **verify_cb** overwriting any existing callback.

The verification callback can be used to customise the operation of certificate verification, either by overriding error conditions or logging errors for debugging purposes.

However a verification callback is **not** essential and the default operation is often sufficient.

The **ok** parameter to the callback indicates the value the callback should return to retain the default behaviour. If it is zero then and error condition is indicated. If it is 1 then no error occurred. If the flag **X509_V_FLAG_NOTIFY_POLICY** is set then **ok** is set to 2 to indicate the policy checking is complete.

The **ctx** parameter to the callback is the **X509_STORE_CTX** structure that is performing the verification operation. A callback can examine this structure and receive additional information about the error, for example by calling X509_STORE_CTX_get_current_cert(). Additional application data can be passed to the callback via the **ex_data** mechanism.

WARNING

In general a verification callback should **NOT** unconditionally return 1 in all circumstances because this will allow verification to succeed no matter what the error. This effectively removes all security from the application because **any** certificate (including untrusted generated ones) will be accepted.

NOTES

The verification callback can be set and inherited from the parent structure performing the operation. In some cases (such as S/MIME verification) the **X509_STORE_CTX** structure is created and destroyed internally and the only way to set a custom verification callback is by inheriting it from the associated **X509_STORE**.

RETURN VALUES

X509_STORE_CTX_set_verify_cb() does not return a value.

EXAMPLES

Default callback operation:

```
int verify_callback(int ok, X509_STORE_CTX *ctx)
{
    return ok;
}
```

Simple example, suppose a certificate in the chain is expired and we wish to continue after this error:

```
int verify_callback(int ok, X509_STORE_CTX *ctx)
{
    /* Tolerate certificate expiration */
    if (X509_STORE_CTX_get_error(ctx) == X509_V_ERR_CERT_HAS_EXPIRED)
                    return 1;
    /* Otherwise don't override */
    return ok;
}
```

More complex example, we don't wish to continue after **any** certificate has expired just one specific case:

```
int verify_callback(int ok, X509_STORE_CTX *ctx)
{
    int err = X509_STORE_CTX_get_error(ctx);
    X509 *err_cert = X509_STORE_CTX_get_current_cert(ctx);
    if (err == X509_V_ERR_CERT_HAS_EXPIRED)
    {
        if (check_is_acceptable_expired_cert(err_cert)
               return 1;
    }
    return ok;
}
```

Full featured logging callback. In this case the **bio_err** is assumed to be a global logging **BIO**, an alternative would to store a BIO in **ctx** using **ex_data**.

```
int verify_callback(int ok, X509_STORE_CTX *ctx)
{
    X509 *err_cert;
    int err,depth;

    err_cert = X509_STORE_CTX_get_current_cert(ctx);
    err =   X509_STORE_CTX_get_error(ctx);
    depth = X509_STORE_CTX_get_error_depth(ctx);

    BIO_printf(bio_err,"depth=%d ",depth);
    if (err_cert)
    {
        X509_NAME_print_ex(bio_err, X509_get_subject_name(err_cert),
                                0, XN_FLAG_ONELINE);
        BIO_puts(bio_err, "\n");
    }
    else
        BIO_puts(bio_err, "<no cert>\n");
    if (!ok)
        BIO_printf(bio_err,"verify error:num=%d:%s\n",err,
                X509_verify_cert_error_string(err));
    switch (err)
            {
    case X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT:
            BIO_puts(bio_err,"issuer= ");
            X509_NAME_print_ex(bio_err, X509_get_issuer_name(err_cert),
                                    0, XN_FLAG_ONELINE);
            BIO_puts(bio_err, "\n");
            break;
    case X509_V_ERR_CERT_NOT_YET_VALID:
    case X509_V_ERR_ERROR_IN_CERT_NOT_BEFORE_FIELD:
            BIO_printf(bio_err,"notBefore=");
            ASN1_TIME_print(bio_err,X509_get_notBefore(err_cert));
            BIO_printf(bio_err,"\n");
            break;
    case X509_V_ERR_CERT_HAS_EXPIRED:
    case X509_V_ERR_ERROR_IN_CERT_NOT_AFTER_FIELD:
            BIO_printf(bio_err,"notAfter=");
            ASN1_TIME_print(bio_err,X509_get_notAfter(err_cert));
            BIO_printf(bio_err,"\n");
            break;
    case X509_V_ERR_NO_EXPLICIT_POLICY:
            policies_print(bio_err, ctx);
            break;
            }
    if (err == X509_V_OK && ok == 2)
        /* print out policies */

    BIO_printf(bio_err,"verify return:%d\n",ok);
    return(ok);
}
```

SEE ALSO

X509_STORE_CTX_get_error(3) X509_STORE_set_verify_cb_func(3) X509_STORE_CTX_get_ex_new_index(3)

HISTORY

X509_STORE_CTX_set_verify_cb() is available in all versions of SSLeay and OpenSSL.

Name

X509_STORE_set_verify_cb_func and X509_STORE_set_verify_cb — set verification callback

Synopsis

```
#include  <openssl/x509_vfy.h>
```

```
void X509_STORE_set_verify_cb(X509_STORE *st,
                               int (*verify_cb)(int ok, X509_STORE_CTX *ctx));
```

```
void X509_STORE_set_verify_cb_func(X509_STORE *st,
                               int (*verify_cb)(int ok, X509_STORE_CTX *ctx));
```

DESCRIPTION

X509_STORE_set_verify_cb() sets the verification callback of **ctx** to **verify_cb** overwriting any existing callback.

X509_STORE_set_verify_cb_func() also sets the verification callback but it is implemented as a macro.

NOTES

The verification callback from an **X509_STORE** is inherited by the corresponding **X509_STORE_CTX** structure when it is initialized. This can be used to set the verification callback when the **X509_STORE_CTX** is otherwise inaccessible (for example during S/MIME verification).

BUGS

The macro version of this function was the only one available before OpenSSL 1.0.0.

RETURN VALUES

X509_STORE_set_verify_cb() and X509_STORE_set_verify_cb_func() do not return a value.

SEE ALSO

X509_STORE_CTX_set_verify_cb(3) CMS_verify(3)

HISTORY

X509_STORE_set_verify_cb_func() is available in all versions of SSLeay and OpenSSL.

X509_STORE_set_verify_cb() was added to OpenSSL 1.0.0.

Name

X509_verify_cert — discover and verify X509 certificte chain

Synopsis

```
#include  <openssl/x509.h>
```

```
int X509_verify_cert(X509_STORE_CTX *ctx);
```

DESCRIPTION

The X509_verify_cert() function attempts to discover and validate a certificate chain based on parameters in **ctx**. A complete description of the process is contained in the verify(1) manual page.

RETURN VALUES

If a complete chain can be built and validated this function returns 1, otherwise it return zero, in exceptional circumstances it can also return a negative code.

If the function fails additional error information can be obtained by examining **ctx** using, for example X509_STORE_CTX_get_error().

NOTES

Applications rarely call this function directly but it is used by OpenSSL internally for certificate validation, in both the S/MIME and SSL/TLS code.

A negative return value from X509_verify_cert() can occur if it is invoked incorrectly, such as with no certificate set in **ctx**, or when it is called twice in succession without reinitialising **ctx** for the second call. A negative return value can also happen due to internal resource problems or if a retry operation is requested during internal lookups (which never happens with standard lookup methods). Applications must check for <= 0 return value on error.

BUGS

This function uses the header **x509.h** as opposed to most chain verification functiosn which use **x509_vfy.h**.

                                               ASN1_OBJECT *policy);
int X509_VERIFY_PARAM_set1_policies(X509_VERIFY_PARAM *param,
                                       STACK_OF(ASN1_OBJECT) *policies);
```

```
void X509_VERIFY_PARAM_set_depth(X509_VERIFY_PARAM *param, int depth);
int X509_VERIFY_PARAM_get_depth(const X509_VERIFY_PARAM *param);
```

DESCRIPTION

These functions manipulate the **X509_VERIFY_PARAM** structure associated with a certificate verification operation.

The X509_VERIFY_PARAM_set_flags() function sets the flags in **param** by oring it with **flags**. See the **VERIFICATION FLAGS** section for a complete description of values the **flags** parameter can take.

X509_VERIFY_PARAM_get_flags() returns the flags in **param**.

X509_VERIFY_PARAM_clear_flags() clears the flags **flags** in **param**.

X509_VERIFY_PARAM_set_purpose() sets the verification purpose in **param** to **purpose**. This determines the acceptable purpose of the certificate chain, for example SSL client or SSL server.

X509_VERIFY_PARAM_set_trust() sets the trust setting in **param** to **trust**.

X509_VERIFY_PARAM_set_time() sets the verification time in **param** to **t**. Normally the current time is used.

X509_VERIFY_PARAM_add0_policy() enables policy checking (it is disabled by default) and adds **policy** to the acceptable policy set.

X509_VERIFY_PARAM_set1_policies() enables policy checking (it is disabled by default) and sets the acceptable policy set to **policies**. Any existing policy set is cleared. The **policies** parameter can be **NULL** to clear an existing policy set.

X509_VERIFY_PARAM_set_depth() sets the maximum verification depth to **depth**. That is the maximum number of untrusted CA certificates that can appear in a chain.

RETURN VALUES

X509_VERIFY_PARAM_set_flags(), X509_VERIFY_PARAM_clear_flags(), X509_VERIFY_PARAM_set_purpose(), X509_VERIFY_PARAM_set_trust(), X509_VERIFY_PARAM_add0_policy() and X509_VERIFY_PARAM_set1_policies() return 1 for success and 0 for failure.

X509_VERIFY_PARAM_get_flags() returns the current verification flags.

X509_VERIFY_PARAM_set_time() and X509_VERIFY_PARAM_set_depth() do not return values.

X509_VERIFY_PARAM_get_depth() returns the current verification depth.

VERIFICATION FLAGS

The verification flags consists of zero or more of the following flags ored together.

X509_V_FLAG_CRL_CHECK enables CRL checking for the certificate chain leaf certificate. An error occurs if a suitable CRL cannot be found.

X509_V_FLAG_CRL_CHECK_ALL enables CRL checking for the entire certificate chain.

X509_V_FLAG_IGNORE_CRITICAL disabled critical extension checking. By default any unhandled critical extensions in certificates or (if checked) CRLs results in a fatal error. If this flag is set unhandled critical extensions are ignored. **WARNING** setting this option for anything other than debugging purposes can be a security risk. Finer control over which extensions are supported can be performed in the verification callback.

THe **X509_V_FLAG_X509_STRICT** flag disables workarounds for some broken certificates and makes the verification strictly apply **X509** rules.

X509_V_FLAG_ALLOW_PROXY_CERTS enables proxy certificate verification.

X509_V_FLAG_POLICY_CHECK enables certificate policy checking, by default no policy checking is peformed. Additional information is sent to the verification callback relating to policy checking.

X509_V_FLAG_EXPLICIT_POLICY, **X509_V_FLAG_INHIBIT_ANY** and **X509_V_FLAG_INHIBIT_MAP** set the **require explicit policy**, **inhibit any policy** and **inhibit policy mapping** flags respectively as defined in **RFC3280**. Policy checking is automatically enabled if any of these flags are set.

If **X509_V_FLAG_NOTIFY_POLICY** is set and the policy checking is successful a special status code is set to the verification callback. This permits it to examine the valid policy tree and perform additional checks or simply log it for debugging purposes.

By default some additional features such as indirect CRLs and CRLs signed by different keys are disabled. If **X509_V_FLAG_EXTENDED_CRL_SUPPORT** is set they are enabled.

If **X509_V_FLAG_USE_DELTAS** ise set delta CRLs (if present) are used to determine certificate status. If not set deltas are ignored.

X509_V_FLAG_CHECK_SS_SIGNATURE enables checking of the root CA self signed cerificate signature. By default this check is disabled because it doesn't add any additional security but in some cases applications might want to check the signature anyway. A side effect of not checking the root CA signature is that disabled or unsupported message digests on the root CA are not treated as fatal errors.

The **X509_V_FLAG_CB_ISSUER_CHECK** flag enables debugging of certificate issuer checks. It is **not** needed unless you are logging certificate verification. If this flag is set then additional status codes will be sent to the verification callback and it **must** be prepared to handle such cases without assuming they are hard errors.

The **X509_V_FLAG_NO_ALT_CHAINS** flag suppresses checking for alternative chains. By default, when building a certificate chain, if the first certificate chain found is not trusted, then OpenSSL will continue to check to see if an alternative chain can be found that is trusted. With this flag set the behaviour will match that of OpenSSL versions prior to 1.0.1n and 1.0.2b.

NOTES

The above functions should be used to manipulate verification parameters instead of legacy functions which work in specific structures such as X509_STORE_CTX_set_flags().

BUGS

Delta CRL checking is currently primitive. Only a single delta can be used and (partly due to limitations of **X509_STORE**) constructed CRLs are not maintained.

If CRLs checking is enable CRLs are expected to be available in the corresponding **X509_STORE** structure. No attempt is made to download CRLs from the CRL distribution points extension.

EXAMPLE

Enable CRL checking when performing certificate verification during SSL connections associated with an **SSL_CTX** structure **ctx**:

```
X509_VERIFY_PARAM *param;
param = X509_VERIFY_PARAM_new();
X509_VERIFY_PARAM_set_flags(param, X509_V_FLAG_CRL_CHECK);
SSL_CTX_set1_param(ctx, param);
X509_VERIFY_PARAM_free(param);
```

HISTORY

The **X509_V_FLAG_NO_ALT_CHAINS** flag was added in OpenSSL 1.0.1n and 1.0.2b

SSL Functions

Name

SSL — OpenSSL SSL/TLS library

Synopsis

DESCRIPTION

The OpenSSL **ssl** library implements the Secure Sockets Layer (SSL v2/v3) and Transport Layer Security (TLS v1) protocols. It provides a rich API which is documented here.

At first the library must be initialized; see SSL_library_init(3).

Then an **SSL_CTX** object is created as a framework to establish TLS/SSL enabled connections (see SSL_CTX_new(3)). Various options regarding certificates, algorithms etc. can be set in this object.

When a network connection has been created, it can be assigned to an **SSL** object. After the **SSL** object has been created using SSL_new(3), SSL_set_fd(3) or SSL_set_bio(3) can be used to associate the network connection with the object.

Then the TLS/SSL handshake is performed using SSL_accept(3) or SSL_connect(3) respectively. SSL_read(3) and SSL_write(3) are used to read and write data on the TLS/SSL connection. SSL_shutdown(3) can be used to shut down the TLS/SSL connection.

DATA STRUCTURES

Currently the OpenSSL **ssl** library functions deals with the following data structures:

SSL_METHOD (SSL Method)

> That's a dispatch structure describing the internal **ssl** library methods/functions which implement the various protocol versions (SSLv1, SSLv2 and TLSv1). It's needed to create an **SSL_CTX**.

SSL_CIPHER (SSL Cipher)

> This structure holds the algorithm information for a particular cipher which are a core part of the SSL/TLS protocol. The available ciphers are configured on a **SSL_CTX** basis and the actually used ones are then part of the **SSL_SESSION**.

SSL_CTX (SSL Context)

> That's the global context structure which is created by a server or client once per program life-time and which holds mainly default values for the **SSL** structures which are later created for the connections.

SSL_SESSION (SSL Session)

> This is a structure containing the current TLS/SSL session details for a connection: **SSL_CIPHER**s, client and server certificates, keys, etc.

SSL (SSL Connection)

> That's the main SSL/TLS structure which is created by a server or client per established connection. This actually is the core structure in the SSL API. Under run-time the application usually deals with this structure which has links to mostly all other structures.

HEADER FILES

Currently the OpenSSL **ssl** library provides the following C header files containing the prototypes for the data structures and and functions:

ssl.h

That's the common header file for the SSL/TLS API. Include it into your program to make the API of the **ssl** library available. It internally includes both more private SSL headers and headers from the **crypto** library. Whenever you need hard-core details on the internals of the SSL API, look inside this header file.

ssl2.h

That's the sub header file dealing with the SSLv2 protocol only. *Usually you don't have to include it explicitly because it's already included by ssl.h*.

ssl3.h

That's the sub header file dealing with the SSLv3 protocol only. *Usually you don't have to include it explicitly because it's already included by ssl.h*.

ssl23.h

That's the sub header file dealing with the combined use of the SSLv2 and SSLv3 protocols. *Usually you don't have to include it explicitly because it's already included by ssl.h*.

tls1.h

That's the sub header file dealing with the TLSv1 protocol only. *Usually you don't have to include it explicitly because it's already included by ssl.h*.

API FUNCTIONS

Currently the OpenSSL **ssl** library exports 214 API functions. They are documented in the following:

DEALING WITH PROTOCOL METHODS

Here we document the various API functions which deal with the SSL/TLS protocol methods defined in **SSL_METHOD** structures.

const SSL_METHOD ***SSLv23_method**(void);

Constructor for the *version-flexible* SSL_METHOD structure for clients, servers or both. See SSL_CTX_new(3) for details.

const SSL_METHOD ***SSLv23_client_method**(void);

Constructor for the *version-flexible* SSL_METHOD structure for clients.

const SSL_METHOD ***SSLv23_client_method**(void);

Constructor for the *version-flexible* SSL_METHOD structure for servers.

const SSL_METHOD ***TLSv1_2_method**(void);

Constructor for the TLSv1.2 SSL_METHOD structure for clients, servers or both.

const SSL_METHOD ***TLSv1_2_client_method**(void);

Constructor for the TLSv1.2 SSL_METHOD structure for clients.

const SSL_METHOD ***TLSv1_2_server_method**(void);

Constructor for the TLSv1.2 SSL_METHOD structure for servers.

const SSL_METHOD ***TLSv1_1_method**(void);

Constructor for the TLSv1.1 SSL_METHOD structure for clients, servers or both.

const SSL_METHOD ***TLSv1_1_client_method**(void);

Constructor for the TLSv1.1 SSL_METHOD structure for clients.

const SSL_METHOD ***TLSv1_1_server_method**(void);

Constructor for the TLSv1.1 SSL_METHOD structure for servers.

const SSL_METHOD ***TLSv1_method**(void);

Constructor for the TLSv1 SSL_METHOD structure for clients, servers or both.

const SSL_METHOD ***TLSv1_client_method**(void);

Constructor for the TLSv1 SSL_METHOD structure for clients.

const SSL_METHOD ***TLSv1_server_method**(void);

Constructor for the TLSv1 SSL_METHOD structure for servers.

const SSL_METHOD ***SSLv3_method**(void);

Constructor for the SSLv3 SSL_METHOD structure for clients, servers or both.

const SSL_METHOD ***SSLv3_client_method**(void);

Constructor for the SSLv3 SSL_METHOD structure for clients.

const SSL_METHOD ***SSLv3_server_method**(void);

Constructor for the SSLv3 SSL_METHOD structure for servers.

const SSL_METHOD ***SSLv2_method**(void);

Constructor for the SSLv2 SSL_METHOD structure for clients, servers or both.

const SSL_METHOD ***SSLv2_client_method**(void);

Constructor for the SSLv2 SSL_METHOD structure for clients.

const SSL_METHOD ***SSLv2_server_method**(void);

Constructor for the SSLv2 SSL_METHOD structure for servers.

DEALING WITH CIPHERS

Here we document the various API functions which deal with the SSL/TLS ciphers defined in **SSL_CIPHER** structures.

char ***SSL_CIPHER_description**(SSL_CIPHER *cipher, char *buf, int len);

Write a string to *buf* (with a maximum size of *len*) containing a human readable description of *cipher*. Returns *buf*.

int **SSL_CIPHER_get_bits**(SSL_CIPHER *cipher, int *alg_bits);

Determine the number of bits in *cipher*. Because of export crippled ciphers there are two bits: The bits the algorithm supports in general (stored to *alg_bits*) and the bits which are actually used (the return value).

const char ***SSL_CIPHER_get_name**(SSL_CIPHER *cipher);

> Return the internal name of *cipher* as a string. These are the various strings defined by the *SSL2_TXT_xxx*, *SSL3_TXT_xxx* and *TLS1_TXT_xxx* definitions in the header files.

char ***SSL_CIPHER_get_version**(SSL_CIPHER *cipher);

> Returns a string like "`TLSv1/SSLv3`" or "`SSLv2`" which indicates the SSL/TLS protocol version to which *cipher* belongs (i.e. where it was defined in the specification the first time).

DEALING WITH PROTOCOL CONTEXTS

Here we document the various API functions which deal with the SSL/TLS protocol context defined in the **SSL_CTX** structure.

int **SSL_CTX_add_client_CA**(SSL_CTX *ctx, X509 *x);
long **SSL_CTX_add_extra_chain_cert**(SSL_CTX *ctx, X509 *x509);
int **SSL_CTX_add_session**(SSL_CTX *ctx, SSL_SESSION *c);
int **SSL_CTX_check_private_key**(const SSL_CTX *ctx);

HISTORY

The ssl(3) document appeared in OpenSSL 0.9.2

Name

d2i_SSL_SESSION and i2d_SSL_SESSION — convert SSL_SESSION object from/to ASN1 representation

Synopsis

```
#include  <openssl/ssl.h>
```

```
SSL_SESSION *d2i_SSL_SESSION(SSL_SESSION **a, const unsigned char **pp, long length);
int i2d_SSL_SESSION(SSL_SESSION *in, unsigned char **pp);
```

DESCRIPTION

d2i_SSL_SESSION() transforms the external ASN1 representation of an SSL/TLS session, stored as binary data at location **pp** with length **length**, into an SSL_SESSION object.

i2d_SSL_SESSION() transforms the SSL_SESSION object **in** into the ASN1 representation and stores it into the memory location pointed to by **pp**. The length of the resulting ASN1 representation is returned. If **pp** is the NULL pointer, only the length is calculated and returned.

NOTES

The SSL_SESSION object is built from several malloc()ed parts, it can therefore not be moved, copied or stored directly. In order to store session data on disk or into a database, it must be transformed into a binary ASN1 representation.

When using d2i_SSL_SESSION(), the SSL_SESSION object is automatically allocated. The reference count is 1, so that the session must be explicitly removed using SSL_SESSION_free(3), unless the SSL_SESSION object is completely taken over, when being called inside the get_session_cb() (see SSL_CTX_sess_set_get_cb(3)).

SSL_SESSION objects keep internal link information about the session cache list, when being inserted into one SSL_CTX object's session cache. One SSL_SESSION object, regardless of its reference count, must therefore only be used with one SSL_CTX object (and the SSL objects created from this SSL_CTX object).

When using i2d_SSL_SESSION(), the memory location pointed to by **pp** must be large enough to hold the binary representation of the session. There is no known limit on the size of the created ASN1 representation, so the necessary amount of space should be obtained by first calling i2d_SSL_SESSION() with **pp=NULL**, and obtain the size needed, then allocate the memory and call i2d_SSL_SESSION() again. Note that this will advance the value contained in ***pp** so it is necessary to save a copy of the original allocation. For example: int i,j; char *p, *temp; i = i2d_SSL_SESSION(sess, NULL); p = temp = malloc(i); j = i2d_SSL_SESSION(sess, &temp); assert(i == j); assert(p+i == temp);

RETURN VALUES

d2i_SSL_SESSION() returns a pointer to the newly allocated SSL_SESSION object. In case of failure the NULL-pointer is returned and the error message can be retrieved from the error stack.

i2d_SSL_SESSION() returns the size of the ASN1 representation in bytes. When the session is not valid, **0** is returned and no operation is performed.

ssl(3), SSL_SESSION_free(3), SSL_CTX_sess_set_get_cb(3)

Name

SSL_accept — wait for a TLS/SSL client to initiate a TLS/SSL handshake

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_accept(SSL *ssl);
```

DESCRIPTION

SSL_accept() waits for a TLS/SSL client to initiate the TLS/SSL handshake. The communication channel must already have been set and assigned to the **ssl** by setting an underlying **BIO**.

NOTES

The behaviour of SSL_accept() depends on the underlying BIO.

If the underlying BIO is **blocking**, SSL_accept() will only return once the handshake has been finished or an error occurred, except for SGC (Server Gated Cryptography). For SGC, SSL_accept() may return with -1, but SSL_get_error() will yield **SSL_ERROR_WANT_READ/WRITE** and SSL_accept() should be called again.

If the underlying BIO is **non-blocking**, SSL_accept() will also return when the underlying BIO could not satisfy the needs of SSL_accept() to continue the handshake, indicating the problem by the return value -1. In this case a call to SSL_get_error() with the return value of SSL_accept() will yield **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**. The calling process then must repeat the call after taking appropriate action to satisfy the needs of SSL_accept(). The action depends on the underlying BIO. When using a non-blocking socket, nothing is to be done, but select() can be used to check for the required condition. When using a buffering BIO, like a BIO pair, data must be written into or retrieved out of the BIO before being able to continue.

RETURN VALUES

The following return values can occur:

0 The TLS/SSL handshake was not successful but was shut down controlled and by the specifications of the TLS/SSL protocol. Call SSL_get_error() with the return value **ret** to find out the reason.

1 The TLS/SSL handshake was successfully completed, a TLS/SSL connection has been established.

<0 The TLS/SSL handshake was not successful because a fatal error occurred either at the protocol level or a connection failure occurred. The shutdown was not clean. It can also occur of action is need to continue the operation for non-blocking BIOs. Call SSL_get_error() with the return value **ret** to find out the reason.

Name

SSL_alert_type_string, SSL_alert_type_string_long, SSL_alert_desc_string and SSL_alert_desc_string_long — get textual description of alert information

Synopsis

```
#include  <openssl/ssl.h>
```

```
const char *SSL_alert_type_string(int value);
const char *SSL_alert_type_string_long(int value);
```

```
const char *SSL_alert_desc_string(int value);
const char *SSL_alert_desc_string_long(int value);
```

DESCRIPTION

SSL_alert_type_string() returns a one letter string indicating the type of the alert specified by **value**.

SSL_alert_type_string_long() returns a string indicating the type of the alert specified by **value**.

SSL_alert_desc_string() returns a two letter string as a short form describing the reason of the alert specified by **value**.

SSL_alert_desc_string_long() returns a string describing the reason of the alert specified by **value**.

NOTES

When one side of an SSL/TLS communication wants to inform the peer about a special situation, it sends an alert. The alert is sent as a special message and does not influence the normal data stream (unless its contents results in the communication being canceled).

A warning alert is sent, when a non-fatal error condition occurs. The "close notify" alert is sent as a warning alert. Other examples for non-fatal errors are certificate errors ("certificate expired", "unsupported certificate"), for which a warning alert may be sent. (The sending party may however decide to send a fatal error.) The receiving side may cancel the connection on reception of a warning alert on it discretion.

Several alert messages must be sent as fatal alert messages as specified by the TLS RFC. A fatal alert always leads to a connection abort.

RETURN VALUES

The following strings can occur for SSL_alert_type_string() or SSL_alert_type_string_long():

"W"/"warning"

"F"/"fatal"

"U"/"unknown" This indicates that no support is available for this alert type. Probably **value** does not contain a correct alert message.

The following strings can occur for SSL_alert_desc_string() or SSL_alert_desc_string_long():

"CN"/"close notify" The connection shall be closed. This is a warning alert.

"UM"/"unexpected message" An inappropriate message was received. This alert is always fatal and should never be observed in communication between proper implementations.

"BM"/"bad record mac" This alert is returned if a record is received with an incorrect MAC. This message is always fatal.

"DF"/"decompression failure"

The decompression function received improper input (e.g. data that would expand to excessive length). This message is always fatal.

"HF"/"handshake failure"

Reception of a handshake_failure alert message indicates that the sender was unable to negotiate an acceptable set of security parameters given the options available. This is a fatal error.

"NC"/"no certificate"

A client, that was asked to send a certificate, does not send a certificate (SSLv3 only).

"BC"/"bad certificate"

A certificate was corrupt, contained signatures that did not verify correctly, etc

"UC"/"unsupported certificate"

A certificate was of an unsupported type.

"CR"/"certificate revoked"

A certificate was revoked by its signer.

"CE"/"certificate expired"

A certificate has expired or is not currently valid.

"CU"/"certificate unknown"

Some other (unspecified) issue arose in processing the certificate, rendering it unacceptable.

"IP"/"illegal parameter"

A field in the handshake was out of range or inconsistent with other fields. This is always fatal.

"DC"/"decryption failed"

A TLSCiphertext decrypted in an invalid way: either it wasn't an even multiple of the block length or its padding values, when checked, weren't correct. This message is always fatal.

"RO"/"record overflow"

A TLSCiphertext record was received which had a length more than 2^14+2048 bytes, or a record decrypted to a TLSCompressed record with more than 2^14+1024 bytes. This message is always fatal.

"CA"/"unknown CA"

A valid certificate chain or partial chain was received, but the certificate was not accepted because the CA certificate could not be located or couldn't be matched with a known, trusted CA. This message is always fatal.

"AD"/"access denied"

A valid certificate was received, but when access control was applied, the sender decided not to proceed with negotiation. This message is always fatal.

"DE"/"decode error"

A message could not be decoded because some field was out of the specified range or the length of the message was incorrect. This message is always fatal.

"CY"/"decrypt error"

A handshake cryptographic operation failed, including being unable to correctly verify a signature, decrypt a key exchange, or validate a finished message.

"ER"/"export restriction"

A negotiation not in compliance with export restrictions was detected; for example, attempting to transfer a 1024 bit ephemeral RSA key for the RSA_EXPORT handshake method. This message is always fatal.

"PV"/"protocol version"

The protocol version the client has attempted to negotiate is recognized, but not supported. (For example, old protocol versions might be avoided for security reasons). This message is always fatal.

"IS"/"insufficient security"

Returned instead of handshake_failure when a negotiation has failed specifically because the server requires ciphers more secure than those supported by the client. This message is always fatal.

"IE"/"internal error"

An internal error unrelated to the peer or the correctness of the protocol makes it impossible to continue (such as a memory allocation failure). This message is always fatal.

"US"/"user canceled"

This handshake is being canceled for some reason unrelated to a protocol failure. If the user cancels an operation after the handshake is complete, just closing the connection by sending a close_notify is more appropriate. This alert should be followed by a close_notify. This message is generally a warning.

"NR"/"no renegotiation"
Sent by the client in response to a hello request or by the server in response to a client hello after initial handshaking. Either of these would normally lead to renegotiation; when that is not appropriate, the recipient should respond with this alert; at that point, the original requester can decide whether to proceed with the connection. One case where this would be appropriate would be where a server has spawned a process to satisfy a request; the process might receive security parameters (key length, authentication, etc.) at startup and it might be difficult to communicate changes to these parameters after that point. This message is always a warning.

"UP"/"unknown PSK identity"
Sent by the server to indicate that it does not recognize a PSK identity or an SRP identity.

"UK"/"unknown"
This indicates that no description is available for this alert type. Probably **value** does not contain a correct alert message.

SEE ALSO

ssl(3), SSL_CTX_set_info_callback(3)

Name

SSL_CIPHER_get_name, SSL_CIPHER_get_bits, SSL_CIPHER_get_version and SSL_CIPHER_description — get SSL_CIPHER properties

Synopsis

```
#include  <openssl/ssl.h>
```

```
const char *SSL_CIPHER_get_name(const SSL_CIPHER *cipher);
int SSL_CIPHER_get_bits(const SSL_CIPHER *cipher, int *alg_bits);
char *SSL_CIPHER_get_version(const SSL_CIPHER *cipher);
char *SSL_CIPHER_description(const SSL_CIPHER *cipher, char *buf, int size);
```

DESCRIPTION

SSL_CIPHER_get_name() returns a pointer to the name of **cipher**. If the argument is the NULL pointer, a pointer to the constant value "NONE" is returned.

SSL_CIPHER_get_bits() returns the number of secret bits used for **cipher**. If **alg_bits** is not NULL, it contains the number of bits processed by the chosen algorithm. If **cipher** is NULL, 0 is returned.

SSL_CIPHER_get_version() returns string which indicates the SSL/TLS protocol version that first defined the cipher. This is currently **SSLv2** or **TLSv1/SSLv3**. In some cases it should possibly return "TLSv1.2" but does not; use SSL_CIPHER_description() instead. If **cipher** is NULL, "(NONE)" is returned.

SSL_CIPHER_description() returns a textual description of the cipher used into the buffer **buf** of length **len** provided. **len** must be at least 128 bytes, otherwise a pointer to the string "Buffer too small" is returned. If **buf** is NULL, a buffer of 128 bytes is allocated using OPENSSL_malloc(). If the allocation fails, a pointer to the string "OPENSSL_malloc Error" is returned.

NOTES

The number of bits processed can be different from the secret bits. An export cipher like e.g. EXP-RC4-MD5 has only 40 secret bits. The algorithm does use the full 128 bits (which would be returned for **alg_bits**), of which however 88bits are fixed. The search space is hence only 40 bits.

The string returned by SSL_CIPHER_description() in case of success consists of cleartext information separated by one or more blanks in the following sequence:

<ciphername>

> Textual representation of the cipher name.

<protocol version>

> Protocol version: **SSLv2**, **SSLv3**, **TLSv1.2**. The TLSv1.0 ciphers are flagged with SSLv3. No new ciphers were added by TLSv1.1.

Kx=<key exchange>

> Key exchange method: **RSA** (for export ciphers as **RSA(512)** or **RSA(1024)**), **DH** (for export ciphers as **DH(512)** or **DH(1024)**), **DH/RSA**, **DH/DSS**, **Fortezza**.

Au=<authentication>

> Authentication method: **RSA**, **DSS**, **DH**, **None**. None is the representation of anonymous ciphers.

Enc=<symmetric encryption method>

Encryption method with number of secret bits: **DES(40)**, **DES(56)**, **3DES(168)**, **RC4(40)**, **RC4(56)**, **RC4(64)**, **RC4(128)**, **RC2(40)**, **RC2(56)**, **RC2(128)**, **IDEA(128)**, **Fortezza**, **None**.

Mac=<message authentication code>

Message digest: **MD5**, **SHA1**.

<export flag>

If the cipher is flagged exportable with respect to old US crypto regulations, the word "**export**" is printed.

EXAMPLES

Some examples for the output of SSL_CIPHER_description():

```
EDH-RSA-DES-CBC3-SHA    SSLv3 Kx=DH       Au=RSA  Enc=3DES(168) Mac=SHA1
EDH-DSS-DES-CBC3-SHA    SSLv3 Kx=DH       Au=DSS  Enc=3DES(168) Mac=SHA1
RC4-MD5                 SSLv3 Kx=RSA      Au=RSA  Enc=RC4(128)  Mac=MD5
EXP-RC4-MD5             SSLv3 Kx=RSA(512) Au=RSA  Enc=RC4(40)   Mac=MD5  export
```

A comp[lete list can be retrieved by invoking the following command:

```
openssl ciphers -v ALL
```

BUGS

If SSL_CIPHER_description() is called with **cipher** being NULL, the library crashes.

If SSL_CIPHER_description() cannot handle a built-in cipher, the according description of the cipher property is **unknown**. This case should not occur.

RETURN VALUES

See DESCRIPTION

SEE ALSO

ssl(3), SSL_get_current_cipher(3), SSL_get_ciphers(3), ciphers(1)

Name

SSL_clear — reset SSL object to allow another connection

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_clear(SSL *ssl);
```

DESCRIPTION

Reset **ssl** to allow another connection. All settings (method, ciphers, BIOs) are kept.

NOTES

SSL_clear is used to prepare an SSL object for a new connection. While all settings are kept, a side effect is the handling of the current SSL session. If a session is still **open**, it is considered bad and will be removed from the session cache, as required by RFC2246. A session is considered open, if SSL_shutdown(3) was not called for the connection or at least SSL_set_shutdown(3) was used to set the SSL_SENT_SHUTDOWN state.

If a session was closed cleanly, the session object will be kept and all settings corresponding. This explicitly means, that e.g. the special method used during the session will be kept for the next handshake. So if the session was a TLSv1 session, a SSL client object will use a TLSv1 client method for the next handshake and a SSL server object will use a TLSv1 server method, even if SSLv23_*_methods were chosen on startup. This will might lead to connection failures (see SSL_new(3)) for a description of the method's properties.

WARNINGS

SSL_clear() resets the SSL object to allow for another connection. The reset operation however keeps several settings of the last sessions (some of these settings were made automatically during the last handshake). It only makes sense for a new connection with the exact same peer that shares these settings, and may fail if that peer changes its settings between connections. Use the sequence SSL_get_session(3); SSL_new(3); SSL_set_session(3); SSL_free(3) instead to avoid such failures (or simply SSL_free(3); SSL_new(3) if session reuse is not desired).

RETURN VALUES

The following return values can occur:

0 The SSL_clear() operation could not be performed. Check the error stack to find out the reason.

1 The SSL_clear() operation was successful.

SSL_new(3), SSL_free(3), SSL_shutdown(3), SSL_set_shutdown(3), SSL_CTX_set_options(3), ssl(3), SSL_CTX_set_client_cert_cb(3)

Name

SSL_COMP_add_compression_method — handle SSL/TLS integrated compression methods

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_COMP_add_compression_method(int id, COMP_METHOD *cm);
```

DESCRIPTION

SSL_COMP_add_compression_method() adds the compression method **cm** with the identifier **id** to the list of available compression methods. This list is globally maintained for all SSL operations within this application. It cannot be set for specific SSL_CTX or SSL objects.

NOTES

The TLS standard (or SSLv3) allows the integration of compression methods into the communication. The TLS RFC does however not specify compression methods or their corresponding identifiers, so there is currently no compatible way to integrate compression with unknown peers. It is therefore currently not recommended to integrate compression into applications. Applications for non-public use may agree on certain compression methods. Using different compression methods with the same identifier will lead to connection failure.

An OpenSSL client speaking a protocol that allows compression (SSLv3, TLSv1) will unconditionally send the list of all compression methods enabled with SSL_COMP_add_compression_method() to the server during the handshake. Unlike the mechanisms to set a cipher list, there is no method available to restrict the list of compression method on a per connection basis.

An OpenSSL server will match the identifiers listed by a client against its own compression methods and will unconditionally activate compression when a matching identifier is found. There is no way to restrict the list of compression methods supported on a per connection basis.

The OpenSSL library has the compression methods **COMP_rle()** and (when especially enabled during compilation) **COMP_zlib()** available.

WARNINGS

Once the identities of the compression methods for the TLS protocol have been standardized, the compression API will most likely be changed. Using it in the current state is not recommended.

RETURN VALUES

SSL_COMP_add_compression_method() may return the following values:

0 The operation succeeded.

1 The operation failed. Check the error queue to find out the reason.

SEE ALSO

ssl(3)

Name

SSL_connect — initiate the TLS/SSL handshake with an TLS/SSL server

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_connect(SSL *ssl);
```

DESCRIPTION

SSL_connect() initiates the TLS/SSL handshake with a server. The communication channel must already have been set and assigned to the **ssl** by setting an underlying **BIO**.

NOTES

The behaviour of SSL_connect() depends on the underlying BIO.

If the underlying BIO is **blocking**, SSL_connect() will only return once the handshake has been finished or an error occurred.

If the underlying BIO is **non-blocking**, SSL_connect() will also return when the underlying BIO could not satisfy the needs of SSL_connect() to continue the handshake, indicating the problem by the return value -1. In this case a call to SSL_get_error() with the return value of SSL_connect() will yield **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**. The calling process then must repeat the call after taking appropriate action to satisfy the needs of SSL_connect(). The action depends on the underlying BIO. When using a non-blocking socket, nothing is to be done, but select() can be used to check for the required condition. When using a buffering BIO, like a BIO pair, data must be written into or retrieved out of the BIO before being able to continue.

RETURN VALUES

The following return values can occur:

0 The TLS/SSL handshake was not successful but was shut down controlled and by the specifications of the TLS/SSL protocol. Call SSL_get_error() with the return value **ret** to find out the reason.

1 The TLS/SSL handshake was successfully completed, a TLS/SSL connection has been established.

<0 The TLS/SSL handshake was not successful, because a fatal error occurred either at the protocol level or a connection failure occurred. The shutdown was not clean. It can also occur of action is need to continue the operation for non-blocking BIOs. Call SSL_get_error() with the return value **ret** to find out the reason.

Name

SSL_CTX_add_extra_chain_cert and SSL_CTX_clear_extra_chain_certs — add or clear extra chain certificates

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_add_extra_chain_cert(SSL_CTX *ctx, X509 *x509);
long SSL_CTX_clear_extra_chain_certs(SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_add_extra_chain_cert() adds the certificate **x509** to the extra chain certificates associated with **ctx**. Several certificates can be added one after another.

SSL_CTX_clear_extra_chain_certs() clears all extra chain certificates associated with **ctx**.

These functions are implemented as macros.

NOTES

When sending a certificate chain, extra chain certificates are sent in order following the end entity certificate.

If no chain is specified, the library will try to complete the chain from the available CA certificates in the trusted CA storage, see SSL_CTX_load_verify_locations(3).

The **x509** certificate provided to SSL_CTX_add_extra_chain_cert() will be freed by the library when the **SSL_CTX** is destroyed. An application **should not** free the **x509** object.

RESTRICTIONS

Only one set of extra chain certificates can be specified per SSL_CTX structure. Different chains for different certificates (for example if both RSA and DSA certificates are specified by the same server) or different SSL structures with the same parent SSL_CTX cannot be specified using this function.

RETURN VALUES

SSL_CTX_add_extra_chain_cert() and SSL_CTX_clear_extra_chain_certs() return 1 on success and 0 for failure. Check out the error stack to find out the reason for failure.

SEE ALSO

Name

SSL_CTX_add_session, SSL_add_session, SSL_CTX_remove_session and SSL_remove_session — manipulate session cache

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_CTX_add_session(SSL_CTX *ctx, SSL_SESSION *c);
int SSL_add_session(SSL_CTX *ctx, SSL_SESSION *c);
```

```
int SSL_CTX_remove_session(SSL_CTX *ctx, SSL_SESSION *c);
int SSL_remove_session(SSL_CTX *ctx, SSL_SESSION *c);
```

DESCRIPTION

SSL_CTX_add_session() adds the session **c** to the context **ctx**. The reference count for session **c** is incremented by 1. If a session with the same session id already exists, the old session is removed by calling SSL_SESSION_free(3).

SSL_CTX_remove_session() removes the session **c** from the context **ctx**. SSL_SESSION_free(3) is called once for **c**.

SSL_add_session() and SSL_remove_session() are synonyms for their SSL_CTX_*() counterparts.

NOTES

When adding a new session to the internal session cache, it is examined whether a session with the same session id already exists. In this case it is assumed that both sessions are identical. If the same session is stored in a different SSL_SESSION object, The old session is removed and replaced by the new session. If the session is actually identical (the SSL_SESSION object is identical), SSL_CTX_add_session() is a no-op, and the return value is 0.

If a server SSL_CTX is configured with the SSL_SESS_CACHE_NO_INTERNAL_STORE flag then the internal cache will not be populated automatically by new sessions negotiated by the SSL/TLS implementation, even though the internal cache will be searched automatically for session-resume requests (the latter can be suppressed by SSL_SESS_CACHE_NO_INTERNAL_LOOKUP). So the application can use SSL_CTX_add_session() directly to have full control over the sessions that can be resumed if desired.

RETURN VALUES

The following values are returned by all functions:

0
```
The operation failed. In case of the add operation, it was tried to add
the same (identical) session twice. In case of the remove operation, the
session was not found in the cache.
```

1
```
The operation succeeded.
```

Name

SSL_CTX_ctrl, SSL_CTX_callback_ctrl, SSL_ctrl and SSL_callback_ctrl — internal handling functions for SSL_CTX and SSL objects

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_ctrl(SSL_CTX *ctx, int cmd, long larg, void *parg);
long SSL_CTX_callback_ctrl(SSL_CTX *, int cmd, void (*fp)());
```

```
long SSL_ctrl(SSL *ssl, int cmd, long larg, void *parg);
long SSL_callback_ctrl(SSL *, int cmd, void (*fp)());
```

DESCRIPTION

The SSL_*_ctrl() family of functions is used to manipulate settings of the SSL_CTX and SSL objects. Depending on the command **cmd** the arguments **larg**, **parg**, or **fp** are evaluated. These functions should never be called directly. All functionalities needed are made available via other functions or macros.

RETURN VALUES

The return values of the SSL*_ctrl() functions depend on the command supplied via the **cmd** parameter.

SEE ALSO

ssl(3)

Name

SSL_CTX_flush_sessions and SSL_flush_sessions — remove expired sessions

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_flush_sessions(SSL_CTX *ctx, long tm);
void SSL_flush_sessions(SSL_CTX *ctx, long tm);
```

DESCRIPTION

SSL_CTX_flush_sessions() causes a run through the session cache of **ctx** to remove sessions expired at time **tm**.

SSL_flush_sessions() is a synonym for SSL_CTX_flush_sessions().

NOTES

If enabled, the internal session cache will collect all sessions established up to the specified maximum number (see SSL_CTX_sess_set_cache_size()). As sessions will not be reused ones they are expired, they should be removed from the cache to save resources. This can either be done automatically whenever 255 new sessions were established (see SSL_CTX_set_session_cache_mode(3)) or manually by calling SSL_CTX_flush_sessions().

The parameter **tm** specifies the time which should be used for the expiration test, in most cases the actual time given by time(0) will be used.

SSL_CTX_flush_sessions() will only check sessions stored in the internal cache. When a session is found and removed, the remove_session_cb is however called to synchronize with the external cache (see SSL_CTX_sess_set_get_cb(3)).

RETURN VALUES

SEE ALSO

ssl(3), SSL_CTX_set_session_cache_mode(3), SSL_CTX_set_timeout(3), SSL_CTX_sess_set_get_cb(3)

Name

SSL_CTX_free — free an allocated SSL_CTX object

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_free(SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_free() decrements the reference count of **ctx**, and removes the SSL_CTX object pointed to by **ctx** and frees up the allocated memory if the the reference count has reached 0.

It also calls the free()ing procedures for indirectly affected items, if applicable: the session cache, the list of ciphers, the list of Client CAs, the certificates and keys.

WARNINGS

If a session-remove callback is set (SSL_CTX_sess_set_remove_cb()), this callback will be called for each session being freed from **ctx**'s session cache. This implies, that all corresponding sessions from an external session cache are removed as well. If this is not desired, the user should explicitly unset the callback by calling SSL_CTX_sess_set_remove_cb(**ctx**, NULL) prior to calling SSL_CTX_free().

RETURN VALUES

SSL_CTX_free() does not provide diagnostic information.

               int idx, long argl, void *argp);
typedef int dup_func(CRYPTO_EX_DATA *to, CRYPTO_EX_DATA *from, void *from_d,
               int idx, long argl, void *argp);
```

DESCRIPTION

Several OpenSSL structures can have application specific data attached to them. These functions are used internally by OpenSSL to manipulate application specific data attached to a specific structure.

SSL_CTX_get_ex_new_index() is used to register a new index for application specific data.

SSL_CTX_set_ex_data() is used to store application data at **arg** for **idx** into the **ctx** object.

SSL_CTX_get_ex_data() is used to retrieve the information for **idx** from **ctx**.

A detailed description for the ***_get_ex_new_index()** functionality can be found in RSA_get_ex_new_index(3). The ***_get_ex_data()** and ***_set_ex_data()** functionality is described in CRYPTO_set_ex_data(3).

SEE ALSO

ssl(3), RSA_get_ex_new_index(3), CRYPTO_set_ex_data(3)

Name

SSL_CTX_get_verify_mode, SSL_get_verify_mode, SSL_CTX_get_verify_depth, SSL_get_verify_depth, SSL_get_verify_callback and SSL_CTX_get_verify_callback — get currently set verification parameters

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_CTX_get_verify_mode(const SSL_CTX *ctx);
int SSL_get_verify_mode(const SSL *ssl);
int SSL_CTX_get_verify_depth(const SSL_CTX *ctx);
int SSL_get_verify_depth(const SSL *ssl);
int (*SSL_CTX_get_verify_callback(const SSL_CTX *ctx))(int, X509_STORE_CTX *);
int (*SSL_get_verify_callback(const SSL *ssl))(int, X509_STORE_CTX *);
```

DESCRIPTION

SSL_CTX_get_verify_mode() returns the verification mode currently set in **ctx**.

SSL_get_verify_mode() returns the verification mode currently set in **ssl**.

SSL_CTX_get_verify_depth() returns the verification depth limit currently set in **ctx**. If no limit has been explicitly set, -1 is returned and the default value will be used.

SSL_get_verify_depth() returns the verification depth limit currently set in **ssl**. If no limit has been explicitly set, -1 is returned and the default value will be used.

SSL_CTX_get_verify_callback() returns a function pointer to the verification callback currently set in **ctx**. If no callback was explicitly set, the NULL pointer is returned and the default callback will be used.

SSL_get_verify_callback() returns a function pointer to the verification callback currently set in **ssl**. If no callback was explicitly set, the NULL pointer is returned and the default callback will be used.

RETURN VALUES

See DESCRIPTION

SEE ALSO

ssl(3), SSL_CTX_set_verify(3)

Name

SSL_CTX_load_verify_locations — set default locations for trusted CA certificates

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_CTX_load_verify_locations(SSL_CTX *ctx, const char *CAfile,
                                  const char *CApath);
```

DESCRIPTION

SSL_CTX_load_verify_locations() specifies the locations for **ctx**, at which CA certificates for verification purposes are located. The certificates available via **CAfile** and **CApath** are trusted.

NOTES

If **CAfile** is not NULL, it points to a file of CA certificates in PEM format. The file can contain several CA certificates identified by

```
-----BEGIN CERTIFICATE-----
… (CA certificate in base64 encoding) …
-----END CERTIFICATE-----
```

sequences. Before, between, and after the certificates text is allowed which can be used e.g. for descriptions of the certificates.

The **CAfile** is processed on execution of the SSL_CTX_load_verify_locations() function.

If **CApath** is not NULL, it points to a directory containing CA certificates in PEM format. The files each contain one CA certificate. The files are looked up by the CA subject name hash value, which must hence be available. If more than one CA certificate with the same name hash value exist, the extension must be different (e.g. 9d66eef0.0, 9d66eef0.1 etc). The search is performed in the ordering of the extension number, regardless of other properties of the certificates. Use the **c_rehash** utility to create the necessary links.

The certificates in **CApath** are only looked up when required, e.g. when building the certificate chain or when actually performing the verification of a peer certificate.

When looking up CA certificates, the OpenSSL library will first search the certificates in **CAfile**, then those in **CApath**. Certificate matching is done based on the subject name, the key identifier (if present), and the serial number as taken from the certificate to be verified. If these data do not match, the next certificate will be tried. If a first certificate matching the parameters is found, the verification process will be performed; no other certificates for the same parameters will be searched in case of failure.

In server mode, when requesting a client certificate, the server must send the list of CAs of which it will accept client certificates. This list is not influenced by the contents of **CAfile** or **CApath** and must explicitly be set using the SSL_CTX_set_client_CA_list(3) family of functions.

When building its own certificate chain, an OpenSSL client/server will try to fill in missing certificates from **CAfile**/**CApath**, if the certificate chain was not explicitly specified (see SSL_CTX_add_extra_chain_cert(3), SSL_CTX_use_certificate(3).

WARNINGS

If several CA certificates matching the name, key identifier, and serial number condition are available, only the first one will be examined. This may lead to unexpected results if the same CA certificate is available with different expiration dates. If a "certificate expired" verification error occurs, no other certificate will be searched. Make sure to not have expired certificates mixed with valid ones.

EXAMPLES

Generate a CA certificate file with descriptive text from the CA certificates ca1.pem ca2.pem ca3.pem:

```
#!/bin/sh
rm CAfile.pem
for i in ca1.pem ca2.pem ca3.pem ; do
  openssl x509 -in $i -text >> CAfile.pem
done
```

Prepare the directory /some/where/certs containing several CA certificates for use as **CApath**:

```
cd /some/where/certs
c_rehash .
```

RETURN VALUES

The following return values can occur:

0 The operation failed because **CAfile** and **CApath** are NULL or the processing at one of the locations specified failed. Check the error stack to find out the reason.

1 The operation succeeded.

DESCRIPTION

SSL_CTX_new() creates a new **SSL_CTX** object as framework to establish TLS/SSL enabled connections.

NOTES

The SSL_CTX object uses **method** as connection method. The methods exist in a generic type (for client and server use), a server only type, and a client only type. **method** can be of the following types:

SSLv23_method(), SSLv23_server_method(), SSLv23_client_method()

> These are the general-purpose *version-flexible* SSL/TLS methods. The actual protocol version used will be negotiated to the highest version mutually supported by the client and the server. The supported protocols are SSLv2, SSLv3, TLSv1, TLSv1.1 and TLSv1.2. Most applications should use these method, and avoid the version specific methods described below.
>
> The list of protocols available can be further limited using the **SSL_OP_NO_SSLv2**, **SSL_OP_NO_SSLv3**, **SSL_OP_NO_TLSv1**, **SSL_OP_NO_TLSv1_1** and **SSL_OP_NO_TLSv1_2** options of the SSL_CTX_set_options(3) or SSL_set_options(3) functions. Clients should avoid creating "holes" in the set of protocols they support, when disabling a protocol, make sure that you also disable either all previous or all subsequent protocol versions. In clients, when a protocol version is disabled without disabling *all* previous protocol versions, the effect is to also disable all subsequent protocol versions.

The SSLv2 and SSLv3 protocols are deprecated and should generally not be used. Applications should typically use SSL_CTX_set_options(3) in combination with the **SSL_OP_NO_SSLv3** flag to disable negotiation of SSLv3 via the above *version-flexible* SSL/TLS methods. The **SSL_OP_NO_SSLv2** option is set by default, and would need to be cleared via SSL_CTX_clear_options(3) in order to enable negotiation of SSLv2.

TLSv1_2_method(), TLSv1_2_server_method(), TLSv1_2_client_method()

A TLS/SSL connection established with these methods will only understand the TLSv1.2 protocol. A client will send out TLSv1.2 client hello messages and will also indicate that it only understand TLSv1.2. A server will only understand TLSv1.2 client hello messages.

TLSv1_1_method(), TLSv1_1_server_method(), TLSv1_1_client_method()

A TLS/SSL connection established with these methods will only understand the TLSv1.1 protocol. A client will send out TLSv1.1 client hello messages and will also indicate that it only understand TLSv1.1. A server will only understand TLSv1.1 client hello messages.

TLSv1_method(), TLSv1_server_method(), TLSv1_client_method()

A TLS/SSL connection established with these methods will only understand the TLSv1 protocol. A client will send out TLSv1 client hello messages and will indicate that it only understands TLSv1. A server will only understand TLSv1 client hello messages.

SSLv3_method(), SSLv3_server_method(), SSLv3_client_method()

A TLS/SSL connection established with these methods will only understand the SSLv3 protocol. A client will send out SSLv3 client hello messages and will indicate that it only understands SSLv3. A server will only understand SSLv3 client hello messages. The SSLv3 protocol is deprecated and should not be used.

SSLv2_method(), SSLv2_server_method(), SSLv2_client_method()

A TLS/SSL connection established with these methods will only understand the SSLv2 protocol. A client will send out SSLv2 client hello messages and will also indicate that it only understand SSLv2. A server will only understand SSLv2 client hello messages. The SSLv2 protocol offers little to no security and should not be used. As of OpenSSL 1.0.1s, EXPORT ciphers and 56-bit DES are no longer available with SSLv2.

DTLSv1_method(), DTLSv1_server_method(), DTLSv1_client_method()

These are the version-specific methods for DTLSv1.

SSL_CTX_new() initializes the list of ciphers, the session cache setting, the callbacks, the keys and certificates and the options to its default values.

RETURN VALUES

The following return values can occur:

NULL
The creation of a new SSL_CTX object failed. Check the error stack to find out the reason.

Pointer to an SSL_CTX object
The return value points to an allocated SSL_CTX object.

Name

SSL_CTX_sessions — access internal session cache

Synopsis

```
#include  <openssl/ssl.h>
```

```
struct lhash_st *SSL_CTX_sessions(SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_sessions() returns a pointer to the lhash databases containing the internal session cache for **ctx**.

NOTES

The sessions in the internal session cache are kept in an lhash(3) type database. It is possible to directly access this database e.g. for searching. In parallel, the sessions form a linked list which is maintained separately from the lhash(3) operations, so that the database must not be modified directly but by using the SSL_CTX_add_session(3) family of functions.

SEE ALSO

Name

SSL_CTX_sess_number, SSL_CTX_sess_connect, SSL_CTX_sess_connect_good, SSL_CTX_sess_connect_renegotiate, SSL_CTX_sess_accept, SSL_CTX_sess_accept_good, SSL_CTX_sess_accept_renegotiate, SSL_CTX_sess_hits, SSL_CTX_sess_cb_hits, SSL_CTX_sess_misses, SSL_CTX_sess_timeouts and SSL_CTX_sess_cache_full — obtain session cache statistics

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_sess_number(SSL_CTX *ctx);
long SSL_CTX_sess_connect(SSL_CTX *ctx);
long SSL_CTX_sess_connect_good(SSL_CTX *ctx);
long SSL_CTX_sess_connect_renegotiate(SSL_CTX *ctx);
long SSL_CTX_sess_accept(SSL_CTX *ctx);
long SSL_CTX_sess_accept_good(SSL_CTX *ctx);
long SSL_CTX_sess_accept_renegotiate(SSL_CTX *ctx);
long SSL_CTX_sess_hits(SSL_CTX *ctx);
long SSL_CTX_sess_cb_hits(SSL_CTX *ctx);
long SSL_CTX_sess_misses(SSL_CTX *ctx);
long SSL_CTX_sess_timeouts(SSL_CTX *ctx);
long SSL_CTX_sess_cache_full(SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_sess_number() returns the current number of sessions in the internal session cache.

SSL_CTX_sess_connect() returns the number of started SSL/TLS handshakes in client mode.

SSL_CTX_sess_connect_good() returns the number of successfully established SSL/TLS sessions in client mode.

SSL_CTX_sess_connect_renegotiate() returns the number of start renegotiations in client mode.

SSL_CTX_sess_accept() returns the number of started SSL/TLS handshakes in server mode.

SSL_CTX_sess_accept_good() returns the number of successfully established SSL/TLS sessions in server mode.

SSL_CTX_sess_accept_renegotiate() returns the number of start renegotiations in server mode.

SSL_CTX_sess_hits() returns the number of successfully reused sessions. In client mode a session set with SSL_set_session(3) successfully reused is counted as a hit. In server mode a session successfully retrieved from internal or external cache is counted as a hit.

SSL_CTX_sess_cb_hits() returns the number of successfully retrieved sessions from the external session cache in server mode.

SSL_CTX_sess_misses() returns the number of sessions proposed by clients that were not found in the internal session cache in server mode.

SSL_CTX_sess_timeouts() returns the number of sessions proposed by clients and either found in the internal or external session cache in server mode, but that were invalid due to timeout. These sessions are not included in the SSL_CTX_sess_hits() count.

SSL_CTX_sess_cache_full() returns the number of sessions that were removed because the maximum session cache size was exceeded.

RETURN VALUES

The functions return the values indicated in the DESCRIPTION section.

SEE ALSO

ssl(3), SSL_set_session(3), SSL_CTX_set_session_cache_mode(3)SSL_CTX_sess_set_cache_size(3)

Name

SSL_CTX_sess_set_cache_size and SSL_CTX_sess_get_cache_size — manipulate session cache size

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_sess_set_cache_size(SSL_CTX *ctx, long t);
long SSL_CTX_sess_get_cache_size(SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_sess_set_cache_size() sets the size of the internal session cache of context **ctx** to **t**.

SSL_CTX_sess_get_cache_size() returns the currently valid session cache size.

NOTES

The internal session cache size is SSL_SESSION_CACHE_MAX_SIZE_DEFAULT, currently 1024*20, so that up to 20000 sessions can be held. This size can be modified using the SSL_CTX_sess_set_cache_size() call. A special case is the size 0, which is used for unlimited size.

When the maximum number of sessions is reached, no more new sessions are added to the cache. New space may be added by calling SSL_CTX_flush_sessions(3) to remove expired sessions.

If the size of the session cache is reduced and more sessions are already in the session cache, old session will be removed at the next time a session shall be added. This removal is not synchronized with the expiration of sessions.

RETURN VALUES

SSL_CTX_sess_set_cache_size() returns the previously valid size.

SSL_CTX_sess_get_cache_size() returns the currently valid size.

void (*SSL_CTX_sess_get_remove_cb(SSL_CTX *ctx))(struct ssl_ctx_st *ctx, SSL_SESSION *sess);
SSL_SESSION *(*SSL_CTX_sess_get_get_cb(SSL_CTX *ctx))(struct ssl_st *ssl, unsigned char *data,
              int len, int *copy);
```

```
int (*new_session_cb)(struct ssl_st *ssl, SSL_SESSION *sess);
void (*remove_session_cb)(struct ssl_ctx_st *ctx, SSL_SESSION *sess);
SSL_SESSION *(*get_session_cb)(struct ssl_st *ssl, unsigned char *data,
              int len, int *copy);
```

DESCRIPTION

SSL_CTX_sess_set_new_cb() sets the callback function, which is automatically called whenever a new session was negotiated.

SSL_CTX_sess_set_remove_cb() sets the callback function, which is automatically called whenever a session is removed by the SSL engine, because it is considered faulty or the session has become obsolete because of exceeding the timeout value.

SSL_CTX_sess_set_get_cb() sets the callback function which is called, whenever a SSL/TLS client proposed to resume a session but the session could not be found in the internal session cache (see SSL_CTX_set_session_cache_mode(3)). (SSL/TLS server only.)

SSL_CTX_sess_get_new_cb(), SSL_CTX_sess_get_remove_cb(), and SSL_CTX_sess_get_get_cb() allow to retrieve the function pointers of the provided callback functions. If a callback function has not been set, the NULL pointer is returned.

NOTES

In order to allow external session caching, synchronization with the internal session cache is realized via callback functions. Inside these callback functions, session can be saved to disk or put into a database using the d2i_SSL_SESSION(3) interface.

The new_session_cb() is called, whenever a new session has been negotiated and session caching is enabled (see SSL_CTX_set_session_cache_mode(3)). The new_session_cb() is passed the **ssl** connection and the ssl session **sess**. If the callback returns **0**, the session will be immediately removed again.

The remove_session_cb() is called, whenever the SSL engine removes a session from the internal cache. This happens when the session is removed because it is expired or when a connection was not shutdown cleanly. It also happens for all sessions in the internal session cache when SSL_CTX_free(3) is called. The remove_session_cb() is passed the **ctx** and the ssl session **sess**. It does not provide any feedback.

The get_session_cb() is only called on SSL/TLS servers with the session id proposed by the client. The get_session_cb() is always called, also when session caching was disabled. The get_session_cb() is passed the **ssl** connection, the session id of length **length** at the memory location **data**. With the parameter **copy** the callback can require the SSL engine to increment the reference count of the SSL_SESSION object, Normally the reference count is not incremented and therefore the session must not be explicitly freed with SSL_SESSION_free(3).

SEE ALSO

ssl(3), d2i_SSL_SESSION(3), SSL_CTX_set_session_cache_mode(3), SSL_CTX_flush_sessions(3), SSL_SESSION_free(3), SSL_CTX_free(3)

Name

SSL_CTX_set_cert_store and SSL_CTX_get_cert_store — manipulate X509 certificate verification storage

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_cert_store(SSL_CTX *ctx, X509_STORE *store);
X509_STORE *SSL_CTX_get_cert_store(const SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_set_cert_store() sets/replaces the certificate verification storage of **ctx** to/with **store**. If another X509_STORE object is currently set in **ctx**, it will be X509_STORE_free()ed.

SSL_CTX_get_cert_store() returns a pointer to the current certificate verification storage.

NOTES

In order to verify the certificates presented by the peer, trusted CA certificates must be accessed. These CA certificates are made available via lookup methods, handled inside the X509_STORE. From the X509_STORE the X509_STORE_CTX used when verifying certificates is created.

Typically the trusted certificate store is handled indirectly via using SSL_CTX_load_verify_locations(3). Using the SSL_CTX_set_cert_store() and SSL_CTX_get_cert_store() functions it is possible to manipulate the X509_STORE object beyond the SSL_CTX_load_verify_locations(3) call.

Currently no detailed documentation on how to use the X509_STORE object is available. Not all members of the X509_STORE are used when the verification takes place. So will e.g. the verify_callback() be overridden with the verify_callback() set via the SSL_CTX_set_verify(3) family of functions. This document must therefore be updated when documentation about the X509_STORE object and its handling becomes available.

RETURN VALUES

SSL_CTX_set_cert_store() does not return diagnostic output.

SSL_CTX_get_cert_store() returns the current setting.

SEE ALSO

ssl(3), SSL_CTX_load_verify_locations(3), SSL_CTX_set_verify(3)

Name

SSL_CTX_set_cert_verify_callback — set peer certificate verification procedure

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_cert_verify_callback(SSL_CTX *ctx, int (*callback)(X509_STORE_CTX *,void *), void *arg);
```

DESCRIPTION

SSL_CTX_set_cert_verify_callback() sets the verification callback function for *ctx*. SSL objects that are created from *ctx* inherit the setting valid at the time when SSL_new(3) is called.

NOTES

Whenever a certificate is verified during a SSL/TLS handshake, a verification function is called. If the application does not explicitly specify a verification callback function, the built-in verification function is used. If a verification callback *callback* is specified via SSL_CTX_set_cert_verify_callback(), the supplied callback function is called instead. By setting *callback* to NULL, the default behaviour is restored.

When the verification must be performed, *callback* will be called with the arguments callback(X509_STORE_CTX *x509_store_ctx, void *arg). The argument *arg* is specified by the application when setting *callback*.

callback should return 1 to indicate verification success and 0 to indicate verification failure. If SSL_VERIFY_PEER is set and *callback* returns 0, the handshake will fail. As the verification procedure may allow to continue the connection in case of failure (by always returning 1) the verification result must be set in any case using the **error** member of *x509_store_ctx* so that the calling application will be informed about the detailed result of the verification procedure!

Within *x509_store_ctx*, *callback* has access to the *verify_callback* function set using SSL_CTX_set_verify(3).

WARNINGS

Do not mix the verification callback described in this function with the **verify_callback** function called during the verification process. The latter is set using the SSL_CTX_set_verify(3) family of functions.

Providing a complete verification procedure including certificate purpose settings etc is a complex task. The built-in procedure is quite powerful and in most cases it should be sufficient to modify its behaviour using the **verify_callback** function.

BUGS

RETURN VALUES

SSL_CTX_set_cert_verify_callback() does not provide diagnostic information.

SEE ALSO

ssl(3), SSL_CTX_set_verify(3), SSL_get_verify_result(3), SSL_CTX_load_verify_locations(3)

HISTORY

Previous to OpenSSL 0.9.7, the *arg* argument to **SSL_CTX_set_cert_verify_callback** was ignored, and *callback* was called simply as int (*callback)(X509_STORE_CTX *) To compile software written for previous versions of OpenSSL, a dummy argument will have to be added to *callback*.

Name

SSL_CTX_set_cipher_list and SSL_set_cipher_list — choose list of available SSL_CIPHERs

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_CTX_set_cipher_list(SSL_CTX *ctx, const char *str);
int SSL_set_cipher_list(SSL *ssl, const char *str);
```

DESCRIPTION

SSL_CTX_set_cipher_list() sets the list of available ciphers for **ctx** using the control string **str**. The format of the string is described in ciphers(1). The list of ciphers is inherited by all **ssl** objects created from **ctx**.

SSL_set_cipher_list() sets the list of ciphers only for **ssl**.

NOTES

The control string **str** should be universally usable and not depend on details of the library configuration (ciphers compiled in). Thus no syntax checking takes place. Items that are not recognized, because the corresponding ciphers are not compiled in or because they are mistyped, are simply ignored. Failure is only flagged if no ciphers could be collected at all.

It should be noted, that inclusion of a cipher to be used into the list is a necessary condition. On the client side, the inclusion into the list is also sufficient. On the server side, additional restrictions apply. All ciphers have additional requirements. ADH ciphers don't need a certificate, but DH-parameters must have been set. All other ciphers need a corresponding certificate and key.

A RSA cipher can only be chosen, when a RSA certificate is available. RSA export ciphers with a keylength of 512 bits for the RSA key require a temporary 512 bit RSA key, as typically the supplied key has a length of 1024 bit (see SSL_CTX_set_tmp_rsa_callback(3)). RSA ciphers using EDH need a certificate and key and additional DH-parameters (see SSL_CTX_set_tmp_dh_callback(3)).

A DSA cipher can only be chosen, when a DSA certificate is available. DSA ciphers always use DH key exchange and therefore need DH-parameters (see SSL_CTX_set_tmp_dh_callback(3)).

When these conditions are not met for any cipher in the list (e.g. a client only supports export RSA ciphers with a asymmetric key length of 512 bits and the server is not configured to use temporary RSA keys), the "no shared cipher" (SSL_R_NO_SHARED_CIPHER) error is generated and the handshake will fail.

If the cipher list does not contain any SSLv2 cipher suites (this is the default) then SSLv2 is effectively disabled and neither clients nor servers will attempt to use SSLv2.

RETURN VALUES

SSL_CTX_set_cipher_list() and SSL_set_cipher_list() return 1 if any cipher could be selected and 0 on complete failure.

SEE ALSO

ssl(3), SSL_get_ciphers(3), SSL_CTX_use_certificate(3), SSL_CTX_set_tmp_rsa_callback(3), SSL_CTX_set_tmp_dh_callback(3), ciphers(1)

Name

SSL_CTX_set_client_CA_list, SSL_set_client_CA_list, SSL_CTX_add_client_CA and SSL_add_client_CA — set list of CAs sent to the client when requesting a client certificate

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_client_CA_list(SSL_CTX *ctx, STACK_OF(X509_NAME) *list);
void SSL_set_client_CA_list(SSL *s, STACK_OF(X509_NAME) *list);
int SSL_CTX_add_client_CA(SSL_CTX *ctx, X509 *cacert);
int SSL_add_client_CA(SSL *ssl, X509 *cacert);
```

DESCRIPTION

SSL_CTX_set_client_CA_list() sets the **list** of CAs sent to the client when requesting a client certificate for **ctx**.

SSL_set_client_CA_list() sets the **list** of CAs sent to the client when requesting a client certificate for the chosen **ssl**, overriding the setting valid for **ssl**'s SSL_CTX object.

SSL_CTX_add_client_CA() adds the CA name extracted from **cacert** to the list of CAs sent to the client when requesting a client certificate for **ctx**.

SSL_add_client_CA() adds the CA name extracted from **cacert** to the list of CAs sent to the client when requesting a client certificate for the chosen **ssl**, overriding the setting valid for **ssl**'s SSL_CTX object.

NOTES

When a TLS/SSL server requests a client certificate (see **SSL_CTX_set_verify(3)**), it sends a list of CAs, for which it will accept certificates, to the client.

This list must explicitly be set using SSL_CTX_set_client_CA_list() for **ctx** and SSL_set_client_CA_list() for the specific **ssl**. The list specified overrides the previous setting. The CAs listed do not become trusted (**list** only contains the names, not the complete certificates); use SSL_CTX_load_verify_locations(3) to additionally load them for verification.

If the list of acceptable CAs is compiled in a file, the SSL_load_client_CA_file(3) function can be used to help importing the necessary data.

SSL_CTX_add_client_CA() and SSL_add_client_CA() can be used to add additional items the list of client CAs. If no list was specified before using SSL_CTX_set_client_CA_list() or SSL_set_client_CA_list(), a new client CA list for **ctx** or **ssl** (as appropriate) is opened.

These functions are only useful for TLS/SSL servers.

RETURN VALUES

SSL_CTX_set_client_CA_list() and SSL_set_client_CA_list() do not return diagnostic information.

SSL_CTX_add_client_CA() and SSL_add_client_CA() have the following return values:

0 A failure while manipulating the STACK_OF(X509_NAME) object occurred or the X509_NAME could not be extracted from **cacert**. Check the error stack to find out the reason.

1 The operation succeeded.

EXAMPLES

Scan all certificates in **CAfile** and list them as acceptable CAs:

```
SSL_CTX_set_client_CA_list(ctx,SSL_load_client_CA_file(CAfile));
```

SEE ALSO

ssl(3), SSL_get_client_CA_list(3), SSL_load_client_CA_file(3), SSL_CTX_load_verify_locations(3)

Name

SSL_CTX_set_client_cert_cb and SSL_CTX_get_client_cert_cb — handle client certificate callback function

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_client_cert_cb(SSL_CTX *ctx, int (*client_cert_cb)(SSL *ssl, X509 **x509,
    EVP_PKEY **pkey));
int (*SSL_CTX_get_client_cert_cb(SSL_CTX *ctx))(SSL *ssl, X509 **x509, EVP_PKEY **pkey);
int (*client_cert_cb)(SSL *ssl, X509 **x509, EVP_PKEY **pkey);
```

DESCRIPTION

SSL_CTX_set_client_cert_cb() sets the **client_cert_cb()** callback, that is called when a client certificate is requested by a server and no certificate was yet set for the SSL object.

When **client_cert_cb()** is NULL, no callback function is used.

SSL_CTX_get_client_cert_cb() returns a pointer to the currently set callback function.

client_cert_cb() is the application defined callback. If it wants to set a certificate, a certificate/private key combination must be set using the **x509** and **pkey** arguments and "1" must be returned. The certificate will be installed into **ssl**, see the NOTES and BUGS sections. If no certificate should be set, "0" has to be returned and no certificate will be sent. A negative return value will suspend the handshake and the handshake function will return immediately. SSL_get_error(3) will return SSL_ERROR_WANT_X509_LOOKUP to indicate, that the handshake was suspended. The next call to the handshake function will again lead to the call of client_cert_cb(). It is the job of the client_cert_cb() to store information about the state of the last call, if required to continue.

NOTES

During a handshake (or renegotiation) a server may request a certificate from the client. A client certificate must only be sent, when the server did send the request.

When a certificate was set using the SSL_CTX_use_certificate(3) family of functions, it will be sent to the server. The TLS standard requires that only a certificate is sent, if it matches the list of acceptable CAs sent by the server. This constraint is violated by the default behavior of the OpenSSL library. Using the callback function it is possible to implement a proper selection routine or to allow a user interaction to choose the certificate to be sent.

If a callback function is defined and no certificate was yet defined for the SSL object, the callback function will be called. If the callback function returns a certificate, the OpenSSL library will try to load the private key and certificate data into the SSL object using the SSL_use_certificate() and SSL_use_private_key() functions. Thus it will permanently install the certificate and key for this SSL object. It will not be reset by calling SSL_clear(3). If the callback returns no certificate, the OpenSSL library will not send a certificate.

BUGS

The client_cert_cb() cannot return a complete certificate chain, it can only return one client certificate. If the chain only has a length of 2, the root CA certificate may be omitted according to the TLS standard and thus a standard conforming answer can be sent to the server. For a longer chain, the client must send the complete chain (with the option to leave out the root CA certificate). This can only be accomplished by either adding the intermediate CA certificates into the trusted certificate store for the SSL_CTX object (resulting in having to add CA certificates that otherwise maybe would not be trusted), or by adding the chain certificates using the SSL_CTX_add_extra_chain_cert(3) function, which is only available for the SSL_CTX object as a whole and that therefore probably can only apply for one client certificate, making the concept of the callback function (to allow the choice from several certificates) questionable.

Once the SSL object has been used in conjunction with the callback function, the certificate will be set for the SSL object and will not be cleared even when SSL_clear(3) is being called. It is therefore mandatory to destroy the SSL object using SSL_free(3) and create a new one to return to the previous state.

Name

SSL_CTX_set_default_passwd_cb and SSL_CTX_set_default_passwd_cb_userdata — set passwd callback for encrypted PEM file handling

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_default_passwd_cb(SSL_CTX *ctx, pem_password_cb *cb);
void SSL_CTX_set_default_passwd_cb_userdata(SSL_CTX *ctx, void *u);
```

```
int pem_passwd_cb(char *buf, int size, int rwflag, void *userdata);
```

DESCRIPTION

SSL_CTX_set_default_passwd_cb() sets the default password callback called when loading/storing a PEM certificate with encryption.

SSL_CTX_set_default_passwd_cb_userdata() sets a pointer to **userdata** which will be provided to the password callback on invocation.

The pem_passwd_cb(), which must be provided by the application, hands back the password to be used during decryption. On invocation a pointer to **userdata** is provided. The pem_passwd_cb must write the password into the provided buffer **buf** which is of size **size**. The actual length of the password must be returned to the calling function. **rwflag** indicates whether the callback is used for reading/decryption (rwflag=0) or writing/encryption (rwflag=1).

NOTES

When loading or storing private keys, a password might be supplied to protect the private key. The way this password can be supplied may depend on the application. If only one private key is handled, it can be practical to have pem_passwd_cb() handle the password dialog interactively. If several keys have to be handled, it can be practical to ask for the password once, then keep it in memory and use it several times. In the last case, the password could be stored into the **userdata** storage and the pem_passwd_cb() only returns the password already stored.

When asking for the password interactively, pem_passwd_cb() can use **rwflag** to check, whether an item shall be encrypted (rwflag=1). In this case the password dialog may ask for the same password twice for comparison in order to catch typos, that would make decryption impossible.

Other items in PEM formatting (certificates) can also be encrypted, it is however not usual, as certificate information is considered public.

RETURN VALUES

SSL_CTX_set_default_passwd_cb() and SSL_CTX_set_default_passwd_cb_userdata() do not provide diagnostic information.

EXAMPLES

The following example returns the password provided as **userdata** to the calling function. The password is considered to be a '\0' terminated string. If the password does not fit into the buffer, the password is truncated.

```
int pem_passwd_cb(char *buf, int size, int rwflag, void *password)
{
 strncpy(buf, (char *)(password), size);
 buf[size - 1] = '\0';
 return(strlen(buf));
}
```

Name

SSL_CTX_set_generate_session_id, SSL_set_generate_session_id and SSL_has_matching_session_id — manipulate generation of SSL session IDs (server only)

Synopsis

```
#include  <openssl/ssl.h>
```

```
typedef int (*GEN_SESSION_CB)(const SSL *ssl, unsigned char *id,
                              unsigned int *id_len);
```

```
int SSL_CTX_set_generate_session_id(SSL_CTX *ctx, GEN_SESSION_CB cb);
int SSL_set_generate_session_id(SSL *ssl, GEN_SESSION_CB, cb);
int SSL_has_matching_session_id(const SSL *ssl, const unsigned char *id,
                                unsigned int id_len);
```

DESCRIPTION

SSL_CTX_set_generate_session_id() sets the callback function for generating new session ids for SSL/TLS sessions for **ctx** to be **cb**.

SSL_set_generate_session_id() sets the callback function for generating new session ids for SSL/TLS sessions for **ssl** to be **cb**.

SSL_has_matching_session_id() checks, whether a session with id **id** (of length **id_len**) is already contained in the internal session cache of the parent context of **ssl**.

NOTES

When a new session is established between client and server, the server generates a session id. The session id is an arbitrary sequence of bytes. The length of the session id is 16 bytes for SSLv2 sessions and between 1 and 32 bytes for SSLv3/TLSv1. The session id is not security critical but must be unique for the server. Additionally, the session id is transmitted in the clear when reusing the session so it must not contain sensitive information.

Without a callback being set, an OpenSSL server will generate a unique session id from pseudo random numbers of the maximum possible length. Using the callback function, the session id can be changed to contain additional information like e.g. a host id in order to improve load balancing or external caching techniques.

The callback function receives a pointer to the memory location to put **id** into and a pointer to the maximum allowed length **id_len**. The buffer at location **id** is only guaranteed to have the size **id_len**. The callback is only allowed to generate a shorter id and reduce **id_len**; the callback **must never** increase **id_len** or write to the location **id** exceeding the given limit.

If a SSLv2 session id is generated and **id_len** is reduced, it will be restored after the callback has finished and the session id will be padded with 0x00. It is not recommended to change the **id_len** for SSLv2 sessions. The callback can use the SSL_get_version(3) function to check, whether the session is of type SSLv2.

The location **id** is filled with 0x00 before the callback is called, so the callback may only fill part of the possible length and leave **id_len** untouched while maintaining reproducibility.

Since the sessions must be distinguished, session ids must be unique. Without the callback a random number is used, so that the probability of generating the same session id is extremely small (2^128 possible ids for an SSLv2 session, 2^256 for SSLv3/TLSv1). In order to assure the uniqueness of the generated session id, the callback must call SSL_has_matching_session_id() and generate another id if a conflict occurs. If an id conflict is not resolved, the handshake will fail. If the application codes e.g. a unique host id, a unique process number, and a unique sequence number into the session id, uniqueness could easily be achieved without randomness added (it should however be taken care that no confidential information is leaked this way). If the application can not guarantee uniqueness, it is recommended to use the maximum **id_len** and fill in the bytes not used to code special information with random data to avoid collisions.

SSL_has_matching_session_id() will only query the internal session cache, not the external one. Since the session id is generated before the handshake is completed, it is not immediately added to the cache. If another thread is using the same internal session cache, a race condition can occur in that another thread generates the same session id. Collisions can also occur when using an external session cache, since the external cache is not tested with SSL_has_matching_session_id() and the same race condition applies.

When calling SSL_has_matching_session_id() for an SSLv2 session with reduced **id_len**, the match operation will be performed using the fixed length required and with a 0x00 padded id.

The callback must return 0 if it cannot generate a session id for whatever reason and return 1 on success.

EXAMPLES

The callback function listed will generate a session id with the server id given, and will fill the rest with pseudo random bytes:

```
const char session_id_prefix = "www-18";

#define MAX_SESSION_ID_ATTEMPTS 10
static int generate_session_id(const SSL *ssl, unsigned char *id,
                             unsigned int *id_len)
     {
     unsigned int count = 0;
     const char *version;

version = SSL_get_version(ssl);
if (!strcmp(version, "SSLv2"))
    /* we must not change id_len */;

do      {
        RAND_pseudo_bytes(id, *id_len);
        /* Prefix the session_id with the required prefix. NB: If our
         * prefix is too long, clip it - but there will be worse effects
         * anyway, eg. the server could only possibly create 1 session
         * ID (ie. the prefix!) so all future session negotiations will
         * fail due to conflicts. */
        memcpy(id, session_id_prefix,
                (strlen(session_id_prefix) < *id_len) ?
                strlen(session_id_prefix) : *id_len);
        }
while(SSL_has_matching_session_id(ssl, id, *id_len) &&
        (++count < MAX_SESSION_ID_ATTEMPTS));
if(count >= MAX_SESSION_ID_ATTEMPTS)
        return 0;
return 1;
}
```

RETURN VALUES

SSL_CTX_set_generate_session_id() and SSL_set_generate_session_id() always return 1.

SSL_has_matching_session_id() returns 1 if another session with the same id is already in the cache.

SEE ALSO

ssl(3), SSL_get_version(3)

HISTORY

SSL_CTX_set_generate_session_id(), SSL_set_generate_session_id() and SSL_has_matching_session_id() have been introduced in OpenSSL 0.9.7.

Name

SSL_CTX_set_info_callback, SSL_CTX_get_info_callback, SSL_set_info_callback and SSL_get_info_callback — handle information callback for SSL connections

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_info_callback(SSL_CTX *ctx, void (*callback)());
void (*SSL_CTX_get_info_callback(const SSL_CTX *ctx))();
```

```
void SSL_set_info_callback(SSL *ssl, void (*callback)());
void (*SSL_get_info_callback(const SSL *ssl))();
```

DESCRIPTION

SSL_CTX_set_info_callback() sets the **callback** function, that can be used to obtain state information for SSL objects created from **ctx** during connection setup and use. The setting for **ctx** is overridden from the setting for a specific SSL object, if specified. When **callback** is NULL, not callback function is used.

SSL_set_info_callback() sets the **callback** function, that can be used to obtain state information for **ssl** during connection setup and use. When **callback** is NULL, the callback setting currently valid for **ctx** is used.

SSL_CTX_get_info_callback() returns a pointer to the currently set information callback function for **ctx**.

SSL_get_info_callback() returns a pointer to the currently set information callback function for **ssl**.

NOTES

When setting up a connection and during use, it is possible to obtain state information from the SSL/TLS engine. When set, an information callback function is called whenever the state changes, an alert appears, or an error occurs.

The callback function is called as **callback(SSL *ssl, int where, int ret)**. The **where** argument specifies information about where (in which context) the callback function was called. If **ret** is 0, an error condition occurred. If an alert is handled, SSL_CB_ALERT is set and **ret** specifies the alert information.

where is a bitmask made up of the following bits:

SSL_CB_LOOP

> Callback has been called to indicate state change inside a loop.

SSL_CB_EXIT

> Callback has been called to indicate error exit of a handshake function. (May be soft error with retry option for non-blocking setups.)

SSL_CB_READ

> Callback has been called during read operation.

SSL_CB_WRITE

> Callback has been called during write operation.

SSL_CB_ALERT

> Callback has been called due to an alert being sent or received.

SSL_CB_READ_ALERT (SSL_CB_ALERT|SSL_CB_READ)

SSL_CB_WRITE_ALERT (SSL_CB_ALERT|SSL_CB_WRITE)

SSL_CB_ACCEPT_LOOP (SSL_ST_ACCEPT|SSL_CB_LOOP)

SSL_CB_ACCEPT_EXIT (SSL_ST_ACCEPT|SSL_CB_EXIT)

SSL_CB_CONNECT_LOOP (SSL_ST_CONNECT|SSL_CB_LOOP)

SSL_CB_CONNECT_EXIT (SSL_ST_CONNECT|SSL_CB_EXIT)

SSL_CB_HANDSHAKE_START

> Callback has been called because a new handshake is started.

SSL_CB_HANDSHAKE_DONE 0x20

> Callback has been called because a handshake is finished.

The current state information can be obtained using the SSL_state_string(3) family of functions.

The **ret** information can be evaluated using the SSL_alert_type_string(3) family of functions.

RETURN VALUES

SSL_set_info_callback() does not provide diagnostic information.

SSL_get_info_callback() returns the current setting.

EXAMPLES

The following example callback function prints state strings, information about alerts being handled and error messages to the **bio_err** BIO.

```
void apps_ssl_info_callback(SSL *s, int where, int ret)
       {
       const char *str;
       int w;

w=where& ~SSL_ST_MASK;

if (w & SSL_ST_CONNECT) str="SSL_connect";
else if (w & SSL_ST_ACCEPT) str="SSL_accept";
else str="undefined";

if (where & SSL_CB_LOOP)
        {
        BIO_printf(bio_err,"%s:%s\n",str,SSL_state_string_long(s));
        }
else if (where & SSL_CB_ALERT)
        {
        str=(where & SSL_CB_READ)?"read":"write";
        BIO_printf(bio_err,"SSL3 alert %s:%s:%s\n",
                str,
                SSL_alert_type_string_long(ret),
                SSL_alert_desc_string_long(ret));
        }
else if (where & SSL_CB_EXIT)
        {
        if (ret == 0)
                BIO_printf(bio_err,"%s:failed in %s\n",
                        str,SSL_state_string_long(s));
        else if (ret < 0)
                {
                BIO_printf(bio_err,"%s:error in %s\n",
                        str,SSL_state_string_long(s));
                }
        }
}
```

SEE ALSO

Name

SSL_CTX_set_max_cert_list, SSL_CTX_get_max_cert_list, SSL_set_max_cert_list and SSL_get_max_cert_list — manipulate allowed for the peer's certificate chain

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_set_max_cert_list(SSL_CTX *ctx, long size);
long SSL_CTX_get_max_cert_list(SSL_CTX *ctx);
```

```
long SSL_set_max_cert_list(SSL *ssl, long size);
long SSL_get_max_cert_list(SSL *ctx);
```

DESCRIPTION

SSL_CTX_set_max_cert_list() sets the maximum size allowed for the peer's certificate chain for all SSL objects created from **ctx** to be <size> bytes. The SSL objects inherit the setting valid for **ctx** at the time SSL_new(3) is being called.

SSL_CTX_get_max_cert_list() returns the currently set maximum size for **ctx**.

SSL_set_max_cert_list() sets the maximum size allowed for the peer's certificate chain for **ssl** to be <size> bytes. This setting stays valid until a new value is set.

SSL_get_max_cert_list() returns the currently set maximum size for **ssl**.

NOTES

During the handshake process, the peer may send a certificate chain. The TLS/SSL standard does not give any maximum size of the certificate chain. The OpenSSL library handles incoming data by a dynamically allocated buffer. In order to prevent this buffer from growing without bounds due to data received from a faulty or malicious peer, a maximum size for the certificate chain is set.

The default value for the maximum certificate chain size is 100kB (30kB on the 16bit DOS platform). This should be sufficient for usual certificate chains (OpenSSL's default maximum chain length is 10, see SSL_CTX_set_verify(3), and certificates without special extensions have a typical size of 1-2kB).

For special applications it can be necessary to extend the maximum certificate chain size allowed to be sent by the peer, see e.g. the work on "Internet X.509 Public Key Infrastructure Proxy Certificate Profile" and "TLS Delegation Protocol" at http://www.ietf.org/ and http://www.globus.org/ .

Under normal conditions it should never be necessary to set a value smaller than the default, as the buffer is handled dynamically and only uses the memory actually required by the data sent by the peer.

If the maximum certificate chain size allowed is exceeded, the handshake will fail with a SSL_R_EXCESSIVE_MESSAGE_SIZE error.

RETURN VALUES

SSL_CTX_set_max_cert_list() and SSL_set_max_cert_list() return the previously set value.

SSL_CTX_get_max_cert_list() and SSL_get_max_cert_list() return the currently set value.

SEE ALSO

ssl(3), SSL_new(3), SSL_CTX_set_verify(3)

HISTORY

SSL*_set/get_max_cert_list() have been introduced in OpenSSL 0.9.7.

Name

SSL_CTX_set_mode, SSL_set_mode, SSL_CTX_get_mode and SSL_get_mode — manipulate SSL engine mode

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_set_mode(SSL_CTX *ctx, long mode);
long SSL_set_mode(SSL *ssl, long mode);
```

```
long SSL_CTX_get_mode(SSL_CTX *ctx);
long SSL_get_mode(SSL *ssl);
```

DESCRIPTION

SSL_CTX_set_mode() adds the mode set via bitmask in **mode** to **ctx**. Options already set before are not cleared.

SSL_set_mode() adds the mode set via bitmask in **mode** to **ssl**. Options already set before are not cleared.

SSL_CTX_get_mode() returns the mode set for **ctx**.

SSL_get_mode() returns the mode set for **ssl**.

NOTES

The following mode changes are available:

SSL_MODE_ENABLE_PARTIAL_WRITE

> Allow SSL_write(…, n) to return r with 0 < r < n (i.e. report success when just a single record has been written). When not set (the default), SSL_write() will only report success once the complete chunk was written. Once SSL_write() returns with r, r bytes have been successfully written and the next call to SSL_write() must only send the n-r bytes left, imitating the behaviour of write().

SSL_MODE_ACCEPT_MOVING_WRITE_BUFFER

> Make it possible to retry SSL_write() with changed buffer location (the buffer contents must stay the same). This is not the default to avoid the misconception that non-blocking SSL_write() behaves like non-blocking write().

SSL_MODE_AUTO_RETRY

> Never bother the application with retries if the transport is blocking. If a renegotiation take place during normal operation, a SSL_read(3) or SSL_write(3) would return with -1 and indicate the need to retry with SSL_ERROR_WANT_READ. In a non-blocking environment applications must be prepared to handle incomplete read/write operations. In a blocking environment, applications are not always prepared to deal with read/write operations returning without success report. The flag SSL_MODE_AUTO_RETRY will cause read/write operations to only return after the handshake and successful completion.

SSL_MODE_RELEASE_BUFFERS

> When we no longer need a read buffer or a write buffer for a given SSL, then release the memory we were using to hold it. Released memory is either appended to a list of unused RAM chunks on the SSL_CTX, or simply freed if the list of unused chunks would become longer than SSL_CTX->freelist_max_len, which defaults to 32. Using this flag can save around 34k per idle SSL connection. This flag has no effect on SSL v2 connections, or on DTLS connections.

SSL_MODE_SEND_FALLBACK_SCSV

> Send TLS_FALLBACK_SCSV in the ClientHello. To be set only by applications that reconnect with a downgraded protocol version; see draft-ietf-tls-downgrade-scsv-00 for details.

DO NOT ENABLE THIS if your application attempts a normal handshake. Only use this in explicit fallback retries, following the guidance in draft-ietf-tls-downgrade-scsv-00.

RETURN VALUES

SSL_CTX_set_mode() and SSL_set_mode() return the new mode bitmask after adding **mode**.

SSL_CTX_get_mode() and SSL_get_mode() return the current bitmask.

SEE ALSO

ssl(3), SSL_read(3), SSL_write(3)

HISTORY

SSL_MODE_AUTO_RETRY as been added in OpenSSL 0.9.6.

Name

SSL_CTX_set_msg_callback, SSL_CTX_set_msg_callback_arg, SSL_set_msg_callback and SSL_get_msg_callback_arg — install callback for observing protocol messages

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_msg_callback(SSL_CTX *ctx, void (*cb)(int write_p, int version, int content_type,
    const void *buf, size_t len, SSL *ssl, void *arg));
void SSL_CTX_set_msg_callback_arg(SSL_CTX *ctx, void *arg);
```

```
void SSL_set_msg_callback(SSL *ssl, void (*cb)(int write_p, int version, int content_type,
    const void *buf, size_t len, SSL *ssl, void *arg));
void SSL_set_msg_callback_arg(SSL *ssl, void *arg);
```

DESCRIPTION

SSL_CTX_set_msg_callback() or SSL_set_msg_callback() can be used to define a message callback function *cb* for observing all SSL/TLS protocol messages (such as handshake messages) that are received or sent. SSL_CTX_set_msg_callback_arg() and SSL_set_msg_callback_arg() can be used to set argument *arg* to the callback function, which is available for arbitrary application use.

SSL_CTX_set_msg_callback() and SSL_CTX_set_msg_callback_arg() specify default settings that will be copied to new **SSL** objects by SSL_new(3). SSL_set_msg_callback() and SSL_set_msg_callback_arg() modify the actual settings of an **SSL** object. Using a **0** pointer for *cb* disables the message callback.

When *cb* is called by the SSL/TLS library for a protocol message, the function arguments have the following meaning:

write_p
: This flag is **0** when a protocol message has been received and **1** when a protocol message has been sent.

version
: The protocol version according to which the protocol message is interpreted by the library. Currently, this is one of **SSL2_VERSION**, **SSL3_VERSION** and **TLS1_VERSION** (for SSL 2.0, SSL 3.0 and TLS 1.0, respectively).

content_type
: In the case of SSL 2.0, this is always **0**. In the case of SSL 3.0 or TLS 1.0, this is one of the **ContentType** values defined in the protocol specification (**change_cipher_spec(20)**, **alert(21)**, **handshake(22)**; but never **application_data(23)** because the callback will only be called for protocol messages).

buf, len
: *buf* points to a buffer containing the protocol message, which consists of *len* bytes. The buffer is no longer valid after the callback function has returned.

ssl
: The **SSL** object that received or sent the message.

arg
: The user-defined argument optionally defined by SSL_CTX_set_msg_callback_arg() or SSL_set_msg_callback_arg().

NOTES

Protocol messages are passed to the callback function after decryption and fragment collection where applicable. (Thus record boundaries are not visible.)

If processing a received protocol message results in an error, the callback function may not be called. For example, the callback function will never see messages that are considered too large to be processed.

Due to automatic protocol version negotiation, *version* is not necessarily the protocol version used by the sender of the message: If a TLS 1.0 ClientHello message is received by an SSL 3.0-only server, *version* will be **SSL3_VERSION**.

SEE ALSO

ssl(3), SSL_new(3)

HISTORY

SSL_CTX_set_msg_callback(), SSL_CTX_set_msg_callback_arg(), SSL_set_msg_callback() and SSL_get_msg_callback_arg() were added in OpenSSL 0.9.7.

Name

SSL_CTX_set_options, SSL_set_options, SSL_CTX_clear_options, SSL_clear_options, SSL_CTX_get_options, SSL_get_options and SSL_get_secure_renegotiation_support — manipulate SSL options

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_set_options(SSL_CTX *ctx, long options);
long SSL_set_options(SSL *ssl, long options);
```

```
long SSL_CTX_clear_options(SSL_CTX *ctx, long options);
long SSL_clear_options(SSL *ssl, long options);
```

```
long SSL_CTX_get_options(SSL_CTX *ctx);
long SSL_get_options(SSL *ssl);
```

```
long SSL_get_secure_renegotiation_support(SSL *ssl);
```

DESCRIPTION

Note: all these functions are implemented using macros.

SSL_CTX_set_options() adds the options set via bitmask in **options** to **ctx**. Options already set before are not cleared!

SSL_set_options() adds the options set via bitmask in **options** to **ssl**. Options already set before are not cleared!

SSL_CTX_clear_options() clears the options set via bitmask in **options** to **ctx**.

SSL_clear_options() clears the options set via bitmask in **options** to **ssl**.

SSL_CTX_get_options() returns the options set for **ctx**.

SSL_get_options() returns the options set for **ssl**.

SSL_get_secure_renegotiation_support() indicates whether the peer supports secure renegotiation.

NOTES

The behaviour of the SSL library can be changed by setting several options. The options are coded as bitmasks and can be combined by a logical **or** operation (|).

SSL_CTX_set_options() and SSL_set_options() affect the (external) protocol behaviour of the SSL library. The (internal) behaviour of the API can be changed by using the similar SSL_CTX_set_mode(3) and SSL_set_mode() functions.

During a handshake, the option settings of the SSL object are used. When a new SSL object is created from a context using SSL_new(), the current option setting is copied. Changes to **ctx** do not affect already created SSL objects. SSL_clear() does not affect the settings.

The following **bug workaround** options are available:

SSL_OP_MICROSOFT_SESS_ID_BUG

> www.microsoft.com - when talking SSLv2, if session-id reuse is performed, the session-id passed back in the server-finished message is different from the one decided upon.

SSL_OP_NETSCAPE_CHALLENGE_BUG

> Netscape-Commerce/1.12, when talking SSLv2, accepts a 32 byte challenge but then appears to only use 16 bytes when generating the encryption keys. Using 16 bytes is ok but it should be ok to use 32. According to the SSLv3 spec, one should

use 32 bytes for the challenge when operating in SSLv2/v3 compatibility mode, but as mentioned above, this breaks this server so 16 bytes is the way to go.

SSL_OP_NETSCAPE_REUSE_CIPHER_CHANGE_BUG

As of OpenSSL 0.9.8q and 1.0.0c, this option has no effect.

SSL_OP_SSLREF2_REUSE_CERT_TYPE_BUG

…

SSL_OP_MICROSOFT_BIG_SSLV3_BUFFER

…

SSL_OP_SAFARI_ECDHE_ECDSA_BUG

Don't prefer ECDHE-ECDSA ciphers when the client appears to be Safari on OS X. OS X 10.8..10.8.3 has broken support for ECDHE-ECDSA ciphers.

SSL_OP_SSLEAY_080_CLIENT_DH_BUG

…

SSL_OP_TLS_D5_BUG

…

SSL_OP_TLS_BLOCK_PADDING_BUG

…

SSL_OP_DONT_INSERT_EMPTY_FRAGMENTS

Disables a countermeasure against a SSL 3.0/TLS 1.0 protocol vulnerability affecting CBC ciphers, which cannot be handled by some broken SSL implementations. This option has no effect for connections using other ciphers.

SSL_OP_TLSEXT_PADDING

Adds a padding extension to ensure the ClientHello size is never between 256 and 511 bytes in length. This is needed as a workaround for some implementations.

SSL_OP_ALL

All of the above bug workarounds.

It is usually safe to use **SSL_OP_ALL** to enable the bug workaround options if compatibility with somewhat broken implementations is desired.

The following **modifying** options are available:

SSL_OP_TLS_ROLLBACK_BUG

Disable version rollback attack detection.

During the client key exchange, the client must send the same information about acceptable SSL/TLS protocol levels as during the first hello. Some clients violate this rule by adapting to the server's answer. (Example: the client sends a SSLv2 hello and accepts up to SSLv3.1=TLSv1, the server only understands up to SSLv3. In this case the client must still use the same

SSLv3.1=TLSv1 announcement. Some clients step down to SSLv3 with respect to the server's answer and violate the version rollback protection.)

SSL_OP_SINGLE_DH_USE

Always create a new key when using temporary/ephemeral DH parameters (see SSL_CTX_set_tmp_dh_callback(3)). This option must be used to prevent small subgroup attacks, when the DH parameters were not generated using "strong" primes (e.g. when using DSA-parameters, see dhparam(1)). If "strong" primes were used, it is not strictly necessary to generate a new DH key during each handshake but it is also recommended. **SSL_OP_SINGLE_DH_USE** should therefore be enabled whenever temporary/ephemeral DH parameters are used.

SSL_OP_EPHEMERAL_RSA

This option is no longer implemented and is treated as no op.

SSL_OP_CIPHER_SERVER_PREFERENCE

When choosing a cipher, use the server's preferences instead of the client preferences. When not set, the SSL server will always follow the clients preferences. When set, the SSLv3/TLSv1 server will choose following its own preferences. Because of the different protocol, for SSLv2 the server will send its list of preferences to the client and the client chooses.

SSL_OP_PKCS1_CHECK_1

…

SSL_OP_PKCS1_CHECK_2

…

SSL_OP_NETSCAPE_CA_DN_BUG

If we accept a netscape connection, demand a client cert, have a non-self-signed CA which does not have its CA in netscape, and the browser has a cert, it will crash/hang. Works for 3.x and 4.xbeta

SSL_OP_NETSCAPE_DEMO_CIPHER_CHANGE_BUG

…

SSL_OP_NO_SSLv2

Do not use the SSLv2 protocol. As of OpenSSL 1.0.1s the **SSL_OP_NO_SSLv2** option is set by default.

SSL_OP_NO_SSLv3

Do not use the SSLv3 protocol. It is recommended that applications should set this option.

SSL_OP_NO_TLSv1

Do not use the TLSv1 protocol.

SSL_OP_NO_TLSv1_1

Do not use the TLSv1.1 protocol.

SSL_OP_NO_TLSv1_2

Do not use the TLSv1.2 protocol.

SSL_OP_NO_SESSION_RESUMPTION_ON_RENEGOTIATION

When performing renegotiation as a server, always start a new session (i.e., session resumption requests are only accepted in the initial handshake). This option is not needed for clients.

SSL_OP_NO_TICKET

Normally clients and servers will, where possible, transparently make use of RFC4507bis tickets for stateless session resumption.

If this option is set this functionality is disabled and tickets will not be used by clients or servers.

SSL_OP_ALLOW_UNSAFE_LEGACY_RENEGOTIATION

Allow legacy insecure renegotiation between OpenSSL and unpatched clients or servers. See the **SECURE RENEGOTIATION** section for more details.

SSL_OP_LEGACY_SERVER_CONNECT

Allow legacy insecure renegotiation between OpenSSL and unpatched servers **only**: this option is currently set by default. See the **SECURE RENEGOTIATION** section for more details.

SECURE RENEGOTIATION

OpenSSL 0.9.8m and later always attempts to use secure renegotiation as described in RFC5746. This counters the prefix attack described in CVE-2009-3555 and elsewhere.

The deprecated and highly broken SSLv2 protocol does not support renegotiation at all: its use is **strongly** discouraged.

This attack has far reaching consequences which application writers should be aware of. In the description below an implementation supporting secure renegotiation is referred to as *patched*. A server not supporting secure renegotiation is referred to as *unpatched*.

The following sections describe the operations permitted by OpenSSL's secure renegotiation implementation.

Patched client and server

Connections and renegotiation are always permitted by OpenSSL implementations.

Unpatched client and patched OpenSSL server

The initial connection succeeds but client renegotiation is denied by the server with a **no_renegotiation** warning alert if TLS v1.0 is used or a fatal **handshake_failure** alert in SSL v3.0.

If the patched OpenSSL server attempts to renegotiate a fatal **handshake_failure** alert is sent. This is because the server code may be unaware of the unpatched nature of the client.

If the option **SSL_OP_ALLOW_UNSAFE_LEGACY_RENEGOTIATION** is set then renegotiation **always** succeeds.

NB: a bug in OpenSSL clients earlier than 0.9.8m (all of which are unpatched) will result in the connection hanging if it receives a **no_renegotiation** alert. OpenSSL versions 0.9.8m and later will regard a **no_renegotiation** alert as fatal and respond with a fatal **handshake_failure** alert. This is because the OpenSSL API currently has no provision to indicate to an application that a renegotiation attempt was refused.

Patched OpenSSL client and unpatched server.

SSL_OP_LEGACY_SERVER_CONNECT
SSL_OP_ALLOW_UNSAFE_LEGACY_RENEGOTIATION

If either the two above options are set then initial connections and renegotiation between patched OpenSSL clients and unpatched servers succeeds. If neither option is set then initial connections to unpatched servers will fail.

The option **SSL_OP_LEGACY_SERVER_CONNECT** is currently set by default even though it has security implications: otherwise it would be impossible to connect to unpatched servers (i.e. all of them initially) and this is clearly not acceptable. Renegotiation is permitted because this does not add any additional security issues: during an attack clients do not see any renegotiations anyway.

As more servers become patched the option **SSL_OP_LEGACY_SERVER_CONNECT** will **not** be set by default in a future version of OpenSSL.

OpenSSL client applications wishing to ensure they can connect to unpatched servers should always **set** **SSL_OP_LEGACY_SERVER_CONNECT**

OpenSSL client applications that want to ensure they can **not** connect to unpatched servers (and thus avoid any security issues) should always **clear** **SSL_OP_LEGACY_SERVER_CONNECT** using SSL_CTX_clear_options() or SSL_clear_options().

The difference between the two options is that **SSL_OP_LEGACY_SERVER_CONNECT** enables initial connections and secure renegotiation between OpenSSL clients and unpatched servers **only**, while **SSL_OP_ALLOW_UNSAFE_LEGACY_RENEGOTIATION** allows initial connections and renegotiation between OpenSSL and unpatched clients or servers.

RETURN VALUES

SSL_CTX_set_options() and SSL_set_options() return the new options bitmask after adding **options**.

SSL_CTX_clear_options() and SSL_clear_options() return the new options bitmask after clearing **options**.

SSL_CTX_get_options() and SSL_get_options() return the current bitmask.

SSL_get_secure_renegotiation_support() returns 1 is the peer supports secure renegotiation and 0 if it does not.

HISTORY

SSL_OP_CIPHER_SERVER_PREFERENCE
SSL_OP_NO_SESSION_RESUMPTION_ON_RENEGOTIATION

These two options have been added in OpenSSL 0.9.7.

SSL_OP_TLS_ROLLBACK_BUG has been added in OpenSSL 0.9.6 and was automatically enabled with **SSL_OP_ALL**. As of 0.9.7, it is no longer included in **SSL_OP_ALL** and must be explicitly set.

SSL_OP_DONT_INSERT_EMPTY_FRAGMENTS has been added in OpenSSL 0.9.6e. Versions up to OpenSSL 0.9.6c do not include the countermeasure that can be disabled with this option (in OpenSSL 0.9.6d, it was always enabled).

SSL_CTX_clear_options() and SSL_clear_options() were first added in OpenSSL 0.9.8m.

SSL_OP_ALLOW_UNSAFE_LEGACY_RENEGOTIATION, **SSL_OP_LEGACY_SERVER_CONNECT** and the function SSL_get_secure_renegotiation_support() were first added in OpenSSL 0.9.8m.

Name

SSL_CTX_set_psk_client_callback and SSL_set_psk_client_callback — set PSK client callback

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_psk_client_callback(SSL_CTX *ctx,
       unsigned int (*callback)(SSL *ssl, const char *hint,
       char *identity, unsigned int max_identity_len,
       unsigned char *psk, unsigned int max_psk_len));
void SSL_set_psk_client_callback(SSL *ssl,
       unsigned int (*callback)(SSL *ssl, const char *hint,
       char *identity, unsigned int max_identity_len,
       unsigned char *psk, unsigned int max_psk_len));
```

DESCRIPTION

A client application must provide a callback function which is called when the client is sending the ClientKeyExchange message to the server.

The purpose of the callback function is to select the PSK identity and the pre-shared key to use during the connection setup phase.

The callback is set using functions SSL_CTX_set_psk_client_callback() or SSL_set_psk_client_callback(). The callback function is given the connection in parameter **ssl**, a **NULL**-terminated PSK identity hint sent by the server in parameter **hint**, a buffer **identity** of length **max_identity_len** bytes where the the resulting **NULL**-terminated identity is to be stored, and a buffer **psk** of length **max_psk_len** bytes where the resulting pre-shared key is to be stored.

NOTES

Note that parameter **hint** given to the callback may be **NULL**.

RETURN VALUES

Return values from the client callback are interpreted as follows:

On success (callback found a PSK identity and a pre-shared key to use) the length (> 0) of **psk** in bytes is returned.

Otherwise or on errors callback should return 0. In this case the connection setup fails.

Name

SSL_CTX_set_quiet_shutdown, SSL_CTX_get_quiet_shutdown, SSL_set_quiet_shutdown and SSL_get_quiet_shutdown — manipulate shutdown behaviour

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_quiet_shutdown(SSL_CTX *ctx, int mode);
int SSL_CTX_get_quiet_shutdown(const SSL_CTX *ctx);
```

```
void SSL_set_quiet_shutdown(SSL *ssl, int mode);
int SSL_get_quiet_shutdown(const SSL *ssl);
```

DESCRIPTION

SSL_CTX_set_quiet_shutdown() sets the "quiet shutdown" flag for **ctx** to be **mode**. SSL objects created from **ctx** inherit the **mode** valid at the time SSL_new(3) is called. **mode** may be 0 or 1.

SSL_CTX_get_quiet_shutdown() returns the "quiet shutdown" setting of **ctx**.

SSL_set_quiet_shutdown() sets the "quiet shutdown" flag for **ssl** to be **mode**. The setting stays valid until **ssl** is removed with SSL_free(3) or SSL_set_quiet_shutdown() is called again. It is not changed when SSL_clear(3) is called. **mode** may be 0 or 1.

SSL_get_quiet_shutdown() returns the "quiet shutdown" setting of **ssl**.

NOTES

Normally when a SSL connection is finished, the parties must send out "close notify" alert messages using SSL_shutdown(3) for a clean shutdown.

When setting the "quiet shutdown" flag to 1, SSL_shutdown(3) will set the internal flags to SSL_SENT_SHUTDOWN | SSL_RECEIVED_SHUTDOWN. (SSL_shutdown(3) then behaves like SSL_set_shutdown(3) called with SSL_SENT_SHUTDOWN | SSL_RECEIVED_SHUTDOWN.) The session is thus considered to be shutdown, but no "close notify" alert is sent to the peer. This behaviour violates the TLS standard.

The default is normal shutdown behaviour as described by the TLS standard.

RETURN VALUES

SSL_CTX_set_quiet_shutdown() and SSL_set_quiet_shutdown() do not return diagnostic information.

SSL_CTX_get_quiet_shutdown() and SSL_get_quiet_shutdown return the current setting.

Name

SSL_CTX_set_read_ahead, SSL_CTX_set_default_read_ahead, SSL_CTX_get_read_ahead, SSL_CTX_get_default_read_ahead, SSL_set_read_ahead and SSL_get_read_ahead — manage whether to read as many input bytes as possible

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_get_read_ahead(const SSL *s);
void SSL_set_read_ahead(SSL *s, int yes);
```

```
#define SSL_CTX_get_default_read_ahead(ctx)
#define SSL_CTX_set_default_read_ahead(ctx,m)
#define SSL_CTX_get_read_ahead(ctx)
#define SSL_CTX_set_read_ahead(ctx,m)
```

DESCRIPTION

SSL_CTX_set_read_ahead() and SSL_set_read_ahead() set whether we should read as many input bytes as possible (for non-blocking reads) or not. For example if **x** bytes are currently required by OpenSSL, but **y** bytes are available from the underlying BIO (where **y** > **x**), then OpenSSL will read all **y** bytes into its buffer (providing that the buffer is large enough) if reading ahead is on, or **x** bytes otherwise. The parameter **yes** or **m** should be 0 to ensure reading ahead is off, or non zero otherwise.

SSL_CTX_set_default_read_ahead is a synonym for SSL_CTX_set_read_ahead, and SSL_CTX_get_default_read_ahead is a synonym for SSL_CTX_get_read_ahead.

SSL_CTX_get_read_ahead() and SSL_get_read_ahead() indicate whether reading ahead has been set or not.

NOTES

These functions have no impact when used with DTLS. The return values for SSL_CTX_get_read_head() and SSL_get_read_ahead() are undefined for DTLS.

RETURN VALUES

SSL_get_read_ahead and SSL_CTX_get_read_ahead return 0 if reading ahead is off, and non zero otherwise.

ssl(3)

Name

SSL_CTX_set_session_cache_mode and SSL_CTX_get_session_cache_mode — enable/disable session caching

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_set_session_cache_mode(SSL_CTX ctx, long mode);
long SSL_CTX_get_session_cache_mode(SSL_CTX ctx);
```

DESCRIPTION

SSL_CTX_set_session_cache_mode() enables/disables session caching by setting the operational mode for **ctx** to <mode>.

SSL_CTX_get_session_cache_mode() returns the currently used cache mode.

NOTES

The OpenSSL library can store/retrieve SSL/TLS sessions for later reuse. The sessions can be held in memory for each **ctx**, if more than one SSL_CTX object is being maintained, the sessions are unique for each SSL_CTX object.

In order to reuse a session, a client must send the session's id to the server. It can only send exactly one id. The server then either agrees to reuse the session or it starts a full handshake (to create a new session).

A server will lookup up the session in its internal session storage. If the session is not found in internal storage or lookups for the internal storage have been deactivated (SSL_SESS_CACHE_NO_INTERNAL_LOOKUP), the server will try the external storage if available.

Since a client may try to reuse a session intended for use in a different context, the session id context must be set by the server (see SSL_CTX_set_session_id_context(3)).

The following session cache modes and modifiers are available:

SSL_SESS_CACHE_OFF

No session caching for client or server takes place.

SSL_SESS_CACHE_CLIENT

Client sessions are added to the session cache. As there is no reliable way for the OpenSSL library to know whether a session should be reused or which session to choose (due to the abstract BIO layer the SSL engine does not have details about the connection), the application must select the session to be reused by using the SSL_set_session(3) function. This option is not activated by default.

SSL_SESS_CACHE_SERVER

Server sessions are added to the session cache. When a client proposes a session to be reused, the server looks for the corresponding session in (first) the internal session cache (unless SSL_SESS_CACHE_NO_INTERNAL_LOOKUP is set), then (second) in the external cache if available. If the session is found, the server will try to reuse the session. This is the default.

SSL_SESS_CACHE_BOTH

Enable both SSL_SESS_CACHE_CLIENT and SSL_SESS_CACHE_SERVER at the same time.

SSL_SESS_CACHE_NO_AUTO_CLEAR

Normally the session cache is checked for expired sessions every 255 connections using the SSL_CTX_flush_sessions(3) function. Since this may lead to a delay which cannot be controlled, the automatic flushing may be disabled and SSL_CTX_flush_sessions(3) can be called explicitly by the application.

SSL_SESS_CACHE_NO_INTERNAL_LOOKUP

By setting this flag, session-resume operations in an SSL/TLS server will not automatically look up sessions in the internal cache, even if sessions are automatically stored there. If external session caching callbacks are in use, this flag guarantees that all lookups are directed to the external cache. As automatic lookup only applies for SSL/TLS servers, the flag has no effect on clients.

SSL_SESS_CACHE_NO_INTERNAL_STORE

Depending on the presence of SSL_SESS_CACHE_CLIENT and/or SSL_SESS_CACHE_SERVER, sessions negotiated in an SSL/TLS handshake may be cached for possible reuse. Normally a new session is added to the internal cache as well as any external session caching (callback) that is configured for the SSL_CTX. This flag will prevent sessions being stored in the internal cache (though the application can add them manually using SSL_CTX_add_session(3)). Note: in any SSL/TLS servers where external caching is configured, any successful session lookups in the external cache (ie. for session-resume requests) would normally be copied into the local cache before processing continues - this flag prevents these additions to the internal cache as well.

SSL_SESS_CACHE_NO_INTERNAL

Enable both SSL_SESS_CACHE_NO_INTERNAL_LOOKUP and SSL_SESS_CACHE_NO_INTERNAL_STORE at the same time.

The default mode is SSL_SESS_CACHE_SERVER.

RETURN VALUES

SSL_CTX_set_session_cache_mode() returns the previously set cache mode.

SSL_CTX_get_session_cache_mode() returns the currently set cache mode.

ssl(3), SSL_set_session(3), SSL_session_reused(3), SSL_CTX_add_session(3), SSL_CTX_sess_number(3), SSL_CTX_sess_set_cache_size(3), SSL_CTX_sess_set_get_cb(3), SSL_CTX_set_session_id_context(3), SSL_CTX_set_timeout(3), SSL_CTX_flush_sessions(3)

HISTORY

SSL_SESS_CACHE_NO_INTERNAL_STORE and SSL_SESS_CACHE_NO_INTERNAL were introduced in OpenSSL 0.9.6h.

Name

SSL_CTX_set_session_id_context and SSL_set_session_id_context — set context within which session can be reused (server side only)

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_CTX_set_session_id_context(SSL_CTX *ctx, const unsigned char *sid_ctx,
                                   unsigned int sid_ctx_len);
int SSL_set_session_id_context(SSL *ssl, const unsigned char *sid_ctx,
                               unsigned int sid_ctx_len);
```

DESCRIPTION

SSL_CTX_set_session_id_context() sets the context **sid_ctx** of length **sid_ctx_len** within which a session can be reused for the **ctx** object.

SSL_set_session_id_context() sets the context **sid_ctx** of length **sid_ctx_len** within which a session can be reused for the **ssl** object.

NOTES

Sessions are generated within a certain context. When exporting/importing sessions with **i2d_SSL_SESSION/d2i_SSL_SESSION** it would be possible, to re-import a session generated from another context (e.g. another application), which might lead to malfunctions. Therefore each application must set its own session id context **sid_ctx** which is used to distinguish the contexts and is stored in exported sessions. The **sid_ctx** can be any kind of binary data with a given length, it is therefore possible to use e.g. the name of the application and/or the hostname and/or service name …

The session id context becomes part of the session. The session id context is set by the SSL/TLS server. The SSL_CTX_set_session_id_context() and SSL_set_session_id_context() functions are therefore only useful on the server side.

OpenSSL clients will check the session id context returned by the server when reusing a session.

The maximum length of the **sid_ctx** is limited to **SSL_MAX_SSL_SESSION_ID_LENGTH**.

WARNINGS

If the session id context is not set on an SSL/TLS server and client certificates are used, stored sessions will not be reused but a fatal error will be flagged and the handshake will fail.

If a server returns a different session id context to an OpenSSL client when reusing a session, an error will be flagged and the handshake will fail. OpenSSL servers will always return the correct session id context, as an OpenSSL server checks the session id context itself before reusing a session as described above.

RETURN VALUES

SSL_CTX_set_session_id_context() and SSL_set_session_id_context() return the following values:

0 The length **sid_ctx_len** of the session id context **sid_ctx** exceeded the maximum allowed length of **SSL_MAX_SSL_SESSION_ID_LENGTH**. The error is logged to the error stack.

1 The operation succeeded.

SEE ALSO

ssl(3)

Name

SSL_CTX_set_ssl_version, SSL_set_ssl_method and SSL_get_ssl_method — choose a new TLS/SSL method

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_CTX_set_ssl_version(SSL_CTX *ctx, const SSL_METHOD *method);
int SSL_set_ssl_method(SSL *s, const SSL_METHOD *method);
const SSL_METHOD *SSL_get_ssl_method(SSL *ssl);
```

DESCRIPTION

SSL_CTX_set_ssl_version() sets a new default TLS/SSL **method** for SSL objects newly created from this **ctx**. SSL objects already created with SSL_new(3) are not affected, except when SSL_clear(3) is being called.

SSL_set_ssl_method() sets a new TLS/SSL **method** for a particular **ssl** object. It may be reset, when SSL_clear() is called.

SSL_get_ssl_method() returns a function pointer to the TLS/SSL method set in **ssl**.

NOTES

The available **method** choices are described in SSL_CTX_new(3).

When SSL_clear(3) is called and no session is connected to an SSL object, the method of the SSL object is reset to the method currently set in the corresponding SSL_CTX object.

RETURN VALUES

The following return values can occur for SSL_CTX_set_ssl_version() and SSL_set_ssl_method():

0 The new choice failed, check the error stack to find out the reason.

1 The operation succeeded.

SEE ALSO

SSL_CTX_new(3), SSL_new(3), SSL_clear(3), ssl(3), SSL_set_connect_state(3)

Name

SSL_CTX_set_timeout and SSL_CTX_get_timeout — manipulate timeout values for session caching

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_CTX_set_timeout(SSL_CTX *ctx, long t);
long SSL_CTX_get_timeout(SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_set_timeout() sets the timeout for newly created sessions for **ctx** to **t**. The timeout value **t** must be given in seconds.

SSL_CTX_get_timeout() returns the currently set timeout value for **ctx**.

NOTES

Whenever a new session is created, it is assigned a maximum lifetime. This lifetime is specified by storing the creation time of the session and the timeout value valid at this time. If the actual time is later than creation time plus timeout, the session is not reused.

Due to this realization, all sessions behave according to the timeout value valid at the time of the session negotiation. Changes of the timeout value do not affect already established sessions.

The expiration time of a single session can be modified using the SSL_SESSION_get_time(3) family of functions.

Expired sessions are removed from the internal session cache, whenever SSL_CTX_flush_sessions(3) is called, either directly by the application or automatically (see SSL_CTX_set_session_cache_mode(3))

The default value for session timeout is decided on a per protocol basis, see SSL_get_default_timeout(3). All currently supported protocols have the same default timeout value of 300 seconds.

RETURN VALUES

SSL_CTX_set_timeout() returns the previously set timeout value.

SSL_CTX_get_timeout() returns the currently set timeout value.

SEE ALSO

Name

SSL_CTX_set_tlsext_status_cb, SSL_CTX_set_tlsext_status_arg, SSL_set_tlsext_status_type, SSL_get_tlsext_status_ocsp_resp and SSL_set_tlsext_status_ocsp_resp — OCSP Certificate Status Request functions

Synopsis

```
#include  <openssl/tls1.h>
```

```
long SSL_CTX_set_tlsext_status_cb(SSL_CTX *ctx,
                                  int (*callback)(SSL *, void *));
long SSL_CTX_set_tlsext_status_arg(SSL_CTX *ctx, void *arg);
```

```
long SSL_set_tlsext_status_type(SSL *s, int type);
```

```
long SSL_get_tlsext_status_ocsp_resp(ssl, unsigned char **resp);
long SSL_set_tlsext_status_ocsp_resp(ssl, unsigned char *resp, int len);
```

DESCRIPTION

A client application may request that a server send back an OCSP status response (also known as OCSP stapling). To do so the client should call the SSL_set_tlsext_status_type() function prior to the start of the handshake. Currently the only supported type is **TLSEXT_STATUSTYPE_ocsp**. This value should be passed in the **type** argument. The client should additionally provide a callback function to decide what to do with the returned OCSP response by calling SSL_CTX_set_tlsext_status_cb(). The callback function should determine whether the returned OCSP response is acceptable or not. The callback will be passed as an argument the value previously set via a call to SSL_CTX_set_tlsext_status_arg(). Note that the callback will not be called in the event of a handshake where session resumption occurs (because there are no Certificates exchanged in such a handshake).

The response returned by the server can be obtained via a call to SSL_get_tlsext_status_ocsp_resp(). The value ***resp** will be updated to point to the OCSP response data and the return value will be the length of that data. Typically a callback would obtain an OCSP_RESPONSE object from this data via a call to the d2i_OCSP_RESPONSE() function. If the server has not provided any response data then ***resp** will be NULL and the return value from SSL_get_tlsext_status_ocsp_resp() will be -1.

A server application must also call the SSL_CTX_set_tlsext_status_cb() function if it wants to be able to provide clients with OCSP Certificate Status responses. Typically the server callback would obtain the server certificate that is being sent back to the client via a call to SSL_get_certificate(); obtain the OCSP response to be sent back; and then set that response data by calling SSL_set_tlsext_status_ocsp_resp(). A pointer to the response data should be provided in the **resp** argument, and the length of that data should be in the **len** argument.

RETURN VALUES

The callback when used on the client side should return a negative value on error; 0 if the response is not acceptable (in which case the handshake will fail) or a positive value if it is acceptable.

The callback when used on the server side should return with either SSL_TLSEXT_ERR_OK (meaning that the OCSP response that has been set should be returned), SSL_TLSEXT_ERR_NOACK (meaning that an OCSP response should not be returned) or SSL_TLSEXT_ERR_ALERT_FATAL (meaning that a fatal error has occurred).

SSL_CTX_set_tlsext_status_cb(), SSL_CTX_set_tlsext_status_arg(), SSL_set_tlsext_status_type() and SSL_set_tlsext_status_ocsp_resp() return 0 on error or 1 on success.

SSL_get_tlsext_status_ocsp_resp() returns the length of the OCSP response data or -1 if there is no OCSP response data.

Name

SSL_CTX_set_tmp_dh_callback, SSL_CTX_set_tmp_dh, SSL_set_tmp_dh_callback and SSL_set_tmp_dh — handle DH keys for ephemeral key exchange

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_tmp_dh_callback(SSL_CTX *ctx,
           DH *(*tmp_dh_callback)(SSL *ssl, int is_export, int keylength));
long SSL_CTX_set_tmp_dh(SSL_CTX *ctx, DH *dh);
```

```
void SSL_set_tmp_dh_callback(SSL *ctx,
           DH *(*tmp_dh_callback)(SSL *ssl, int is_export, int keylength));
long SSL_set_tmp_dh(SSL *ssl, DH *dh)
```

DESCRIPTION

SSL_CTX_set_tmp_dh_callback() sets the callback function for **ctx** to be used when a DH parameters are required to **tmp_dh_callback**. The callback is inherited by all **ssl** objects created from **ctx**.

SSL_CTX_set_tmp_dh() sets DH parameters to be used to be **dh**. The key is inherited by all **ssl** objects created from **ctx**.

SSL_set_tmp_dh_callback() sets the callback only for **ssl**.

SSL_set_tmp_dh() sets the parameters only for **ssl**.

These functions apply to SSL/TLS servers only.

NOTES

When using a cipher with RSA authentication, an ephemeral DH key exchange can take place. Ciphers with DSA keys always use ephemeral DH keys as well. In these cases, the session data are negotiated using the ephemeral/temporary DH key and the key supplied and certified by the certificate chain is only used for signing. Anonymous ciphers (without a permanent server key) also use ephemeral DH keys.

Using ephemeral DH key exchange yields forward secrecy, as the connection can only be decrypted, when the DH key is known. By generating a temporary DH key inside the server application that is lost when the application is left, it becomes impossible for an attacker to decrypt past sessions, even if he gets hold of the normal (certified) key, as this key was only used for signing.

In order to perform a DH key exchange the server must use a DH group (DH parameters) and generate a DH key. The server will always generate a new DH key during the negotiation.

As generating DH parameters is extremely time consuming, an application should not generate the parameters on the fly but supply the parameters. DH parameters can be reused, as the actual key is newly generated during the negotiation. The risk in reusing DH parameters is that an attacker may specialize on a very often used DH group. Applications should therefore generate their own DH parameters during the installation process using the openssl dhparam(1) application. This application guarantees that "strong" primes are used.

Files dh2048.pem, and dh4096.pem in the 'apps' directory of the current version of the OpenSSL distribution contain the 'SKIP' DH parameters, which use safe primes and were generated verifiably pseudo-randomly. These files can be converted into C code using the **-C** option of the dhparam(1) application. Generation of custom DH parameters during installation should still be preferred to stop an attacker from specializing on a commonly used group. Files dh1024.pem and dh512.pem contain old parameters that must not be used by applications.

An application may either directly specify the DH parameters or can supply the DH parameters via a callback function.

Previous versions of the callback used **is_export** and **keylength** parameters to control parameter generation for export and non-export cipher suites. Modern servers that do not support export ciphersuites are advised to either use SSL_CTX_set_tmp_dh() or alternatively, use the callback but ignore **keylength** and **is_export** and simply supply at least 2048-bit parameters in the callback.

EXAMPLES

Setup DH parameters with a key length of 2048 bits. (Error handling partly left out.)

```
Command-line parameter generation:
$ openssl dhparam -out dh_param_2048.pem 2048

Code for setting up parameters during server initialization:

…
SSL_CTX ctx = SSL_CTX_new();
…

/* Set up ephemeral DH parameters. */
DH *dh_2048 = NULL;
FILE *paramfile;
paramfile = fopen("dh_param_2048.pem", "r");
if (paramfile) {
  dh_2048 = PEM_read_DHparams(paramfile, NULL, NULL, NULL);
  fclose(paramfile);
} else {
  /* Error. */
}
if (dh_2048 == NULL) {
 /* Error. */
}
if (SSL_CTX_set_tmp_dh(ctx, dh_2048) != 1) {
  /* Error. */
}
…
```

RETURN VALUES

SSL_CTX_set_tmp_dh_callback() and SSL_set_tmp_dh_callback() do not return diagnostic output.

SSL_CTX_set_tmp_dh() and SSL_set_tmp_dh() do return 1 on success and 0 on failure. Check the error queue to find out the reason of failure.

Name

SSL_CTX_set_tmp_rsa_callback, SSL_CTX_set_tmp_rsa, SSL_CTX_need_tmp_rsa, SSL_set_tmp_rsa_callback, SSL_set_tmp_rsa and SSL_need_tmp_rsa — handle RSA keys for ephemeral key exchange

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_tmp_rsa_callback(SSL_CTX *ctx,
           RSA *(*tmp_rsa_callback)(SSL *ssl, int is_export, int keylength));
long SSL_CTX_set_tmp_rsa(SSL_CTX *ctx, RSA *rsa);
long SSL_CTX_need_tmp_rsa(SSL_CTX *ctx);
```

```
void SSL_set_tmp_rsa_callback(SSL_CTX *ctx,
           RSA *(*tmp_rsa_callback)(SSL *ssl, int is_export, int keylength));
long SSL_set_tmp_rsa(SSL *ssl, RSA *rsa)
long SSL_need_tmp_rsa(SSL *ssl)
```

```
RSA *(*tmp_rsa_callback)(SSL *ssl, int is_export, int keylength);
```

DESCRIPTION

SSL_CTX_set_tmp_rsa_callback() sets the callback function for **ctx** to be used when a temporary/ephemeral RSA key is required to **tmp_rsa_callback**. The callback is inherited by all SSL objects newly created from **ctx** with <SSL_new(3)|SSL_new(3)>. Already created SSL objects are not affected.

SSL_CTX_set_tmp_rsa() sets the temporary/ephemeral RSA key to be used to be **rsa**. The key is inherited by all SSL objects newly created from **ctx** with <SSL_new(3)|SSL_new(3)>. Already created SSL objects are not affected.

SSL_CTX_need_tmp_rsa() returns 1, if a temporary/ephemeral RSA key is needed for RSA-based strength-limited 'exportable' ciphersuites because a RSA key with a keysize larger than 512 bits is installed.

SSL_set_tmp_rsa_callback() sets the callback only for **ssl**.

SSL_set_tmp_rsa() sets the key only for **ssl**.

SSL_need_tmp_rsa() returns 1, if a temporary/ephemeral RSA key is needed, for RSA-based strength-limited 'exportable' ciphersuites because a RSA key with a keysize larger than 512 bits is installed.

These functions apply to SSL/TLS servers only.

NOTES

When using a cipher with RSA authentication, an ephemeral RSA key exchange can take place. In this case the session data are negotiated using the ephemeral/temporary RSA key and the RSA key supplied and certified by the certificate chain is only used for signing.

Under previous export restrictions, ciphers with RSA keys shorter (512 bits) than the usual key length of 1024 bits were created. To use these ciphers with RSA keys of usual length, an ephemeral key exchange must be performed, as the normal (certified) key cannot be directly used.

Using ephemeral RSA key exchange yields forward secrecy, as the connection can only be decrypted, when the RSA key is known. By generating a temporary RSA key inside the server application that is lost when the application is left, it becomes impossible for an attacker to decrypt past sessions, even if he gets hold of the normal (certified) RSA key, as this key was used for signing only. The downside is that creating a RSA key is computationally expensive.

Additionally, the use of ephemeral RSA key exchange is only allowed in the TLS standard, when the RSA key can be used for signing only, that is for export ciphers. Using ephemeral RSA key exchange for other purposes violates the standard and can break interoperability with clients. It is therefore strongly recommended to not use ephemeral RSA key exchange and use EDH (Ephemeral Diffie-Hellman) key exchange instead in order to achieve forward secrecy (see SSL_CTX_set_tmp_dh_callback(3)).

An application may either directly specify the key or can supply the key via a callback function. The callback approach has the advantage, that the callback may generate the key only in case it is actually needed. As the generation of a RSA key is however costly, it will lead to a significant delay in the handshake procedure. Another advantage of the callback function is that it can supply keys of different size while the explicit setting of the key is only useful for key size of 512 bits to satisfy the export restricted ciphers and does give away key length if a longer key would be allowed.

The **tmp_rsa_callback** is called with the **keylength** needed and the **is_export** information. The **is_export** flag is set, when the ephemeral RSA key exchange is performed with an export cipher.

EXAMPLES

Generate temporary RSA keys to prepare ephemeral RSA key exchange. As the generation of a RSA key costs a lot of computer time, they saved for later reuse. For demonstration purposes, two keys for 512 bits and 1024 bits respectively are generated.

```
…
/* Set up ephemeral RSA stuff */
RSA *rsa_512 = NULL;
RSA *rsa_1024 = NULL;

rsa_512 = RSA_generate_key(512,RSA_F4,NULL,NULL);
if (rsa_512 == NULL)
    evaluate_error_queue();

rsa_1024 = RSA_generate_key(1024,RSA_F4,NULL,NULL);
if (rsa_1024 == NULL)
  evaluate_error_queue();

…

RSA *tmp_rsa_callback(SSL *s, int is_export, int keylength)
{
   RSA *rsa_tmp=NULL;

   switch (keylength) {
   case 512:
     if (rsa_512)
       rsa_tmp = rsa_512;
     else { /* generate on the fly, should not happen in this example */
       rsa_tmp = RSA_generate_key(keylength,RSA_F4,NULL,NULL);
       rsa_512 = rsa_tmp; /* Remember for later reuse */
     }
     break;
   case 1024:
     if (rsa_1024)
       rsa_tmp=rsa_1024;
     else
       should_not_happen_in_this_example();
     break;
   default:
     /* Generating a key on the fly is very costly, so use what is there */
     if (rsa_1024)
       rsa_tmp=rsa_1024;
     else
       rsa_tmp=rsa_512; /* Use at least a shorter key */
   }
   return(rsa_tmp);
}
```

RETURN VALUES

SSL_CTX_set_tmp_rsa_callback() and SSL_set_tmp_rsa_callback() do not return diagnostic output.

SSL_CTX_set_tmp_rsa() and SSL_set_tmp_rsa() do return 1 on success and 0 on failure. Check the error queue to find out the reason of failure.

SSL_CTX_need_tmp_rsa() and SSL_need_tmp_rsa() return 1 if a temporary RSA key is needed and 0 otherwise.

Name

SSL_CTX_set_verify, SSL_set_verify, SSL_CTX_set_verify_depth and SSL_set_verify_depth — set peer certificate verification parameters

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_CTX_set_verify(SSL_CTX *ctx, int mode,
                        int (*verify_callback)(int, X509_STORE_CTX *));
void SSL_set_verify(SSL *s, int mode,
                    int (*verify_callback)(int, X509_STORE_CTX *));
void SSL_CTX_set_verify_depth(SSL_CTX *ctx,int depth);
void SSL_set_verify_depth(SSL *s, int depth);
```

```
int verify_callback(int preverify_ok, X509_STORE_CTX *x509_ctx);
```

DESCRIPTION

SSL_CTX_set_verify() sets the verification flags for **ctx** to be **mode** and specifies the **verify_callback** function to be used. If no callback function shall be specified, the NULL pointer can be used for **verify_callback**.

SSL_set_verify() sets the verification flags for **ssl** to be **mode** and specifies the **verify_callback** function to be used. If no callback function shall be specified, the NULL pointer can be used for **verify_callback**. In this case last **verify_callback** set specifically for this **ssl** remains. If no special **callback** was set before, the default callback for the underlying **ctx** is used, that was valid at the time **ssl** was created with SSL_new(3).

SSL_CTX_set_verify_depth() sets the maximum **depth** for the certificate chain verification that shall be allowed for **ctx**. (See the BUGS section.)

SSL_set_verify_depth() sets the maximum **depth** for the certificate chain verification that shall be allowed for **ssl**. (See the BUGS section.)

NOTES

The verification of certificates can be controlled by a set of logically or'ed **mode** flags:

SSL_VERIFY_NONE

> **Server mode:** the server will not send a client certificate request to the client, so the client will not send a certificate.
>
> **Client mode:** if not using an anonymous cipher (by default disabled), the server will send a certificate which will be checked. The result of the certificate verification process can be checked after the TLS/SSL handshake using the SSL_get_verify_result(3) function. The handshake will be continued regardless of the verification result.

SSL_VERIFY_PEER

> **Server mode:** the server sends a client certificate request to the client. The certificate returned (if any) is checked. If the verification process fails, the TLS/SSL handshake is immediately terminated with an alert message containing the reason for the verification failure. The behaviour can be controlled by the additional SSL_VERIFY_FAIL_IF_NO_PEER_CERT and SSL_VERIFY_CLIENT_ONCE flags.
>
> **Client mode:** the server certificate is verified. If the verification process fails, the TLS/SSL handshake is immediately terminated with an alert message containing the reason for the verification failure. If no server certificate is sent, because an anonymous cipher is used, SSL_VERIFY_PEER is ignored.

SSL_VERIFY_FAIL_IF_NO_PEER_CERT

> **Server mode:** if the client did not return a certificate, the TLS/SSL handshake is immediately terminated with a "handshake failure" alert. This flag must be used together with SSL_VERIFY_PEER.
>
> **Client mode:** ignored

SSL_VERIFY_CLIENT_ONCE

> **Server mode:** only request a client certificate on the initial TLS/SSL handshake. Do not ask for a client certificate again in case of a renegotiation. This flag must be used together with SSL_VERIFY_PEER.
>
> **Client mode:** ignored

Exactly one of the **mode** flags SSL_VERIFY_NONE and SSL_VERIFY_PEER must be set at any time.

The actual verification procedure is performed either using the built-in verification procedure or using another application provided verification function set with SSL_CTX_set_cert_verify_callback(3). The following descriptions apply in the case of the built-in procedure. An application provided procedure also has access to the verify depth information and the verify_callback() function, but the way this information is used may be different.

SSL_CTX_set_verify_depth() and SSL_set_verify_depth() set the limit up to which depth certificates in a chain are used during the verification procedure. If the certificate chain is longer than allowed, the certificates above the limit are ignored. Error messages are generated as if these certificates would not be present, most likely a X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT_LOCALLY will be issued. The depth count is "level 0:peer certificate", "level 1: CA certificate", "level 2: higher level CA certificate", and so on. Setting the maximum depth to 2 allows the levels 0, 1, and 2. The default depth limit is 100, allowing for the peer certificate and additional 100 CA certificates.

The **verify_callback** function is used to control the behaviour when the SSL_VERIFY_PEER flag is set. It must be supplied by the application and receives two arguments: **preverify_ok** indicates, whether the verification of the certificate in question was passed (preverify_ok=1) or not (preverify_ok=0). **x509_ctx** is a pointer to the complete context used for the certificate chain verification.

The certificate chain is checked starting with the deepest nesting level (the root CA certificate) and worked upward to the peer's certificate. At each level signatures and issuer attributes are checked. Whenever a verification error is found, the error number is stored in **x509_ctx** and **verify_callback** is called with **preverify_ok**=0. By applying X509_CTX_store_* functions **verify_callback** can locate the certificate in question and perform additional steps (see EXAMPLES). If no error is found for a certificate, **verify_callback** is called with **preverify_ok**=1 before advancing to the next level.

The return value of **verify_callback** controls the strategy of the further verification process. If **verify_callback** returns 0, the verification process is immediately stopped with "verification failed" state. If SSL_VERIFY_PEER is set, a verification failure alert is sent to the peer and the TLS/SSL handshake is terminated. If **verify_callback** returns 1, the verification process is continued. If **verify_callback** always returns 1, the TLS/SSL handshake will not be terminated with respect to verification failures and the connection will be established. The calling process can however retrieve the error code of the last verification error using SSL_get_verify_result(3) or by maintaining its own error storage managed by **verify_callback**.

If no **verify_callback** is specified, the default callback will be used. Its return value is identical to **preverify_ok**, so that any verification failure will lead to a termination of the TLS/SSL handshake with an alert message, if SSL_VERIFY_PEER is set.

BUGS

In client mode, it is not checked whether the SSL_VERIFY_PEER flag is set, but whether SSL_VERIFY_NONE is not set. This can lead to unexpected behaviour, if the SSL_VERIFY_PEER and SSL_VERIFY_NONE are not used as required (exactly one must be set at any time).

The certificate verification depth set with SSL[_CTX]_verify_depth() stops the verification at a certain depth. The error message produced will be that of an incomplete certificate chain and not X509_V_ERR_CERT_CHAIN_TOO_LONG as may be expected.

RETURN VALUES

The SSL*_set_verify*() functions do not provide diagnostic information.

EXAMPLES

The following code sequence realizes an example **verify_callback** function that will always continue the TLS/SSL handshake regardless of verification failure, if wished. The callback realizes a verification depth limit with more informational output.

All verification errors are printed; information about the certificate chain is printed on request. The example is realized for a server that does allow but not require client certificates.

The example makes use of the ex_data technique to store application data into/retrieve application data from the SSL structure (see SSL_get_ex_new_index(3), SSL_get_ex_data_X509_STORE_CTX_idx(3)).

```
…
typedef struct {
  int verbose_mode;
  int verify_depth;
  int always_continue;
} mydata_t;
int mydata_index;
…
static int verify_callback(int preverify_ok, X509_STORE_CTX *ctx)
{
   char    buf[256];
   X509   *err_cert;
   int     err, depth;
   SSL    *ssl;
   mydata_t *mydata;

err_cert = X509_STORE_CTX_get_current_cert(ctx);
err = X509_STORE_CTX_get_error(ctx);
depth = X509_STORE_CTX_get_error_depth(ctx);

/*
 * Retrieve the pointer to the SSL of the connection currently treated
 * and the application specific data stored into the SSL object.
 */
ssl = X509_STORE_CTX_get_ex_data(ctx, SSL_get_ex_data_X509_STORE_CTX_idx());
mydata = SSL_get_ex_data(ssl, mydata_index);

X509_NAME_oneline(X509_get_subject_name(err_cert), buf, 256);

/*
 * Catch a too long certificate chain. The depth limit set using
 * SSL_CTX_set_verify_depth() is by purpose set to "limit+1" so
 * that whenever the "depth>verify_depth" condition is met, we
 * have violated the limit and want to log this error condition.
 * We must do it here, because the CHAIN_TOO_LONG error would not
 * be found explicitly; only errors introduced by cutting off the
 * additional certificates would be logged.
 */
if (depth > mydata->verify_depth) {
    preverify_ok = 0;
    err = X509_V_ERR_CERT_CHAIN_TOO_LONG;
    X509_STORE_CTX_set_error(ctx, err);
}
if (!preverify_ok) {
    printf("verify error:num=%d:%s:depth=%d:%s\n", err,
             X509_verify_cert_error_string(err), depth, buf);
}
else if (mydata->verbose_mode)
{
    printf("depth=%d:%s\n", depth, buf);
}

/*
 * At this point, err contains the last verification error. We can use
 * it for something special
 */
if (!preverify_ok && (err == X509_V_ERR_UNABLE_TO_GET_ISSUER_CERT))

DESCRIPTION

These functions load the certificates and private keys into the SSL_CTX or SSL object, respectively.

The SSL_CTX_* class of functions loads the certificates and keys into the SSL_CTX object **ctx**. The information is passed to SSL objects **ssl** created from **ctx** with SSL_new(3) by copying, so that changes applied to **ctx** do not propagate to already existing SSL objects.

The SSL_* class of functions only loads certificates and keys into a specific SSL object. The specific information is kept, when SSL_clear(3) is called for this SSL object.

SSL_CTX_use_certificate() loads the certificate **x** into **ctx**, SSL_use_certificate() loads **x** into **ssl**. The rest of the certificates needed to form the complete certificate chain can be specified using the SSL_CTX_add_extra_chain_cert(3) function.

SSL_CTX_use_certificate_ASN1() loads the ASN1 encoded certificate from the memory location **d** (with length **len**) into **ctx**, SSL_use_certificate_ASN1() loads the ASN1 encoded certificate into **ssl**.

SSL_CTX_use_certificate_file() loads the first certificate stored in **file** into **ctx**. The formatting **type** of the certificate must be specified from the known types SSL_FILETYPE_PEM, SSL_FILETYPE_ASN1. SSL_use_certificate_file() loads the certificate from **file** into **ssl**. See the NOTES section on why SSL_CTX_use_certificate_chain_file() should be preferred.

SSL_CTX_use_certificate_chain_file() loads a certificate chain from **file** into **ctx**. The certificates must be in PEM format and must be sorted starting with the subject's certificate (actual client or server certificate), followed by intermediate CA certificates if applicable, and ending at the highest level (root) CA. There is no corresponding function working on a single SSL object.

SSL_CTX_use_PrivateKey() adds **pkey** as private key to **ctx**. SSL_CTX_use_RSAPrivateKey() adds the private key **rsa** of type RSA to **ctx**. SSL_use_PrivateKey() adds **pkey** as private key to **ssl**; SSL_use_RSAPrivateKey() adds **rsa** as private key of type RSA to **ssl**. If a certificate has already been set and the private does not belong to the certificate an error is returned. To change a certificate, private key pair the new certificate needs to be set with SSL_use_certificate() or SSL_CTX_use_certificate() before setting the private key with SSL_CTX_use_PrivateKey() or SSL_use_PrivateKey().

SSL_CTX_use_PrivateKey_ASN1() adds the private key of type **pk** stored at memory location **d** (length **len**) to **ctx**. SSL_CTX_use_RSAPrivateKey_ASN1() adds the private key of type RSA stored at memory location **d** (length **len**) to **ctx**. SSL_use_PrivateKey_ASN1() and SSL_use_RSAPrivateKey_ASN1() add the private key to **ssl**.

SSL_CTX_use_PrivateKey_file() adds the first private key found in **file** to **ctx**. The formatting **type** of the certificate must be specified from the known types SSL_FILETYPE_PEM, SSL_FILETYPE_ASN1. SSL_CTX_use_RSAPrivateKey_file() adds the first private RSA key found in **file** to **ctx**. SSL_use_PrivateKey_file() adds the first private key found in **file** to **ssl**; SSL_use_RSAPrivateKey_file() adds the first private RSA key found to **ssl**.

SSL_CTX_check_private_key() checks the consistency of a private key with the corresponding certificate loaded into **ctx**. If more than one key/certificate pair (RSA/DSA) is installed, the last item installed will be checked. If e.g. the last item was a RSA certificate or key, the RSA key/certificate pair will be checked. SSL_check_private_key() performs the same check for **ssl**. If no key/certificate was explicitly added for this **ssl**, the last item added into **ctx** will be checked.

NOTES

The internal certificate store of OpenSSL can hold two private key/certificate pairs at a time: one key/certificate of type RSA and one key/certificate of type DSA. The certificate used depends on the cipher select, see also SSL_CTX_set_cipher_list(3).

When reading certificates and private keys from file, files of type SSL_FILETYPE_ASN1 (also known as **DER**, binary encoding) can only contain one certificate or private key, consequently SSL_CTX_use_certificate_chain_file() is only applicable to PEM formatting. Files of type SSL_FILETYPE_PEM can contain more than one item.

SSL_CTX_use_certificate_chain_file() adds the first certificate found in the file to the certificate store. The other certificates are added to the store of chain certificates using SSL_CTX_add_extra_chain_cert(3). There exists only one extra chain store, so that the same chain is appended to both types of certificates, RSA and DSA! If it is not intended to use both type of certificate at the same time, it is recommended to use the SSL_CTX_use_certificate_chain_file() instead of the SSL_CTX_use_certificate_file() function in order to allow the use of complete certificate chains even when no trusted CA storage is used or when the CA issuing the certificate shall not be added to the trusted CA storage.

If additional certificates are needed to complete the chain during the TLS negotiation, CA certificates are additionally looked up in the locations of trusted CA certificates, see SSL_CTX_load_verify_locations(3).

The private keys loaded from file can be encrypted. In order to successfully load encrypted keys, a function returning the passphrase must have been supplied, see SSL_CTX_set_default_passwd_cb(3). (Certificate files might be encrypted as well from the technical point of view, it however does not make sense as the data in the certificate is considered public anyway.)

RETURN VALUES

On success, the functions return 1. Otherwise check out the error stack to find out the reason.

SEE ALSO

HISTORY

Support for DER encoded private keys (SSL_FILETYPE_ASN1) in SSL_CTX_use_PrivateKey_file() and SSL_use_PrivateKey_file() was added in 0.9.8 .

Name

SSL_CTX_use_psk_identity_hint, SSL_use_psk_identity_hint, SSL_CTX_set_psk_server_callback and SSL_set_psk_server_callback — set PSK identity hint to use

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_CTX_use_psk_identity_hint(SSL_CTX *ctx, const char *hint);
int SSL_use_psk_identity_hint(SSL *ssl, const char *hint);
```

```
void SSL_CTX_set_psk_server_callback(SSL_CTX *ctx,
       unsigned int (*callback)(SSL *ssl, const char *identity,
       unsigned char *psk, int max_psk_len));
void SSL_set_psk_server_callback(SSL *ssl,
       unsigned int (*callback)(SSL *ssl, const char *identity,
       unsigned char *psk, int max_psk_len));
```

DESCRIPTION

SSL_CTX_use_psk_identity_hint() sets the given **NULL**-terminated PSK identity hint **hint** to SSL context object **ctx**. SSL_use_psk_identity_hint() sets the given **NULL**-terminated PSK identity hint **hint** to SSL connection object **ssl**. If **hint** is **NULL** the current hint from **ctx** or **ssl** is deleted.

In the case where PSK identity hint is **NULL**, the server does not send the ServerKeyExchange message to the client.

A server application must provide a callback function which is called when the server receives the ClientKeyExchange message from the client. The purpose of the callback function is to validate the received PSK identity and to fetch the pre-shared key used during the connection setup phase. The callback is set using functions SSL_CTX_set_psk_server_callback() or SSL_set_psk_server_callback(). The callback function is given the connection in parameter **ssl**, **NULL**-terminated PSK identity sent by the client in parameter **identity**, and a buffer **psk** of length **max_psk_len** bytes where the pre-shared key is to be stored.

RETURN VALUES

SSL_CTX_use_psk_identity_hint() and SSL_use_psk_identity_hint() return 1 on success, 0 otherwise.

Return values from the server callback are interpreted as follows:

> 0 PSK identity was found and the server callback has provided the PSK successfully in parameter **psk**. Return value is the length of **psk** in bytes. It is an error to return a value greater than **max_psk_len**.

If the PSK identity was not found but the callback instructs the protocol to continue anyway, the callback must provide some random data to **psk** and return the length of the random data, so the connection will fail with decryption_error before it will be finished completely.

0 PSK identity was not found. An "unknown_psk_identity" alert message will be sent and the connection setup fails.

Name

SSL_do_handshake — perform a TLS/SSL handshake

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_do_handshake(SSL *ssl);
```

DESCRIPTION

SSL_do_handshake() will wait for a SSL/TLS handshake to take place. If the connection is in client mode, the handshake will be started. The handshake routines may have to be explicitly set in advance using either SSL_set_connect_state(3) or SSL_set_accept_state(3).

NOTES

The behaviour of SSL_do_handshake() depends on the underlying BIO.

If the underlying BIO is **blocking**, SSL_do_handshake() will only return once the handshake has been finished or an error occurred, except for SGC (Server Gated Cryptography). For SGC, SSL_do_handshake() may return with -1, but SSL_get_error() will yield **SSL_ERROR_WANT_READ/WRITE** and SSL_do_handshake() should be called again.

If the underlying BIO is **non-blocking**, SSL_do_handshake() will also return when the underlying BIO could not satisfy the needs of SSL_do_handshake() to continue the handshake. In this case a call to SSL_get_error() with the return value of SSL_do_handshake() will yield **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**. The calling process then must repeat the call after taking appropriate action to satisfy the needs of SSL_do_handshake(). The action depends on the underlying BIO. When using a non-blocking socket, nothing is to be done, but select() can be used to check for the required condition. When using a buffering BIO, like a BIO pair, data must be written into or retrieved out of the BIO before being able to continue.

RETURN VALUES

The following return values can occur:

0 The TLS/SSL handshake was not successful but was shut down controlled and by the specifications of the TLS/SSL protocol. Call SSL_get_error() with the return value **ret** to find out the reason.

1 The TLS/SSL handshake was successfully completed, a TLS/SSL connection has been established.

<0 The TLS/SSL handshake was not successful because a fatal error occurred either at the protocol level or a connection failure occurred. The shutdown was not clean. It can also occur of action is need to continue the operation for non-blocking BIOs. Call SSL_get_error() with the return value **ret** to find out the reason.

SEE ALSO

SSL_get_error(3), SSL_connect(3), SSL_accept(3), ssl(3), bio(3), SSL_set_connect_state(3)

Name

SSL_free — free an allocated SSL structure

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_free(SSL *ssl);
```

DESCRIPTION

SSL_free() decrements the reference count of **ssl**, and removes the SSL structure pointed to by **ssl** and frees up the allocated memory if the reference count has reached 0.

NOTES

SSL_free() also calls the free()ing procedures for indirectly affected items, if applicable: the buffering BIO, the read and write BIOs, cipher lists specially created for this **ssl**, the **SSL_SESSION**. Do not explicitly free these indirectly freed up items before or after calling SSL_free(), as trying to free things twice may lead to program failure.

The ssl session has reference counts from two users: the SSL object, for which the reference count is removed by SSL_free() and the internal session cache. If the session is considered bad, because SSL_shutdown(3) was not called for the connection and SSL_set_shutdown(3) was not used to set the SSL_SENT_SHUTDOWN state, the session will also be removed from the session cache as required by RFC2246.

RETURN VALUES

SSL_free() does not provide diagnostic information.

SSL_new(3), SSL_clear(3), SSL_shutdown(3), SSL_set_shutdown(3), ssl(3)

Name

SSL_get_ciphers and SSL_get_cipher_list — get list of available SSL_CIPHERs

Synopsis

```
#include  <openssl/ssl.h>
```

```
STACK_OF(SSL_CIPHER) *SSL_get_ciphers(const SSL *ssl);
const char *SSL_get_cipher_list(const SSL *ssl, int priority);
```

DESCRIPTION

SSL_get_ciphers() returns the stack of available SSL_CIPHERs for **ssl**, sorted by preference. If **ssl** is NULL or no ciphers are available, NULL is returned.

SSL_get_cipher_list() returns a pointer to the name of the SSL_CIPHER listed for **ssl** with **priority**. If **ssl** is NULL, no ciphers are available, or there are less ciphers than **priority** available, NULL is returned.

NOTES

The details of the ciphers obtained by SSL_get_ciphers() can be obtained using the SSL_CIPHER_get_name(3) family of functions.

Call SSL_get_cipher_list() with **priority** starting from 0 to obtain the sorted list of available ciphers, until NULL is returned.

RETURN VALUES

See DESCRIPTION

SEE ALSO

ssl(3), SSL_CTX_set_cipher_list(3), SSL_CIPHER_get_name(3)

Name

SSL_get_client_CA_list and SSL_CTX_get_client_CA_list — get list of client CAs

Synopsis

```
#include  <openssl/ssl.h>
```

```
STACK_OF(X509_NAME) *SSL_get_client_CA_list(const SSL *s);
STACK_OF(X509_NAME) *SSL_CTX_get_client_CA_list(const SSL_CTX *ctx);
```

DESCRIPTION

SSL_CTX_get_client_CA_list() returns the list of client CAs explicitly set for **ctx** using SSL_CTX_set_client_CA_list(3).

SSL_get_client_CA_list() returns the list of client CAs explicitly set for **ssl** using SSL_set_client_CA_list() or **ssl**'s SSL_CTX object with SSL_CTX_set_client_CA_list(3), when in server mode. In client mode, SSL_get_client_CA_list returns the list of client CAs sent from the server, if any.

RETURN VALUES

SSL_CTX_set_client_CA_list() and SSL_set_client_CA_list() do not return diagnostic information.

SSL_CTX_add_client_CA() and SSL_add_client_CA() have the following return values:

STACK_OF(X509_NAMES) List of CA names explicitly set (for **ctx** or in server mode) or send by the server (client mode).

NULL No client CA list was explicitly set (for **ctx** or in server mode) or the server did not send a list of CAs (client mode).

SEE ALSO

ssl(3), SSL_CTX_set_client_CA_list(3), SSL_CTX_set_client_cert_cb(3)

Name

SSL_get_current_cipher, SSL_get_cipher, SSL_get_cipher_name, SSL_get_cipher_bits and SSL_get_cipher_version — get SSL_CIPHER of a connection

Synopsis

```
#include  <openssl/ssl.h>
```

```
SSL_CIPHER *SSL_get_current_cipher(const SSL *ssl);
#define SSL_get_cipher(s) \
               SSL_CIPHER_get_name(SSL_get_current_cipher(s))
#define SSL_get_cipher_name(s) \
               SSL_CIPHER_get_name(SSL_get_current_cipher(s))
#define SSL_get_cipher_bits(s,np) \
               SSL_CIPHER_get_bits(SSL_get_current_cipher(s),np)
#define SSL_get_cipher_version(s) \
               SSL_CIPHER_get_version(SSL_get_current_cipher(s))
```

DESCRIPTION

SSL_get_current_cipher() returns a pointer to an SSL_CIPHER object containing the description of the actually used cipher of a connection established with the **ssl** object.

SSL_get_cipher() and SSL_get_cipher_name() are identical macros to obtain the name of the currently used cipher. SSL_get_cipher_bits() is a macro to obtain the number of secret/algorithm bits used and SSL_get_cipher_version() returns the protocol name. See SSL_CIPHER_get_name(3) for more details.

RETURN VALUES

SSL_get_current_cipher() returns the cipher actually used or NULL, when no session has been established.

SEE ALSO

ssl(3), SSL_CIPHER_get_name(3)

Name

SSL_get_default_timeout — get default session timeout value

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_get_default_timeout(const SSL *ssl);
```

DESCRIPTION

SSL_get_default_timeout() returns the default timeout value assigned to SSL_SESSION objects negotiated for the protocol valid for **ssl**.

NOTES

Whenever a new session is negotiated, it is assigned a timeout value, after which it will not be accepted for session reuse. If the timeout value was not explicitly set using SSL_CTX_set_timeout(3), the hardcoded default timeout for the protocol will be used.

SSL_get_default_timeout() return this hardcoded value, which is 300 seconds for all currently supported protocols (SSLv2, SSLv3, and TLSv1).

RETURN VALUES

See description.

SEE ALSO

ssl(3), SSL_CTX_set_session_cache_mode(3), SSL_SESSION_get_time(3), SSL_CTX_flush_sessions(3), SSL_get_default_timeout(3)

Name

SSL_get_error — obtain result code for TLS/SSL I/O operation

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_get_error(const SSL *ssl, int ret);
```

DESCRIPTION

SSL_get_error() returns a result code (suitable for the C "switch" statement) for a preceding call to SSL_connect(), SSL_accept(), SSL_do_handshake(), SSL_read(), SSL_peek(), or SSL_write() on **ssl**. The value returned by that TLS/SSL I/O function must be passed to SSL_get_error() in parameter **ret**.

In addition to **ssl** and **ret**, SSL_get_error() inspects the current thread's OpenSSL error queue. Thus, SSL_get_error() must be used in the same thread that performed the TLS/SSL I/O operation, and no other OpenSSL function calls should appear in between. The current thread's error queue must be empty before the TLS/SSL I/O operation is attempted, or SSL_get_error() will not work reliably.

RETURN VALUES

The following return values can currently occur:

SSL_ERROR_NONE

> The TLS/SSL I/O operation completed. This result code is returned if and only if **ret > 0**.

SSL_ERROR_ZERO_RETURN

> The TLS/SSL connection has been closed. If the protocol version is SSL 3.0 or TLS 1.0, this result code is returned only if a closure alert has occurred in the protocol, i.e. if the connection has been closed cleanly. Note that in this case **SSL_ERROR_ZERO_RETURN** does not necessarily indicate that the underlying transport has been closed.

SSL_ERROR_WANT_READ, SSL_ERROR_WANT_WRITE

> The operation did not complete; the same TLS/SSL I/O function should be called again later. If, by then, the underlying **BIO** has data available for reading (if the result code is **SSL_ERROR_WANT_READ**) or allows writing data (**SSL_ERROR_WANT_WRITE**), then some TLS/SSL protocol progress will take place, i.e. at least part of an TLS/SSL record will be read or written. Note that the retry may again lead to a **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE** condition. There is no fixed upper limit for the number of iterations that may be necessary until progress becomes visible at application protocol level.
>
> For socket **BIO**s (e.g. when SSL_set_fd() was used), select() or poll() on the underlying socket can be used to find out when the TLS/SSL I/O function should be retried.
>
> Caveat: Any TLS/SSL I/O function can lead to either of **SSL_ERROR_WANT_READ** and **SSL_ERROR_WANT_WRITE**. In particular, SSL_read() or SSL_peek() may want to write data and SSL_write() may want to read data. This is mainly because TLS/SSL handshakes may occur at any time during the protocol (initiated by either the client or the server); SSL_read(), SSL_peek(), and SSL_write() will handle any pending handshakes.

SSL_ERROR_WANT_CONNECT, SSL_ERROR_WANT_ACCEPT

> The operation did not complete; the same TLS/SSL I/O function should be called again later. The underlying BIO was not connected yet to the peer and the call would block in connect()/accept(). The SSL function should be called again when the

connection is established. These messages can only appear with a BIO_s_connect() or BIO_s_accept() BIO, respectively. In order to find out, when the connection has been successfully established, on many platforms select() or poll() for writing on the socket file descriptor can be used.

SSL_ERROR_WANT_X509_LOOKUP

The operation did not complete because an application callback set by SSL_CTX_set_client_cert_cb() has asked to be called again. The TLS/SSL I/O function should be called again later. Details depend on the application.

SSL_ERROR_SYSCALL

Some I/O error occurred. The OpenSSL error queue may contain more information on the error. If the error queue is empty (i.e. ERR_get_error() returns 0), **ret** can be used to find out more about the error: If **ret == 0**, an EOF was observed that violates the protocol. If **ret == -1**, the underlying **BIO** reported an I/O error (for socket I/O on Unix systems, consult **errno** for details).

SSL_ERROR_SSL

A failure in the SSL library occurred, usually a protocol error. The OpenSSL error queue contains more information on the error.

SEE ALSO

ssl(3), err(3)

HISTORY

SSL_get_error() was added in SSLeay 0.8.

Name

SSL_get_ex_data_X509_STORE_CTX_idx — get ex_data index to access SSL structure from X509_STORE_CTX

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_get_ex_data_X509_STORE_CTX_idx(void);
```

DESCRIPTION

SSL_get_ex_data_X509_STORE_CTX_idx() returns the index number under which the pointer to the SSL object is stored into the X509_STORE_CTX object.

NOTES

Whenever a X509_STORE_CTX object is created for the verification of the peers certificate during a handshake, a pointer to the SSL object is stored into the X509_STORE_CTX object to identify the connection affected. To retrieve this pointer the X509_STORE_CTX_get_ex_data() function can be used with the correct index. This index is globally the same for all X509_STORE_CTX objects and can be retrieved using SSL_get_ex_data_X509_STORE_CTX_idx(). The index value is set when SSL_get_ex_data_X509_STORE_CTX_idx() is first called either by the application program directly or indirectly during other SSL setup functions or during the handshake.

The value depends on other index values defined for X509_STORE_CTX objects before the SSL index is created.

RETURN VALUES

>=0 The index value to access the pointer.

<0 An error occurred, check the error stack for a detailed error message.

EXAMPLES

The index returned from SSL_get_ex_data_X509_STORE_CTX_idx() allows to access the SSL object for the connection to be accessed during the verify_callback() when checking the peers certificate. Please check the example in SSL_CTX_set_verify(3),

SEE ALSO

typedef int dup_func(CRYPTO_EX_DATA *to, CRYPTO_EX_DATA *from, void *from_d,
               int idx, long argl, void *argp);
```

DESCRIPTION

Several OpenSSL structures can have application specific data attached to them. These functions are used internally by OpenSSL to manipulate application specific data attached to a specific structure.

SSL_get_ex_new_index() is used to register a new index for application specific data.

SSL_set_ex_data() is used to store application data at **arg** for **idx** into the **ssl** object.

SSL_get_ex_data() is used to retrieve the information for **idx** from **ssl**.

A detailed description for the ***_get_ex_new_index()** functionality can be found in RSA_get_ex_new_index(3). The ***_get_ex_data()** and ***_set_ex_data()** functionality is described in CRYPTO_set_ex_data(3).

EXAMPLES

An example on how to use the functionality is included in the example verify_callback() in SSL_CTX_set_verify(3).

SEE ALSO

ssl(3), RSA_get_ex_new_index(3), CRYPTO_set_ex_data(3), SSL_CTX_set_verify(3)

Name

SSL_get_fd — get file descriptor linked to an SSL object

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_get_fd(const SSL *ssl);
int SSL_get_rfd(const SSL *ssl);
int SSL_get_wfd(const SSL *ssl);
```

DESCRIPTION

SSL_get_fd() returns the file descriptor which is linked to **ssl**. SSL_get_rfd() and SSL_get_wfd() return the file descriptors for the read or the write channel, which can be different. If the read and the write channel are different, SSL_get_fd() will return the file descriptor of the read channel.

RETURN VALUES

The following return values can occur:

-1 The operation failed, because the underlying BIO is not of the correct type (suitable for file descriptors).

>=0 The file descriptor linked to **ssl**.

SEE ALSO

SSL_set_fd(3), ssl(3) , bio(3)

Name

SSL_get_peer_cert_chain — get the X509 certificate chain of the peer

Synopsis

```
#include  <openssl/ssl.h>
```

```
STACK_OF(X509) *SSL_get_peer_cert_chain(const SSL *ssl);
```

DESCRIPTION

SSL_get_peer_cert_chain() returns a pointer to STACK_OF(X509) certificates forming the certificate chain of the peer. If called on the client side, the stack also contains the peer's certificate; if called on the server side, the peer's certificate must be obtained separately using SSL_get_peer_certificate(3). If the peer did not present a certificate, NULL is returned.

NOTES

The peer certificate chain is not necessarily available after reusing a session, in which case a NULL pointer is returned.

The reference count of the STACK_OF(X509) object is not incremented. If the corresponding session is freed, the pointer must not be used any longer.

RETURN VALUES

The following return values can occur:

NULL

> No certificate was presented by the peer or no connection was established or the certificate chain is no longer available when a session is reused.

Pointer to a STACK_OF(X509)

> The return value points to the certificate chain presented by the peer.

SEE ALSO

ssl(3), SSL_get_peer_certificate(3)

Name

SSL_get_peer_certificate — get the X509 certificate of the peer

Synopsis

```
#include  <openssl/ssl.h>
```

```
X509 *SSL_get_peer_certificate(const SSL *ssl);
```

DESCRIPTION

SSL_get_peer_certificate() returns a pointer to the X509 certificate the peer presented. If the peer did not present a certificate, NULL is returned.

NOTES

Due to the protocol definition, a TLS/SSL server will always send a certificate, if present. A client will only send a certificate when explicitly requested to do so by the server (see SSL_CTX_set_verify(3)). If an anonymous cipher is used, no certificates are sent.

That a certificate is returned does not indicate information about the verification state, use SSL_get_verify_result(3) to check the verification state.

The reference count of the X509 object is incremented by one, so that it will not be destroyed when the session containing the peer certificate is freed. The X509 object must be explicitly freed using X509_free().

RETURN VALUES

The following return values can occur:

NULL

> No certificate was presented by the peer or no connection was established.

Pointer to an X509 certificate

> The return value points to the certificate presented by the peer.

SEE ALSO

ssl(3), SSL_get_verify_result(3), SSL_CTX_set_verify(3)

Name

SSL_get_psk_identity and SSL_get_psk_identity_hint — get PSK client identity and hint

Synopsis

```
#include  <openssl/ssl.h>
```

```
const char *SSL_get_psk_identity_hint(const SSL *ssl);
const char *SSL_get_psk_identity(const SSL *ssl);
```

DESCRIPTION

SSL_get_psk_identity_hint() is used to retrieve the PSK identity hint used during the connection setup related to SSL object **ssl**. Similarly, SSL_get_psk_identity() is used to retrieve the PSK identity used during the connection setup.

RETURN VALUES

If non-**NULL**, SSL_get_psk_identity_hint() returns the PSK identity hint and SSL_get_psk_identity() returns the PSK identity. Both are **NULL**-terminated. SSL_get_psk_identity_hint() may return **NULL** if no PSK identity hint was used during the connection setup.

Note that the return value is valid only during the lifetime of the SSL object **ssl**.

Name

SSL_get_rbio — get BIO linked to an SSL object

Synopsis

```
#include  <openssl/ssl.h>
```

```
BIO *SSL_get_rbio(SSL *ssl);
BIO *SSL_get_wbio(SSL *ssl);
```

DESCRIPTION

SSL_get_rbio() and SSL_get_wbio() return pointers to the BIOs for the read or the write channel, which can be different. The reference count of the BIO is not incremented.

RETURN VALUES

The following return values can occur:

NULL

No BIO was connected to the SSL object

Any other pointer

The BIO linked to **ssl**.

SEE ALSO

SSL_set_bio(3), ssl(3) , bio(3)

Name

SSL_get_session — retrieve TLS/SSL session data

Synopsis

```
#include  <openssl/ssl.h>
```

```
SSL_SESSION *SSL_get_session(const SSL *ssl);
SSL_SESSION *SSL_get0_session(const SSL *ssl);
SSL_SESSION *SSL_get1_session(SSL *ssl);
```

DESCRIPTION

SSL_get_session() returns a pointer to the **SSL_SESSION** actually used in **ssl**. The reference count of the **SSL_SESSION** is not incremented, so that the pointer can become invalid by other operations.

SSL_get0_session() is the same as SSL_get_session().

SSL_get1_session() is the same as SSL_get_session(), but the reference count of the **SSL_SESSION** is incremented by one.

NOTES

The ssl session contains all information required to re-establish the connection without a new handshake.

SSL_get0_session() returns a pointer to the actual session. As the reference counter is not incremented, the pointer is only valid while the connection is in use. If SSL_clear(3) or SSL_free(3) is called, the session may be removed completely (if considered bad), and the pointer obtained will become invalid. Even if the session is valid, it can be removed at any time due to timeout during SSL_CTX_flush_sessions(3).

If the data is to be kept, SSL_get1_session() will increment the reference count, so that the session will not be implicitly removed by other operations but stays in memory. In order to remove the session SSL_SESSION_free(3) must be explicitly called once to decrement the reference count again.

SSL_SESSION objects keep internal link information about the session cache list, when being inserted into one SSL_CTX object's session cache. One SSL_SESSION object, regardless of its reference count, must therefore only be used with one SSL_CTX object (and the SSL objects created from this SSL_CTX object).

RETURN VALUES

The following return values can occur:

NULL

> There is no session available in **ssl**.

Pointer to an SSL

> The return value points to the data of an SSL session.

SEE ALSO

ssl(3), SSL_free(3), SSL_clear(3), SSL_SESSION_free(3)

Name

SSL_get_SSL_CTX — get the SSL_CTX from which an SSL is created

Synopsis

```
#include  <openssl/ssl.h>
```

```
SSL_CTX *SSL_get_SSL_CTX(const SSL *ssl);
```

DESCRIPTION

SSL_get_SSL_CTX() returns a pointer to the SSL_CTX object, from which **ssl** was created with SSL_new(3).

RETURN VALUES

The pointer to the SSL_CTX object is returned.

SEE ALSO

ssl(3), SSL_new(3)

Name

SSL_get_verify_result — get result of peer certificate verification

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_get_verify_result(const SSL *ssl);
```

DESCRIPTION

SSL_get_verify_result() returns the result of the verification of the X509 certificate presented by the peer, if any.

NOTES

SSL_get_verify_result() can only return one error code while the verification of a certificate can fail because of many reasons at the same time. Only the last verification error that occurred during the processing is available from SSL_get_verify_result().

The verification result is part of the established session and is restored when a session is reused.

BUGS

If no peer certificate was presented, the returned result code is X509_V_OK. This is because no verification error occurred, it does however not indicate success. SSL_get_verify_result() is only useful in connection with SSL_get_peer_certificate(3).

RETURN VALUES

The following return values can currently occur:

X509_V_OK

> The verification succeeded or no peer certificate was presented.

Any other value

> Documented in verify(1).

SEE ALSO

ssl(3), SSL_set_verify_result(3), SSL_get_peer_certificate(3), verify(1)

Name

SSL_get_version — get the protocol version of a connection.

Synopsis

```
#include  <openssl/ssl.h>
```

```
const char *SSL_get_version(const SSL *ssl);
```

DESCRIPTION

SSL_get_version() returns the name of the protocol used for the connection **ssl**.

RETURN VALUES

The following strings can be returned:

SSLv2

> The connection uses the SSLv2 protocol.

SSLv3

> The connection uses the SSLv3 protocol.

TLSv1

> The connection uses the TLSv1.0 protocol.

TLSv1.1

> The connection uses the TLSv1.1 protocol.

TLSv1.2

> The connection uses the TLSv1.2 protocol.

unknown

> This indicates that no version has been set (no connection established).

SEE ALSO

ssl(3)

Name

SSL_library_init, OpenSSL_add_ssl_algorithms and SSLeay_add_ssl_algorithms — initialize SSL library by registering algorithms

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_library_init(void);
#define OpenSSL_add_ssl_algorithms()    SSL_library_init()
#define SSLeay_add_ssl_algorithms()     SSL_library_init()
```

DESCRIPTION

SSL_library_init() registers the available SSL/TLS ciphers and digests.

OpenSSL_add_ssl_algorithms() and SSLeay_add_ssl_algorithms() are synonyms for SSL_library_init().

NOTES

SSL_library_init() must be called before any other action takes place. SSL_library_init() is not reentrant.

WARNING

SSL_library_init() adds ciphers and digests used directly and indirectly by SSL/TLS.

EXAMPLES

A typical TLS/SSL application will start with the library initialization, and provide readable error messages.

```
SSL_load_error_strings();                /* readable error messages */
SSL_library_init();                      /* initialize library */
```

RETURN VALUES

SSL_library_init() always returns "1", so it is safe to discard the return value.

NOTES

OpenSSL 0.9.8o and 1.0.0a and later added SHA2 algorithms to SSL_library_init(). Applications which need to use SHA2 in earlier versions of OpenSSL should call OpenSSL_add_all_algorithms() as well.

SEE ALSO

ssl(3), SSL_load_error_strings(3), RAND_add(3)

Name

SSL_load_client_CA_file — load certificate names from file

Synopsis

```
#include  <openssl/ssl.h>
```

```
STACK_OF(X509_NAME) *SSL_load_client_CA_file(const char *file);
```

DESCRIPTION

SSL_load_client_CA_file() reads certificates from **file** and returns a STACK_OF(X509_NAME) with the subject names found.

NOTES

SSL_load_client_CA_file() reads a file of PEM formatted certificates and extracts the X509_NAMES of the certificates found. While the name suggests the specific usage as support function for SSL_CTX_set_client_CA_list(3), it is not limited to CA certificates.

EXAMPLES

Load names of CAs from file and use it as a client CA list:

```
SSL_CTX *ctx;
STACK_OF(X509_NAME) *cert_names;

…
cert_names = SSL_load_client_CA_file("/path/to/CAfile.pem");
if (cert_names != NULL)
  SSL_CTX_set_client_CA_list(ctx, cert_names);
else
  error_handling();
…
```

RETURN VALUES

The following return values can occur:

NULL

> The operation failed, check out the error stack for the reason.

Pointer to STACK_OF(X509_NAME)

> Pointer to the subject names of the successfully read certificates.

SEE ALSO

ssl(3), SSL_CTX_set_client_CA_list(3)

Name

SSL_new — create a new SSL structure for a connection

Synopsis

```
#include  <openssl/ssl.h>
```

```
SSL *SSL_new(SSL_CTX *ctx);
```

DESCRIPTION

SSL_new() creates a new **SSL** structure which is needed to hold the data for a TLS/SSL connection. The new structure inherits the settings of the underlying context **ctx**: connection method (SSLv2/v3/TLSv1), options, verification settings, timeout settings.

RETURN VALUES

The following return values can occur:

NULL

> The creation of a new SSL structure failed. Check the error stack to find out the reason.

Pointer to an SSL structure

> The return value points to an allocated SSL structure.

SEE ALSO

SSL_free(3), SSL_clear(3), SSL_CTX_set_options(3), SSL_get_SSL_CTX(3), ssl(3)

Name

SSL_pending — obtain number of readable bytes buffered in an SSL object

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_pending(const SSL *ssl);
```

DESCRIPTION

SSL_pending() returns the number of bytes which are available inside **ssl** for immediate read.

NOTES

Data are received in blocks from the peer. Therefore data can be buffered inside **ssl** and are ready for immediate retrieval with SSL_read(3).

RETURN VALUES

The number of bytes pending is returned.

BUGS

SSL_pending() takes into account only bytes from the TLS/SSL record that is currently being processed (if any). If the **SSL** object's *read_ahead* flag is set (see SSL_CTX_set_read_ahead(3)), additional protocol bytes may have been read containing more TLS/SSL records; these are ignored by SSL_pending().

Up to OpenSSL 0.9.6, SSL_pending() does not check if the record type of pending data is application data.

SEE ALSO

SSL_read(3), SSL_CTX_set_read_ahead(3), ssl(3)

Name

SSL_read — read bytes from a TLS/SSL connection.

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_read(SSL *ssl, void *buf, int num);
```

DESCRIPTION

SSL_read() tries to read **num** bytes from the specified **ssl** into the buffer **buf**.

NOTES

If necessary, SSL_read() will negotiate a TLS/SSL session, if not already explicitly performed by SSL_connect(3) or SSL_accept(3). If the peer requests a re-negotiation, it will be performed transparently during the SSL_read() operation. The behaviour of SSL_read() depends on the underlying BIO.

For the transparent negotiation to succeed, the **ssl** must have been initialized to client or server mode. This is being done by calling SSL_set_connect_state(3) or SSL_set_accept_state() before the first call to an SSL_read() or SSL_write(3) function.

SSL_read() works based on the SSL/TLS records. The data are received in records (with a maximum record size of 16kB for SSLv3/TLSv1). Only when a record has been completely received, it can be processed (decryption and check of integrity). Therefore data that was not retrieved at the last call of SSL_read() can still be buffered inside the SSL layer and will be retrieved on the next call to SSL_read(). If **num** is higher than the number of bytes buffered, SSL_read() will return with the bytes buffered. If no more bytes are in the buffer, SSL_read() will trigger the processing of the next record. Only when the record has been received and processed completely, SSL_read() will return reporting success. At most the contents of the record will be returned. As the size of an SSL/TLS record may exceed the maximum packet size of the underlying transport (e.g. TCP), it may be necessary to read several packets from the transport layer before the record is complete and SSL_read() can succeed.

If the underlying BIO is **blocking**, SSL_read() will only return, once the read operation has been finished or an error occurred, except when a renegotiation take place, in which case a SSL_ERROR_WANT_READ may occur. This behaviour can be controlled with the SSL_MODE_AUTO_RETRY flag of the SSL_CTX_set_mode(3) call.

If the underlying BIO is **non-blocking**, SSL_read() will also return when the underlying BIO could not satisfy the needs of SSL_read() to continue the operation. In this case a call to SSL_get_error(3) with the return value of SSL_read() will yield **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**. As at any time a re-negotiation is possible, a call to SSL_read() can also cause write operations! The calling process then must repeat the call after taking appropriate action to satisfy the needs of SSL_read(). The action depends on the underlying BIO. When using a non-blocking socket, nothing is to be done, but select() can be used to check for the required condition. When using a buffering BIO, like a BIO pair, data must be written into or retrieved out of the BIO before being able to continue.

SSL_pending(3) can be used to find out whether there are buffered bytes available for immediate retrieval. In this case SSL_read() can be called without blocking or actually receiving new data from the underlying socket.

WARNING

When an SSL_read() operation has to be repeated because of **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**, it must be repeated with the same arguments.

RETURN VALUES

The following return values can occur:

>0 The read operation was successful; the return value is the number of bytes actually read from the TLS/SSL connection.

0 The read operation was not successful. The reason may either be a clean shutdown due to a "close notify" alert sent by the peer (in which case the SSL_RECEIVED_SHUTDOWN flag in the ssl shutdown state is set (see SSL_shutdown(3), SSL_set_shutdown(3)). It is also possible, that the peer simply shut down the underlying transport and the shutdown is incomplete. Call SSL_get_error() with the return value **ret** to find out, whether an error occurred or the connection was shut down cleanly (SSL_ERROR_ZERO_RETURN).

SSLv2 (deprecated) does not support a shutdown alert protocol, so it can only be detected, whether the underlying connection was closed. It cannot be checked, whether the closure was initiated by the peer or by something else.

<0 The read operation was not successful, because either an error occurred or action must be taken by the calling process. Call SSL_get_error() with the return value **ret** to find out the reason.

Name

SSL_rstate_string and SSL_rstate_string_long — get textual description of state of an SSL object during read operation

Synopsis

```
#include  <openssl/ssl.h>
```

```
const char *SSL_rstate_string(SSL *ssl);
const char *SSL_rstate_string_long(SSL *ssl);
```

DESCRIPTION

SSL_rstate_string() returns a 2 letter string indicating the current read state of the SSL object **ssl**.

SSL_rstate_string_long() returns a string indicating the current read state of the SSL object **ssl**.

NOTES

When performing a read operation, the SSL/TLS engine must parse the record, consisting of header and body. When working in a blocking environment, SSL_rstate_string[_long]() should always return "RD"/"read done".

This function should only seldom be needed in applications.

RETURN VALUES

SSL_rstate_string() and SSL_rstate_string_long() can return the following values:

"RH"/"read header"	The header of the record is being evaluated.
"RB"/"read body"	The body of the record is being evaluated.
"RD"/"read done"	The record has been completely processed.
"unknown"/"unknown"	The read state is unknown. This should never happen.

SEE ALSO

ssl(3)

Name

SSL_SESSION_free — free an allocated SSL_SESSION structure

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_SESSION_free(SSL_SESSION *session);
```

DESCRIPTION

SSL_SESSION_free() decrements the reference count of **session** and removes the **SSL_SESSION** structure pointed to by **session** and frees up the allocated memory, if the reference count has reached 0.

NOTES

SSL_SESSION objects are allocated, when a TLS/SSL handshake operation is successfully completed. Depending on the settings, see SSL_CTX_set_session_cache_mode(3), the SSL_SESSION objects are internally referenced by the SSL_CTX and linked into its session cache. SSL objects may be using the SSL_SESSION object; as a session may be reused, several SSL objects may be using one SSL_SESSION object at the same time. It is therefore crucial to keep the reference count (usage information) correct and not delete a SSL_SESSION object that is still used, as this may lead to program failures due to dangling pointers. These failures may also appear delayed, e.g. when an SSL_SESSION object was completely freed as the reference count incorrectly became 0, but it is still referenced in the internal session cache and the cache list is processed during a SSL_CTX_flush_sessions(3) operation.

SSL_SESSION_free() must only be called for SSL_SESSION objects, for which the reference count was explicitly incremented (e.g. by calling SSL_get1_session(), see SSL_get_session(3)) or when the SSL_SESSION object was generated outside a TLS handshake operation, e.g. by using d2i_SSL_SESSION(3). It must not be called on other SSL_SESSION objects, as this would cause incorrect reference counts and therefore program failures.

RETURN VALUES

SSL_SESSION_free() does not provide diagnostic information.

SEE ALSO

ssl(3), SSL_get_session(3), SSL_CTX_set_session_cache_mode(3), SSL_CTX_flush_sessions(3), d2i_SSL_SESSION(3)

Name

SSL_SESSION_get_ex_new_index, SSL_SESSION_set_ex_data and SSL_SESSION_get_ex_data — internal application specific data functions

Synopsis

```

```
typedef int new_func(void *parent, void *ptr, CRYPTO_EX_DATA *ad,
               int idx, long argl, void *argp);
typedef void free_func(void *parent, void *ptr, CRYPTO_EX_DATA *ad,
               int idx, long argl, void *argp);
typedef int dup_func(CRYPTO_EX_DATA *to, CRYPTO_EX_DATA *from, void *from_d,
               int idx, long argl, void *argp);
```

DESCRIPTION

Several OpenSSL structures can have application specific data attached to them. These functions are used internally by OpenSSL to manipulate application specific data attached to a specific structure.

SSL_SESSION_get_ex_new_index() is used to register a new index for application specific data.

SSL_SESSION_set_ex_data() is used to store application data at **arg** for **idx** into the **session** object.

SSL_SESSION_get_ex_data() is used to retrieve the information for **idx** from **session**.

A detailed description for the ***_get_ex_new_index()** functionality can be found in RSA_get_ex_new_index(3). The ***_get_ex_data()** and ***_set_ex_data()** functionality is described in CRYPTO_set_ex_data(3).

WARNINGS

The application data is only maintained for sessions held in memory. The application data is not included when dumping the session with i2d_SSL_SESSION() (and all functions indirectly calling the dump functions like PEM_write_SSL_SESSION() and PEM_write_bio_SSL_SESSION()) and can therefore not be restored.

SEE ALSO

ssl(3), RSA_get_ex_new_index(3), CRYPTO_set_ex_data(3)

Name

SSL_SESSION_get_time, SSL_SESSION_set_time, SSL_SESSION_get_timeout and SSL_SESSION_set_timeout — retrieve and manipulate session time and timeout settings

Synopsis

```
#include  <openssl/ssl.h>
```

```
long SSL_SESSION_get_time(const SSL_SESSION *s);
long SSL_SESSION_set_time(SSL_SESSION *s, long tm);
long SSL_SESSION_get_timeout(const SSL_SESSION *s);
long SSL_SESSION_set_timeout(SSL_SESSION *s, long tm);
```

```
long SSL_get_time(const SSL_SESSION *s);
long SSL_set_time(SSL_SESSION *s, long tm);
long SSL_get_timeout(const SSL_SESSION *s);
long SSL_set_timeout(SSL_SESSION *s, long tm);
```

DESCRIPTION

SSL_SESSION_get_time() returns the time at which the session **s** was established. The time is given in seconds since the Epoch and therefore compatible to the time delivered by the time() call.

SSL_SESSION_set_time() replaces the creation time of the session **s** with the chosen value **tm**.

SSL_SESSION_get_timeout() returns the timeout value set for session **s** in seconds.

SSL_SESSION_set_timeout() sets the timeout value for session **s** in seconds to **tm**.

The SSL_get_time(), SSL_set_time(), SSL_get_timeout(), and SSL_set_timeout() functions are synonyms for the SSL_SESSION_*() counterparts.

NOTES

Sessions are expired by examining the creation time and the timeout value. Both are set at creation time of the session to the actual time and the default timeout value at creation, respectively, as set by SSL_CTX_set_timeout(3). Using these functions it is possible to extend or shorten the lifetime of the session.

RETURN VALUES

SSL_SESSION_get_time() and SSL_SESSION_get_timeout() return the currently valid values.

SSL_SESSION_set_time() and SSL_SESSION_set_timeout() return 1 on success.

If any of the function is passed the NULL pointer for the session **s**, 0 is returned.

SEE ALSO

ssl(3), SSL_CTX_set_timeout(3), SSL_get_default_timeout(3)

Name

SSL_session_reused — query whether a reused session was negotiated during handshake

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_session_reused(SSL *ssl);
```

DESCRIPTION

Query, whether a reused session was negotiated during the handshake.

NOTES

During the negotiation, a client can propose to reuse a session. The server then looks up the session in its cache. If both client and server agree on the session, it will be reused and a flag is being set that can be queried by the application.

RETURN VALUES

The following return values can occur:

0 A new session was negotiated.

1 A session was reused.

SEE ALSO

ssl(3), SSL_set_session(3), SSL_CTX_set_session_cache_mode(3)

Name

SSL_set_bio — connect the SSL object with a BIO

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_set_bio(SSL *ssl, BIO *rbio, BIO *wbio);
```

DESCRIPTION

SSL_set_bio() connects the BIOs **rbio** and **wbio** for the read and write operations of the TLS/SSL (encrypted) side of **ssl**.

The SSL engine inherits the behaviour of **rbio** and **wbio**, respectively. If a BIO is non-blocking, the **ssl** will also have non-blocking behaviour.

If there was already a BIO connected to **ssl**, BIO_free() will be called (for both the reading and writing side, if different).

RETURN VALUES

SSL_set_bio() cannot fail.

SEE ALSO

SSL_get_rbio(3), SSL_connect(3), SSL_accept(3), SSL_shutdown(3), ssl(3), bio(3)

Name

SSL_set_connect_state and SSL_get_accept_state — prepare SSL object to work in client or server mode

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_set_connect_state(SSL *ssl);
```

```
void SSL_set_accept_state(SSL *ssl);
```

DESCRIPTION

SSL_set_connect_state() sets **ssl** to work in client mode.

SSL_set_accept_state() sets **ssl** to work in server mode.

NOTES

When the SSL_CTX object was created with SSL_CTX_new(3), it was either assigned a dedicated client method, a dedicated server method, or a generic method, that can be used for both client and server connections. (The method might have been changed with SSL_CTX_set_ssl_version(3) or SSL_set_ssl_method().)

When beginning a new handshake, the SSL engine must know whether it must call the connect (client) or accept (server) routines. Even though it may be clear from the method chosen, whether client or server mode was requested, the handshake routines must be explicitly set.

When using the SSL_connect(3) or SSL_accept(3) routines, the correct handshake routines are automatically set. When performing a transparent negotiation using SSL_write(3) or SSL_read(3), the handshake routines must be explicitly set in advance using either SSL_set_connect_state() or SSL_set_accept_state().

RETURN VALUES

SSL_set_connect_state() and SSL_set_accept_state() do not return diagnostic information.

SEE ALSO

ssl(3), SSL_new(3), SSL_CTX_new(3), SSL_connect(3), SSL_accept(3), SSL_write(3), SSL_read(3), SSL_do_handshake(3), SSL_CTX_set_ssl_version(3)

Name

SSL_set_fd — connect the SSL object with a file descriptor

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_set_fd(SSL *ssl, int fd);
int SSL_set_rfd(SSL *ssl, int fd);
int SSL_set_wfd(SSL *ssl, int fd);
```

DESCRIPTION

SSL_set_fd() sets the file descriptor **fd** as the input/output facility for the TLS/SSL (encrypted) side of **ssl**. **fd** will typically be the socket file descriptor of a network connection.

When performing the operation, a **socket BIO** is automatically created to interface between the **ssl** and **fd**. The BIO and hence the SSL engine inherit the behaviour of **fd**. If **fd** is non-blocking, the **ssl** will also have non-blocking behaviour.

If there was already a BIO connected to **ssl**, BIO_free() will be called (for both the reading and writing side, if different).

SSL_set_rfd() and SSL_set_wfd() perform the respective action, but only for the read channel or the write channel, which can be set independently.

RETURN VALUES

The following return values can occur:

0 The operation failed. Check the error stack to find out why.

1 The operation succeeded.

SEE ALSO

SSL_get_fd(3), SSL_set_bio(3), SSL_connect(3), SSL_accept(3), SSL_shutdown(3), ssl(3) , bio(3)

Name

SSL_set_session — set a TLS/SSL session to be used during TLS/SSL connect

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_set_session(SSL *ssl, SSL_SESSION *session);
```

DESCRIPTION

SSL_set_session() sets **session** to be used when the TLS/SSL connection is to be established. SSL_set_session() is only useful for TLS/SSL clients. When the session is set, the reference count of **session** is incremented by 1. If the session is not reused, the reference count is decremented again during SSL_connect(). Whether the session was reused can be queried with the SSL_session_reused(3) call.

If there is already a session set inside **ssl** (because it was set with SSL_set_session() before or because the same **ssl** was already used for a connection), SSL_SESSION_free() will be called for that session.

NOTES

SSL_SESSION objects keep internal link information about the session cache list, when being inserted into one SSL_CTX object's session cache. One SSL_SESSION object, regardless of its reference count, must therefore only be used with one SSL_CTX object (and the SSL objects created from this SSL_CTX object).

RETURN VALUES

The following return values can occur:

0 The operation failed; check the error stack to find out the reason.

1 The operation succeeded.

SEE ALSO

ssl(3), SSL_SESSION_free(3), SSL_get_session(3), SSL_session_reused(3), SSL_CTX_set_session_cache_mode(3)

Name

SSL_set_shutdown and SSL_get_shutdown — manipulate shutdown state of an SSL connection

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_set_shutdown(SSL *ssl, int mode);
```

```
int SSL_get_shutdown(const SSL *ssl);
```

DESCRIPTION

SSL_set_shutdown() sets the shutdown state of **ssl** to **mode**.

SSL_get_shutdown() returns the shutdown mode of **ssl**.

NOTES

The shutdown state of an ssl connection is a bitmask of:

0

No shutdown setting, yet.

SSL_SENT_SHUTDOWN

A "close notify" shutdown alert was sent to the peer, the connection is being considered closed and the session is closed and correct.

SSL_RECEIVED_SHUTDOWN

A shutdown alert was received form the peer, either a normal "close notify" or a fatal error.

SSL_SENT_SHUTDOWN and SSL_RECEIVED_SHUTDOWN can be set at the same time.

The shutdown state of the connection is used to determine the state of the ssl session. If the session is still open, when SSL_clear(3) or SSL_free(3) is called, it is considered bad and removed according to RFC2246. The actual condition for a correctly closed session is SSL_SENT_SHUTDOWN (according to the TLS RFC, it is acceptable to only send the "close notify" alert but to not wait for the peer's answer, when the underlying connection is closed). SSL_set_shutdown() can be used to set this state without sending a close alert to the peer (see SSL_shutdown(3)).

If a "close notify" was received, SSL_RECEIVED_SHUTDOWN will be set, for setting SSL_SENT_SHUTDOWN the application must however still call SSL_shutdown(3) or SSL_set_shutdown() itself.

RETURN VALUES

SSL_set_shutdown() does not return diagnostic information.

SSL_get_shutdown() returns the current setting.

SEE ALSO

ssl(3), SSL_shutdown(3), SSL_CTX_set_quiet_shutdown(3), SSL_clear(3), SSL_free(3)

Name

SSL_set_verify_result — override result of peer certificate verification

Synopsis

```
#include  <openssl/ssl.h>
```

```
void SSL_set_verify_result(SSL *ssl, long verify_result);
```

DESCRIPTION

SSL_set_verify_result() sets **verify_result** of the object **ssl** to be the result of the verification of the X509 certificate presented by the peer, if any.

NOTES

SSL_set_verify_result() overrides the verification result. It only changes the verification result of the **ssl** object. It does not become part of the established session, so if the session is to be reused later, the original value will reappear.

The valid codes for **verify_result** are documented in verify(1).

RETURN VALUES

SSL_set_verify_result() does not provide a return value.

SEE ALSO

ssl(3), SSL_get_verify_result(3), SSL_get_peer_certificate(3), verify(1)

Name

SSL_shutdown — shut down a TLS/SSL connection

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_shutdown(SSL *ssl);
```

DESCRIPTION

SSL_shutdown() shuts down an active TLS/SSL connection. It sends the "close notify" shutdown alert to the peer.

NOTES

SSL_shutdown() tries to send the "close notify" shutdown alert to the peer. Whether the operation succeeds or not, the SSL_SENT_SHUTDOWN flag is set and a currently open session is considered closed and good and will be kept in the session cache for further reuse.

The shutdown procedure consists of 2 steps: the sending of the "close notify" shutdown alert and the reception of the peer's "close notify" shutdown alert. According to the TLS standard, it is acceptable for an application to only send its shutdown alert and then close the underlying connection without waiting for the peer's response (this way resources can be saved, as the process can already terminate or serve another connection). When the underlying connection shall be used for more communications, the complete shutdown procedure (bidirectional "close notify" alerts) must be performed, so that the peers stay synchronized.

SSL_shutdown() supports both uni- and bidirectional shutdown by its 2 step behaviour.

- When the application is the first party to send the "close notify" alert, SSL_shutdown() will only send the alert and then set the SSL_SENT_SHUTDOWN flag (so that the session is considered good and will be kept in cache). SSL_shutdown() will then return with 0. If a unidirectional shutdown is enough (the underlying connection shall be closed anyway), this first call to SSL_shutdown() is sufficient. In order to complete the bidirectional shutdown handshake, SSL_shutdown() must be called again. The second call will make SSL_shutdown() wait for the peer's "close notify" shutdown alert. On success, the second call to SSL_shutdown() will return with 1.
- If the peer already sent the "close notify" alert **and** it was already processed implicitly inside another function (SSL_read(3)), the SSL_RECEIVED_SHUTDOWN flag is set. SSL_shutdown() will send the "close notify" alert, set the SSL_SENT_SHUTDOWN flag and will immediately return with 1. Whether SSL_RECEIVED_SHUTDOWN is already set can be checked using the SSL_get_shutdown() (see also SSL_set_shutdown(3) call.

It is therefore recommended, to check the return value of SSL_shutdown() and call SSL_shutdown() again, if the bidirectional shutdown is not yet complete (return value of the first call is 0). As the shutdown is not specially handled in the SSLv2 protocol, SSL_shutdown() will succeed on the first call.

The behaviour of SSL_shutdown() additionally depends on the underlying BIO.

If the underlying BIO is **blocking**, SSL_shutdown() will only return once the handshake step has been finished or an error occurred.

If the underlying BIO is **non-blocking**, SSL_shutdown() will also return when the underlying BIO could not satisfy the needs of SSL_shutdown() to continue the handshake. In this case a call to SSL_get_error() with the return value of SSL_shutdown() will yield **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**. The calling process then must repeat the call after taking appropriate action to satisfy the needs of SSL_shutdown(). The action depends on the underlying BIO. When using a non-blocking socket, nothing is to be done, but select() can be used to check for the required condition. When using a buffering BIO, like a BIO pair, data must be written into or retrieved out of the BIO before being able to continue.

SSL_shutdown() can be modified to only set the connection to "shutdown" state but not actually send the "close notify" alert messages, see SSL_CTX_set_quiet_shutdown(3). When "quiet shutdown" is enabled, SSL_shutdown() will always succeed and return 1.

RETURN VALUES

The following return values can occur:

0 The shutdown is not yet finished. Call SSL_shutdown() for a second time, if a bidirectional shutdown shall be performed. The output of SSL_get_error(3) may be misleading, as an erroneous SSL_ERROR_SYSCALL may be flagged even though no error occurred.

1 The shutdown was successfully completed. The "close notify" alert was sent and the peer's "close notify" alert was received.

-1 The shutdown was not successful because a fatal error occurred either at the protocol level or a connection failure occurred. It can also occur if action is need to continue the operation for non-blocking BIOs. Call SSL_get_error(3) with the return value **ret** to find out the reason.

SEE ALSO

Name

SSL_state_string and SSL_state_string_long — get textual description of state of an SSL object

Synopsis

```
#include  <openssl/ssl.h>
```

```
const char *SSL_state_string(const SSL *ssl);
const char *SSL_state_string_long(const SSL *ssl);
```

DESCRIPTION

SSL_state_string() returns a 6 letter string indicating the current state of the SSL object **ssl**.

SSL_state_string_long() returns a string indicating the current state of the SSL object **ssl**.

NOTES

During its use, an SSL objects passes several states. The state is internally maintained. Querying the state information is not very informative before or when a connection has been established. It however can be of significant interest during the handshake.

When using non-blocking sockets, the function call performing the handshake may return with SSL_ERROR_WANT_READ or SSL_ERROR_WANT_WRITE condition, so that SSL_state_string[_long]() may be called.

For both blocking or non-blocking sockets, the details state information can be used within the info_callback function set with the SSL_set_info_callback() call.

RETURN VALUES

Detailed description of possible states to be included later.

SEE ALSO

ssl(3), SSL_CTX_set_info_callback(3)

Name

SSL_want, SSL_want_nothing, SSL_want_read, SSL_want_write and SSL_want_x509_lookup — obtain state information TLS/SSL I/O operation

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_want(const SSL *ssl);
int SSL_want_nothing(const SSL *ssl);
int SSL_want_read(const SSL *ssl);
int SSL_want_write(const SSL *ssl);
int SSL_want_x509_lookup(const SSL *ssl);
```

DESCRIPTION

SSL_want() returns state information for the SSL object **ssl**.

The other SSL_want_*() calls are shortcuts for the possible states returned by SSL_want().

NOTES

SSL_want() examines the internal state information of the SSL object. Its return values are similar to that of SSL_get_error(3). Unlike SSL_get_error(3), which also evaluates the error queue, the results are obtained by examining an internal state flag only. The information must therefore only be used for normal operation under non-blocking I/O. Error conditions are not handled and must be treated using SSL_get_error(3).

The result returned by SSL_want() should always be consistent with the result of SSL_get_error(3).

RETURN VALUES

The following return values can currently occur for SSL_want():

SSL_NOTHING

> There is no data to be written or to be read.

SSL_WRITING

> There are data in the SSL buffer that must be written to the underlying **BIO** layer in order to complete the actual SSL_*() operation. A call to SSL_get_error(3) should return SSL_ERROR_WANT_WRITE.

SSL_READING

> More data must be read from the underlying **BIO** layer in order to complete the actual SSL_*() operation. A call to SSL_get_error(3) should return SSL_ERROR_WANT_READ.

SSL_X509_LOOKUP

> The operation did not complete because an application callback set by SSL_CTX_set_client_cert_cb() has asked to be called again. A call to SSL_get_error(3) should return SSL_ERROR_WANT_X509_LOOKUP.

SSL_want_nothing(), SSL_want_read(), SSL_want_write(), SSL_want_x509_lookup() return 1, when the corresponding condition is true or 0 otherwise.

SEE ALSO

ssl(3), err(3), SSL_get_error(3)

Name

SSL_write — write bytes to a TLS/SSL connection.

Synopsis

```
#include  <openssl/ssl.h>
```

```
int SSL_write(SSL *ssl, const void *buf, int num);
```

DESCRIPTION

SSL_write() writes **num** bytes from the buffer **buf** into the specified **ssl** connection.

NOTES

If necessary, SSL_write() will negotiate a TLS/SSL session, if not already explicitly performed by SSL_connect(3) or SSL_accept(3). If the peer requests a re-negotiation, it will be performed transparently during the SSL_write() operation. The behaviour of SSL_write() depends on the underlying BIO.

For the transparent negotiation to succeed, the **ssl** must have been initialized to client or server mode. This is being done by calling SSL_set_connect_state(3) or SSL_set_accept_state() before the first call to an SSL_read(3) or SSL_write() function.

If the underlying BIO is **blocking**, SSL_write() will only return, once the write operation has been finished or an error occurred, except when a renegotiation take place, in which case a SSL_ERROR_WANT_READ may occur. This behaviour can be controlled with the SSL_MODE_AUTO_RETRY flag of the SSL_CTX_set_mode(3) call.

If the underlying BIO is **non-blocking**, SSL_write() will also return, when the underlying BIO could not satisfy the needs of SSL_write() to continue the operation. In this case a call to SSL_get_error(3) with the return value of SSL_write() will yield **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**. As at any time a re-negotiation is possible, a call to SSL_write() can also cause read operations! The calling process then must repeat the call after taking appropriate action to satisfy the needs of SSL_write(). The action depends on the underlying BIO. When using a non-blocking socket, nothing is to be done, but select() can be used to check for the required condition. When using a buffering BIO, like a BIO pair, data must be written into or retrieved out of the BIO before being able to continue.

SSL_write() will only return with success, when the complete contents of **buf** of length **num** has been written. This default behaviour can be changed with the SSL_MODE_ENABLE_PARTIAL_WRITE option of SSL_CTX_set_mode(3). When this flag is set, SSL_write() will also return with success, when a partial write has been successfully completed. In this case the SSL_write() operation is considered completed. The bytes are sent and a new SSL_write() operation with a new buffer (with the already sent bytes removed) must be started. A partial write is performed with the size of a message block, which is 16kB for SSLv3/TLSv1.

WARNING

When an SSL_write() operation has to be repeated because of **SSL_ERROR_WANT_READ** or **SSL_ERROR_WANT_WRITE**, it must be repeated with the same arguments.

When calling SSL_write() with num=0 bytes to be sent the behaviour is undefined.

RETURN VALUES

The following return values can occur:

>0 The write operation was successful, the return value is the number of bytes actually written to the TLS/SSL connection.

0 The write operation was not successful. Probably the underlying connection was closed. Call SSL_get_error() with the return value **ret** to find out, whether an error occurred or the connection was shut down cleanly (SSL_ERROR_ZERO_RETURN).

SSLv2 (deprecated) does not support a shutdown alert protocol, so it can only be detected, whether the underlying connection was closed. It cannot be checked, why the closure happened.

<0 The write operation was not successful, because either an error occurred or action must be taken by the calling process. Call SSL_get_error() with the return value **ret** to find out the reason.

Part XLVIII. Mbed TLS

Table of Contents

Chapter 180. Mbed TLS overview

Introduction

The CYGPKG_MBEDTLS package provides a standard Mbed TLS world to eCos applications.

This package is covered by the Apache 2.0 license as distributed in the original Mbed TLS package:

Example 180.1. Apache 2.0 License

```
                                 Apache License
                           Version 2.0, January 2004
                        http://www.apache.org/licenses/

   TERMS AND CONDITIONS FOR USE, REPRODUCTION, AND DISTRIBUTION

   1. Definitions.

      "License" shall mean the terms and conditions for use, reproduction,
      and distribution as defined by Sections 1 through 9 of this document.

      "Licensor" shall mean the copyright owner or entity authorized by
      the copyright owner that is granting the License.

      "Legal Entity" shall mean the union of the acting entity and all
      other entities that control, are controlled by, or are under common
      control with that entity. For the purposes of this definition,
      "control" means (i) the power, direct or indirect, to cause the
      direction or management of such entity, whether by contract or
      otherwise, or (ii) ownership of fifty percent (50%) or more of the
      outstanding shares, or (iii) beneficial ownership of such entity.

      "You" (or "Your") shall mean an individual or Legal Entity
      exercising permissions granted by this License.

      "Source" form shall mean the preferred form for making modifications,
      including but not limited to software source code, documentation
      source, and configuration files.

      "Object" form shall mean any form resulting from mechanical
      transformation or translation of a Source form, including but
      not limited to compiled object code, generated documentation,
      and conversions to other media types.

      "Work" shall mean the work of authorship, whether in Source or
      Object form, made available under the License, as indicated by a
      copyright notice that is included in or attached to the work
      (an example is provided in the Appendix below).

      "Derivative Works" shall mean any work, whether in Source or Object
      form, that is based on (or derived from) the Work and for which the
      editorial revisions, annotations, elaborations, or other modifications
      represent, as a whole, an original work of authorship. For the purposes
      of this License, Derivative Works shall not include works that remain
      separable from, or merely link (or bind by name) to the interfaces of,
      the Work and Derivative Works thereof.

      "Contribution" shall mean any work of authorship, including
      the original version of the Work and any modifications or additions
      to that Work or Derivative Works thereof, that is intentionally
      submitted to Licensor for inclusion in the Work by the copyright owner
      or by an individual or Legal Entity authorized to submit on behalf of
      the copyright owner. For the purposes of this definition, "submitted"
      means any form of electronic, verbal, or written communication sent
      to the Licensor or its representatives, including but not limited to
      communication on electronic mailing lists, source code control systems,
      and issue tracking systems that are managed by, or on behalf of, the
      Licensor for the purpose of discussing and improving the Work, but
      excluding communication that is conspicuously marked or otherwise
      designated in writing by the copyright owner as "Not a Contribution."

      "Contributor" shall mean Licensor and any individual or Legal Entity
      on behalf of whom a Contribution has been received by Licensor and
      subsequently incorporated within the Work.

   2. Grant of Copyright License. Subject to the terms and conditions of
      this License, each Contributor hereby grants to You a perpetual,
      worldwide, non-exclusive, no-charge, royalty-free, irrevocable
      copyright license to reproduce, prepare Derivative Works of,
      publicly display, publicly perform, sublicense, and distribute the
      Work and such Derivative Works in Source or Object form.

   3. Grant of Patent License. Subject to the terms and conditions of
      this License, each Contributor hereby grants to You a perpetual,
      worldwide, non-exclusive, no-charge, royalty-free, irrevocable
      (except as stated in this section) patent license to make, have made,
      use, offer to sell, sell, import, and otherwise transfer the Work,
      where such license applies only to those patent claims licensable
      by such Contributor that are necessarily infringed by their
      Contribution(s) alone or by combination of their Contribution(s)
      with the Work to which such Contribution(s) was submitted. If You
      institute patent litigation against any entity (including a
      cross-claim or counterclaim in a lawsuit) alleging that the Work
      or a Contribution incorporated within the Work constitutes direct
      or contributory patent infringement, then any patent licenses
      granted to You under this License for that Work shall terminate
      as of the date such litigation is filed.

   4. Redistribution. You may reproduce and distribute copies of the
      Work or Derivative Works thereof in any medium, with or without
      modifications, and in Source or Object form, provided that You
      meet the following conditions:

      (a) You must give any other recipients of the Work or
          Derivative Works a copy of this License; and

      (b) You must cause any modified files to carry prominent notices
          stating that You changed the files; and

      (c) You must retain, in the Source form of any Derivative Works
          that You distribute, all copyright, patent, trademark, and
          attribution notices from the Source form of the Work,
          excluding those notices that do not pertain to any part of
          the Derivative Works; and

      (d) If the Work includes a "NOTICE" text file as part of its
          distribution, then any Derivative Works that You distribute must
          include a readable copy of the attribution notices contained
          within such NOTICE file, excluding those notices that do not
          pertain to any part of the Derivative Works, in at least one
          of the following places: within a NOTICE text file distributed
          as part of the Derivative Works; within the Source form or
          documentation, if provided along with the Derivative Works; or,
          within a display generated by the Derivative Works, if and
          wherever such third-party notices normally appear. The contents
          of the NOTICE file are for informational purposes only and
          do not modify the License. You may add Your own attribution
          notices within Derivative Works that You distribute, alongside
          or as an addendum to the NOTICE text from the Work, provided
          that such additional attribution notices cannot be construed
          as modifying the License.

      You may add Your own copyright statement to Your modifications and
      may provide additional or different license terms and conditions
      for use, reproduction, or distribution of Your modifications, or
      for any such Derivative Works as a whole, provided Your use,
      reproduction, and distribution of the Work otherwise complies with
      the conditions stated in this License.

   5. Submission of Contributions. Unless You explicitly state otherwise,
      any Contribution intentionally submitted for inclusion in the Work
      by You to the Licensor shall be under the terms and conditions of
      this License, without any additional terms or conditions.
      Notwithstanding the above, nothing herein shall supersede or modify
      the terms of any separate license agreement you may have executed
      with Licensor regarding such Contributions.

   6. Trademarks. This License does not grant permission to use the trade
      names, trademarks, service marks, or product names of the Licensor,
      except as required for reasonable and customary use in describing the
      origin of the Work and reproducing the content of the NOTICE file.

   7. Disclaimer of Warranty. Unless required by applicable law or
      agreed to in writing, Licensor provides the Work (and each
      Contributor provides its Contributions) on an "AS IS" BASIS,
      WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or
      implied, including, without limitation, any warranties or conditions
      of TITLE, NON-INFRINGEMENT, MERCHANTABILITY, or FITNESS FOR A
      PARTICULAR PURPOSE. You are solely responsible for determining the
      appropriateness of using or redistributing the Work and assume any
      risks associated with Your exercise of permissions under this License.

   8. Limitation of Liability. In no event and under no legal theory,
      whether in tort (including negligence), contract, or otherwise,
      unless required by applicable law (such as deliberate and grossly
      negligent acts) or agreed to in writing, shall any Contributor be
      liable to You for damages, including any direct, indirect, special,
      incidental, or consequential damages of any character arising as a
      result of this License or out of the use or inability to use the
      Work (including but not limited to damages for loss of goodwill,
      work stoppage, computer failure or malfunction, or any and all
      other commercial damages or losses), even if such Contributor
      has been advised of the possibility of such damages.

   9. Accepting Warranty or Additional Liability. While redistributing
      the Work or Derivative Works thereof, You may choose to offer,
      and charge a fee for, acceptance of support, warranty, indemnity,
      or other liability obligations and/or rights consistent with this
      License. However, in accepting such obligations, You may act only
      on Your own behalf and on Your sole responsibility, not on behalf
      of any other Contributor, and only if You agree to indemnify,
      defend, and hold each Contributor harmless for any liability
      incurred by, or claims asserted against, such Contributor by reason
      of your accepting any such warranty or additional liability.

   END OF TERMS AND CONDITIONS

   APPENDIX: How to apply the Apache License to your work.

      To apply the Apache License to your work, attach the following
      boilerplate notice, with the fields enclosed by brackets "[]"
      replaced with your own identifying information. (Don't include
      the brackets!)  The text should be enclosed in the appropriate
      comment syntax for the file format. We also recommend that a
      file or class name and description of purpose be included on the
      same "printed page" as the copyright notice for easier
      identification within third-party archives.

   Copyright [yyyy] [name of copyright owner]

   Licensed under the Apache License, Version 2.0 (the "License");
   you may not use this file except in compliance with the License.
   You may obtain a copy of the License at

       http://www.apache.org/licenses/LICENSE-2.0

   Unless required by applicable law or agreed to in writing, software
   distributed under the License is distributed on an "AS IS" BASIS,
   WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied.
   See the License for the specific language governing permissions and
   limitations under the License.
```

For definitive Mbed TLS documentation please refer to the main Mbed TLS Dev Corner website. We do not duplicate that documentation here.

Mbed TLS is now part of Trusted Firmware. The Trusted Firmware Mbed TLS wiki providing a useful overview.

Chapter 181. Configuration

This chapter shows how to incorporate the Mbed TLS support into an eCos configuration, and how to configure it once included.

Configuration Overview

The Mbed TLS support is contained in a single eCos package `CYGPKG_MBEDTLS`. However, some functionality is dependant on other eCos features. e.g. the eCos networking stack support.

Quick Start

Incorporating the Mbed TLS support into your application is straightforward. The essential starting point is to incorporate the Mbed TLS eCos package (`CYGPKG_MBEDTLS`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Depending on the Mbed TLS package configuration other packages may be required (e.g. network stack support). The package requires that the `CYGPKG_INFRA` and `CYGPKG_MEMALLOC` packages are included in the eCos application configuration.

Chapter 182. eCos port

Overview

The goal for the `CYGPKG_MBEDTLS` package is to avoid where possible having to have any core Mbed TLS source file changes made specifically for eCos. This is to ensure that re-imports of newer versions of the Mbed TLS world involve minimal effort. The files are as provided in the official Mbed TLS release package as imported, with the following exceptions:

1. Files have been moved, unmodified, to create a standard eCos package tree structure to integrate with the eCosPro build environment
2. The files `src/platform.c`, `include/platform.h` and `include/config.h` have changes to allow compilation as an eCos package
3. The file `src/ecos_net_sockets.c` provides the internal Mbed TLS network API (as originally provided by `src/net_sockets.c`) to support the eCos network stacks (e.g. `CYGPKG_NET_LWIP` or `CYGPKG_NET_FREEBSD_STACK`).
4. The file `tests/selftest.c` has been modified with some eCos specific code to allow use in the eCos automated test farm. The core of the selftest functionality is unchanged however

The current Mbed TLS version provided by the eCos package is `2.28.7` (with `2.28` being a Long Term Support (LTS) release supported until at least 2024Q4). Please read the package `ChangeLog` file for the original Mbed TLS release notes which are interleaved with the commments covering eCosCentric changes.

Entropy

Cryptographic security is dependent on the use of **strong** keys. Strong keys are dependent on the quality of entropy used in their generation.

The eCosPro port of Mbed TLS provides both a default portable weak entropy mechanism, and the ability to implement a target platform specific mechanism to gather high-quality entropy.

We strongly recommend that you use as high a quality source of entropy as possible when using Mbed TLS on your target platform. The use of the generic weak entropy mechanism (provided by `MBEDTLS_TIMING_C`) is **NOT** recommended for anything other than simplifying initial bring-up and testing.

For eCos we define `MBEDTLS_ENTROPY_HARDWARE_ALT` for the configuration (in `include/mbedtls/config.h`) since the default Mbed TLS platform entropy implementation is Un*x/Windows only. The use of `MBEDTLS_ENTROPY_HARDWARE_ALT` provides for a link-time entropy source to be provided by the platform support. Other entropy sources are dynamically added at runtime via the `mbedtls_entropy_add_source()` functionality.

Note

In the following *weak* refers to the linker preference when linking an application and not to a weak entropy source.

The Mbed TLS package `src/platform.c` source file provides a **weak** function definition for the `mbedtls_hardware_poll()` implementation that will return `MBEDTLS_ERR_ENTROPY_SOURCE_FAILED` since we expect the platform support or application code to provide a cryptographically strong implementation. Ideally such an implementation will use TRNG (True Random Number Generator) hardware support by the HAL, variant, architecture, etc. as appropriate.

The function prototype:

#include <mbedtls/entropy_poll.h>

`int **mbedtls_hardware_poll**(*data*, *output*, *len*, *olen*);`

conforms to the entropy provision API for routines declared via the `mbedtls_entropy_add_source()` API (in fact the Mbed TLS run-time will add `mbedtls_hardware_poll()` automatically via that mechanism).

The callback specific (context data pointer) parameter *`data`* will normally be `NULL` for the Mbed TLS registered implementation. The *`output`* parameter references a buffer of at least *`len`* bytes to receive random data. The *`olen`* pointer is filled by the function to report the number of **valid** bytes actually written, and may be 0 (zero) if the function is not able to satisfy the request for true random data. The function should return 0 to indicate no errors occurred, or `MBEDTLS_ERR_ENTROPY_SOURCE_FAILED` on error.

As an example of a platform specific implementation, the STM32 port of eCos provides an Mbed TLS entropy source based on the STM32's `RNG` hardware.

Chapter 183. Test Programs

Test Programs

Some Mbed TLS specific tests are built and can be used to verify correct operation of the Mbed TLS library.

1. `selftest`

   This test executes the internal Mbed TLS sanity tests to verify correct operation of the various features.

2. `cpp_dummy_build`

   This is a simple sanity test that the Mbed TLS headers can be included in C++ compilations.

3. `lb_ssl`

   When an eCos network configuration is available (lwIP or FreeBSD) then this test will perform a client/server local loopback SSL connection using certificates. This is a complete test of a secure `HTTPS` connection using BSD style sockets. To make it easier to work with either the client or the server side the source for the test is split into multiple files, with the client and server side implementations being in their own source files. The relevant client and server side sources are, lightly modified for eCos, versions of the original Mbed TLS source files found respectively in `mbedtls-mbedtls-2.28.5/programs/ssl/ssl_client1.c` and `mbedtls-mbedtls-2.28.5/programs/ssl/ssl_server.c`.

   The following is example output from a run of the test:

   ### Example 183.1. lb_ssl test run

Part XLIX. eCosPro-SecureShell

Important

eCosPro-SecureShell is distributed as an optional set of eCos add-on packages that may not be included in your release of eCosPro. If these packages are not listed in either the graphical or command line eCos Configuration tool, please contact eCosCentric for availability and pricing.

Name

CYGPKG_NET_DROPBEAR — provide ssh support

Description

Note

The *eCosPro-SecureShell* package is the formal product name of the eCos Dropbear Port and the two can be used interchangeably to refer to this package.

CYGPKG_NET_DROPBEAR is a port to eCos of some of the ssh functionality of the dropbear code. It supports the following:

1. Server support. This allows remote clients to log in to an eCos system and run commands. Of course eCos does not have a full-blown shell and the ability to run arbitrary commands loaded from disk. Instead the ssh connection is passed on to functions within the application code which can read the data coming from the remote ssh client and take appropriate action. The package ships with two examples: a simple shell-like application and an interactive game.

2. Client support. This allows the eCos application to establish a secure connection to a remote server, for example a PC running Linux and openssh, run a command on that server, and interact with that command.

3. Client-side scp support. This builds on the generic client support. It allows eCos applications to read and write files on a remote server over a secure connection.

The port only provides a core subset of the standard dropbear functionality. For example more advanced features like agent forwarding and X11 forwarding are not supported because those would add significantly to the overhead and complexity of the code, and would rarely be used in practice.

Ssh secure communication comes at a price. Depending on the architecture it will typically add 100-200K to the application's code size. The data requirements are considerable, including a need for 32K data buffers and multiple threads. The code will require a lot of cpu cycles. A typical embedded processor running eCos is much slower than the typical cpu of a desktop PC, and the dropbear code will take correspondingly longer to perform a given operation. Establishing an ssh connection is especially expensive and may take some seconds or even tens of seconds of cpu time. Once the connection has been established the cpu overheads are lower, but still significant. Finally the dropbear code makes extensive demands on the lower-level TCP/IP and I/O layers and various configuration options in those layers may need adjusting, as described below.

Configuration

The eCos dropbear port is intended to work in conjunction with the full BSD TCP/IP package and has numerous dependencies. Most of these can be satisfied simply by creating the eCos configuration using the net template. The dropbear package has additional dependencies on the LibTomMath multi-precision arithmetic package CYGPKG_MATH_LIBTOMMATH and the LibTomCrypt cryptography library CYGPKG_CRYPT_LIBTOMCRYPT, so those packages will have to be added explicitly to the configuration alongside CYGPKG_NET_DROPBEAR.

Usually the dropbear code depends on the presence of a file system for holding public and private keys and other data. In the eCos port this dependency has been eliminated and no file system is required. Instead all the required data is embedded directly in the eCos application and passed to the dropbear code as function arguments.

Ssh connections impose considerable demands on the lower-level TCP/IP and I/O layers, and various configuration options in those layers may need adjusting from their small default values. For example each outgoing ssh connection involves five sockets, plus one statically allocated socket shared between all connections. By default the file I/O package only supports 16 open file descriptors, three of which are used for stdin/stdout/stderr and some of the remainder may be used by other packages like DNS. That should leave enough free file descriptors for one or two ssh connections, but only if the application does not use them for other networking or file I/O activities. Increasing the configuration options CYGNUM_FILEIO_NFD and CYGNUM_FILEIO_NFILE would avoid problems in this area.

When it comes to the TCP/IP stack, the first option to consider is CYGPKG_NET_MAXSOCKETS. Closing down a network connection does not immediately free all resources associated with that connection because it is necessary to synchronize with the other end and make sure that that will not send any more packets. Hence if the application attempts multiple ssh connections in quick succession then the TCP/IP stack may run out socket resources. Increasing CYGPKG_NET_MAXSOCKETS avoids this problem. If the connections involve large amount of data then it may also be necessary to increase CYGPKG_NET_MEMPOOL_SIZE.

Port

Porting dropbear to eCos involved non-trivial modifications to the source code. The package's src subdirectory corresponds to the contents of a standard dropbear tarball. New files ecosmain.c, ecos.h and config.h have been added, and various existing files have had to be modified. A CDL script, documentation and an example application have been added to the appropriate package subdirectories, and a new header dropbear.h has been written to export the API provided by the eCos port. Two example server-side applications can be found in the package's misc subdirectory, and testcases can be found in the tests subdirectory.

Name

Dropbear — Ssh daemon support

Synopsis

#include <dropbear.h> extern int cyg_dropbear_connections;

void **cyg_dropbear_init**(*data*);

void **cyg_dropbear_done**(*handle*, *exit_code*);

int **cyg_dropbear_get_stderr**(*handle*);

const char* **cyg_dropbear_get_username**(*handle*);

const struct sockaddr_storage* **cyg_dropbear_get_addr**(*handle*);

Description

This document assumes the reader has a basic understanding of both ssh operation and of TCP/IP network programming. Information on both of these can be readily obtained from other sources. The eCos port of dropbear does behave rather differently from dropbear or other ssh implementations in a conventional setup such as a network of Linux workstations. eCos does not support multiple processes or shell executables. The dropbear code runs in separate threads within the eCos application, started by a call to `cyg_dropbear_init`, rather than as a separate daemon process. Authentication does not involve reading in files such as `~/.ssh/authorized_keys2` or `/etc/passwd`. Instead the application developer has to write a number of callback functions to supply the necessary information and can decide how best to implement those functions - which may involve file I/O if that happens to be convenient. When an ssh connection is established the dropbear code will not start up a new shell process inside a pseudo terminal. Instead the dropbear code will create a local TCP/IP socket and pass one end of this to the application. Data coming from the network will be decrypted and sent down the local socket, to be read by application code. Data written by the application to the local socket will be encrypted and sent over the network to the ssh client.

The eCos dropbear package comes with two working examples in the `misc/hangman` and `misc/shell` directories which should be examined in conjunction with this documentation.

API

The internals of the dropbear code are not directly accessible to application code. Instead dropbear runs in a number of internal threads, interacting with the application via local TCP/IP sockets and a number of callback functions.

Initialization

The main entry point to dropbear functionality is the function `cyg_dropbear_init`. This should be called by the application when the dropbear code can start running, any time after the network connection has been activated. It takes a single argument, a pointer to a cyg_dropbear_data data structure. That structure should be filled in by the application with information needed by the dropbear code, including pointers to various callback functions.

```
typedef struct cyg_dropbear_data {
    const char*     db_rsa_private_host_key;
    int             db_rsa_private_host_keylen;
    const char*     db_dss_private_host_key;
    int             db_dss_private_host_keylen;
    cyg_bool        (*db_accept_connection)(struct sockaddr_storage*);
    void            (*db_connected)(int, cyg_dropbear_handle);
    void            (*db_get_public_keys)(char*, char*,
                                 struct sockaddr_storage*, char **);
    void            (*db_free_public_keys)(char**);
    cyg_bool        (*db_authenticate_password)(char*,
                                  struct sockaddr_storage *, char*);
    void            (*db_logger)(const char*, va_list);
} cyg_dropbear_data;
```

The *cyg_dropbear_data* structure will be accessed regularly by the dropbear code so must not be overwritten or freed by the application. Typically it will be statically allocated.

The initialization function will start the main dropbear thread, running at configurable priority `CYGNUM_NET_DROPBEAR_THREAD_PRI`. This thread will initialize the dropbear package. It will then bind to the desired TCP/IP port on address `INADDR_ANY`. The default port is 22 as per ssh but this can be changed via `CYGNUM_NET_DROPBEAR_NETWORK_PORT`. The thread will accept new connections from remote clients and start a separate worker thread for each connection, again running at priority `CYGNUM_NET_DROPBEAR_THREAD_PRI`. Usually the main dropbear thread will also assist with setting up the local connection. `cyg_dropbear_init` will return once the main thread has been started.

Host Keys

As an ssh daemon the dropbear code requires a private host key. This can be either a DSS key or an RSA key, but preferably both should be supplied. Private keys can be generated using the **dropbearkey** host utility. The host key is used primarily by clients to uniquely identify a given machine, in conjunction with the `~/.ssh/known_hosts` file.

The application should supply one or two host keys via the *db_rsa_private_host_key*, *db_rsa_private_host_keylen*, *db_dss_private_host_key* and *db_dss_private_host_keylen* fields of the cyg_dropbear_data structure passed to `cyg_dropbear_init`.

Conventional ssh usage dictates that all units should have unique private host keys. That implies that the host keys are held in a file system or in non-volatile flash memory and customized on a per-unit basis. Generating new host keys on startup is undesirable because it would result in different keys after every reboot, defeating the purpose of the `known_hosts` file. In practice it may be acceptable to use a single set of host keys for all units, but it is up to the application developer to consider the security implications.

New Connections Callback

When the main dropbear thread accepts a new ssh connection from the network it will start a new worker thread to handle that connection. Before any data is exchanged over the TCP/IP socket the worker thread will call back into the application so that the latter can decide whether or not a new connection should be accepted at this time.

```
cyg_bool
application_accept_connection_callback(struct sockaddr_storage* addr)
{
    …
}
```

A pointer to this callback function should be stored in the *db_accept_connection* field of the cyg_dropbear_data structure passed to `cyg_dropbear_init`. The callback's argument is the address of the connecting client. Typically this will be an IPv4 sockaddr_in address but the *ss_family* field of the sockaddr_storage structure should be checked. The client's address can be used to restrict incoming connections to certain networks or even to individual hosts. This offers some increased security along similar lines to a firewall, albeit only for ssh traffic, but it may cause problems in future if it ever becomes necessary to access the unit from a different network or host.

Another common use for the new connections callback is to limit the number of concurrent connections, and thus limit the resources consumed. To facilitate this the dropbear code exports an integer `cyg_dropbear_connections` which holds the current number of client connections.

The callback should return zero if the new connection should be declined, non-zero if the dropbear code should proceed with key exchange and authentication.

The use of a new connection callback is optional. If the application does not want to perform any checks at this time then it can use a NULL pointer for the *db_accept_connection* field.

Key Authentication Callback

After the new connections callback the dropbear worker thread will engage in a key exchange with the client. This allows the client to verify information in the `known_hosts` file with the daemon's private host key or keys. The exchange also involves negotiating a mutually acceptable encryption protocol and deciding what user authentication mechanisms are supported. The eCos dropbear daemon supports public/private key authentication and password authentication.

For public/private key authentication the client will generate a message using the private key, and the daemon can validate this message using the public key. In a conventional ssh setup the public keys come from a file `~/.ssh/authorized_keys` or `~/.ssh/authorized_keys2`, but the eCos dropbear port does not assume the presence of a file system. Instead it is the application's responsibility to provide the public keys, and a callback mechanism is used.

```
void
application_get_public_keys(char* algo,
                            char* username,
                            struct sockaddr_storage* addr,
                            char** keys)
{
    …
}

void
application_free_public_keys(char** keys)
{
    …
}
```

Pointers to these callback functions should be stored in the *`db_get_public_keys`* and *`db_free_public_keys`* fields of the cyg_dropbear_data structure passed to `cyg_dropbear_init`. The first argument to the get_public_keys callback identifies the type of key, usually `ssh-dss` or `ssh-rsa`. The second and third arguments supply the user name and the client's network address. Together these three arguments can be used to restrict which public keys are supplied to the dropbear code for validation. Strictly this is optional since the public keys for e.g. a different user are not going to match anyway, but the validation requires significant cpu cycles.

The fourth argument points at a static array of up to `CYGNUM_NET_DROPBEAR_MAXIMUM_PUBLIC_KEYS` entries. This array will be initialized to NULL pointers. The get_public_keys callback should fill in zero or more array entries with pointers to public key strings. These strings may be statically or dynamically allocated. In case of the latter, the free_public_keys callback will be invoked to release the memory when the validation has finished.

Within the dropbear code a mutex is used to ensure that only one worker thread at a time will attempt public key authentication. Hence the callback functions can assume that there will be only one call to get_public_keys at a time and that free_public_keys will be called before the next get_public_keys. This allows the callbacks to use static data with no need for additional locking.

Support for public/private key authentication is optional. If the application is only interested in password authentication then it can use a NULL pointer for the *`db_get_public_keys`* field. If all public keys are statically allocated then a NULL pointer can be used for *`db_free_public_keys`* field.

Password Authentication Callback

If public/private key authentication fails then the dropbear code can support password authentication instead. The ssh client will encrypt the password before sending it over the wires. The dropbear code will decrypt it and will pass the plain text password to an application callback for verification.

```
cyg_bool
application_authenticate_password(char* username,
                                  struct sockaddr_storage* addr,
                                  char* password)
{
    …
}
```

A pointer to this callback function should be stored in the *`db_authenticate_password`* field of the cyg_dropbear_data structure passed to `cyg_dropbear_init`. It is up to the application developer to decide how to validate the password. A very simple approach would just involve comparing it with a constant string. However that approach is not very secure: if there is any way to read the unit's memory directly, for example via jtag debug hardware, then it will be possible to extract the password directly from memory. A more advanced approach would involve encryption, for example using much the same techniques as for a Unix `/etc/passwd` file.

Support for password authentication is optional and can be disabled simply by not supplying the callback function.

Connected Callback

In a conventional ssh environment, once authentication has succeeded the daemon will open a pseudo tty, fork a new process, and start a shell running in that process. eCos does not have pseudo ttys, processes, or shells, so a different approach is needed. The dropbear worker thread for this ssh session will establish a local socket connection and will pass this socket on to the application. Encrypted data coming from the network will be decrypted by the dropbear worker thread and then sent down the local socket to the application. When the application writes plain text data down the local socket the dropbear worker thread will read it, encrypt it, and sent it to the ssh client over the network. As far as the application is concerned it can just `read` and `write` data via the local socket, and it need not concern itself with ssh protocols or encryption. Other standard network programming techniques such as `select` can be used as desired.

To inform the application that authentication has succeeded and that the local socket connection has been established, the dropbear code will invoke another callback function:

```
void
application_connected(int socket, cyg_dropbear_handle handle)
{
    …
}
```

A pointer to this function should be placed in the *`db_connected`* field of the cyg_dropbear_data structure passed to `cyg_dropbear_init`. The first argument is a file descriptor for the local socket, for use by the application code. The second argument is a handle that can be used to get additional information about the connection, and that must be used to shut down the connection.

The connected callback runs from inside the main dropbear thread. It should not run the relevant application code directly, since that would prevent the dropbear code from accepting any new ssh connections. Instead the callback should arrange for some other part of the application to handle traffic for this connection. This can be done in various ways, for example by waking up an existing thread, creating a new one, or adding the socket file descriptor to an fd_set structure which gets monitored via `select` elsewhere in the application.

The socket passed to the connected callback is still an ordinary blocking socket, but can be turned into a non-blocking socket if desired using the standard `FIONBIO` `ioctl`. In the absence of pseudo tty support the socket provides raw terminal functionality. Typically input will appear a character at a time rather than a line at a time, and any line editing functionality has to be supplied by the application. It is also up to the application to implement carriage return/linefeed processing, to handle special input characters like ctrl-C or ctrl-D, and so on.

Strictly the use of the connected callback is optional. Application developers can choose to accept the local socket connection in their own code rather than leave it to the main dropbear thread, as that may make it easier to port existing code. It is still necessary to obtain the cyg_dropbear_handle so that the connection can be closed down correctly. The hangman example program illustrates how to do this.

`stderr` channel

By default the dropbear code only sets up stdin and stdout channels. If a stderr channel is needed as well then the configuration option `CYGIMP_NET_DROPBEAR_SUPPORT_STDERR` should be enabled. An additional function `cyg_dropbear_get_stderr` then becomes available. This function should be called only from the connected callback. It returns a file descriptor for a new local socket which can be used for stderr output, or -1 if the system has run out of sockets or file descriptors.

Use of `cyg_dropbear_get_stderr` is optional, so applications can decide on a per-connection basis whether or not a stderr channel is needed.

Connection Information

Once a connection has been established and the connected callback has been invoked, application code can retrieve some additional information about this connection. `cyg_dropbear_get_username` will provide the user name supplied during authentication, and `cyg_dropbear_get_addr` will return the network address of the ssh client.

Closing Connection

An ssh connection can be shut down in one of two ways. If the client is terminated then the eCos application will detect an end of file condition on the local socket and can close its end of the connection. Alternatively the eCos application can decide to close its end unilaterally. Either way closing the connection involves two steps. The `close` system call should be used on the file descriptor for the local socket, and on the one for the stderr socket if `cyg_dropbear_get_stderr` has been used. Next `cyg_dropbear_done` should be invoked using the cyg_dropbear_handle provided by the connected callback. Calling `cyg_dropbear_done` is analogous to the shell process exiting in a conventional ssh environment. The second argument corresponds to the exit code of that process, so a value of 0 indicates no error. The cyg_dropbear_handle ceases to be valid during the call to `cyg_dropbear_done` so the application must ensure the handle will not be used concurrently by another thread or after the done call.

Note

If `cyg_dropbear_done` is not called when closing down an ssh connection then the dropbear worker thread associated with that connection will never terminate, and any resources allocated will not be released. If this happens repeatedly then the system will run out of memory and fail.

Logging Callback

The dropbear code includes support for logging various events. In a conventional ssh environment these log messages will end up in the system log files, but when running under eCos that approach is usually inappropriate. Instead by default the log messages will just be discarded, but if desired the application can capture the messages by installing a logging callback in the *`db_logger`* field of the cyg_dropbear_data structure:

```
void
application_logger(char* format, va_list args)
{
    …
}
```

Configuration

The dropbear package provides a number of additional configuration options.

`CYGIMP_NET_DROPBEAR_SUPPORT_STDERR`

When a new secure connection is established, by default the dropbear code only provides stdin and stdout channels. If this option is enabled then application code can also request a stderr channel for certain connections. This consumes one extra file descriptor allocated during initialization, plus another two file descriptors for every connection that uses stderr.

`CYGNUM_NET_DROPBEAR_MAX_PAYLOAD_LEN`

While establishing a secure connection the client and daemon negotiate an upper limit for the packet size. This has to be large enough to cope with the initial key exchange and related information. For eCos the default size is set to 1K, which should be sufficient but is still rather smaller than the dropbear default on other platforms. If the application involves transferring large amounts of data over ssh then throughput may be improved by increasing this packet size, at the cost of increased memory usage.

`CYGNUM_NET_DROPBEAR_MAXIMUM_PUBLIC_KEYS`

During the authentication phase the dropbear code may invoke a get_public_keys callback function provided by the application. One of the arguments to that function is a fixed-size array of pointers to public key strings. This configuration option determines the size of that array, and has a default value of 8. If for some reason the application supports large numbers of public keys then it may be necessary to increase this setting.

`CYGNUM_NET_DROPBEAR_NETWORK_PORT`

By default the dropbear main thread listens on port 22, the standard TCP/IP port for ssh. An alternative network port can be specified if desired. This provides a rather limited amount of protection against network attacks which attempt to connect directly to the ssh port, but will be of no use against a determined attack. Using a non-standard port will also be an inconvenience on the client side: the user has to either specify the port number on the command line or modify a configuration file such as `~/.ssh/config`.

`CYGNUM_NET_DROPBEAR_LOCAL_PORT`

This configuration option controls the TCP/IP port used to establish the local socket for each ssh connection.

`CYGNUM_NET_DROPBEAR_STDERR_PORT`

This configuration option controls the TCP/IP port used to establish the stderr socket during a call to `cyg_dropbear_get_stderr`.

`CYGNUM_NET_DROPBEAR_THREAD_PRI`

The dropbear package involves one thread started by `cyg_dropbear_init` plus additional worker threads, one per ssh connection. These threads all run at the same priority, controlled by this configuration option. The ssh protocol involves computationally intensive operations such as encrypting and decrypting packets, so these threads may have a significiant impact on the number of cpu cycles available to the rest of the system. It may be necessary to manipulate the thread priority to achieve an acceptable balance between overall system performance and the achievable ssh bandwidth.

`CYGNUM_NET_DROPBEAR_THREAD_STACKSIZE`

This configuration option controls the size of the stacks allocated for the main dropbear thread and for each worker thread. Fairly large stacks are needed to implement the ssh protocol, and in addition the various application callback functions will also run on these stacks. The default value should suffice for all architectures, but this can be checked by using a debug build with stack checking enabled. If the stack sizes are reduced to save memory then it is strongly recommended that the system be tested with stack checking enabled.

`CYGNUM_NET_DROPBEAR_CONNECTION_DELAY`

The main dropbear thread can delay for a configurable number of system clock ticks between accepting each ssh connection from the network. This provides a limited amount of protection against denial of service attacks, especially when used in conjunction with an accept_connection callback function which limits the number of open connections. Obviously if the eCos system is the target of a denial of service attack then it will still be very hard for legitimate users to get ssh access to the unit, but there is an increased chance that the unit will continue operating rather than run out of resources and fail.

`CYGNUM_NET_DROPBEAR_RETRY_DELAY`

Within the main dropbear code, if the system runs out of resources and for example a `malloc` call fails then this is treated as a serious failure and the ssh connection should get shut down, which will release resources back to the system. Where appropriate some of the eCos-specific code will instead sleep for a while and then retry, in the hope that other parts of the system have released sufficient resources during the delay. This configuration option specifies the number of system clock ticks that should be spent sleeping before retrying.

A further three configuration options in other packages may have a significant impact on the behaviour of the dropbear code. The dropbear code involves a fixed overhead of two sockets, one for the network port and one for the local port, plus an additional three sockets for each ssh connection, one for the network side and two locally. If stderr support is enabled then there is an additional fixed overhead of another socket plus another two sockets for each connection. Depending on how many concurrent ssh connections the application is expected to support it may be necessary to increase the limits on the number of file descriptors and sockets, controlled by `CYGNUM_FILEIO_NFILE`, `CYGNUM_FILEIO_NFD` and `CYGPKG_NET_MAXSOCKETS`. If C library stdio functions are used then `FOPEN_MAX` may also need to be increased. If the system runs out of sockets or file descriptors when a client attempts to establish a new connection, this will normally be detected and the connection will be shut down immediately. However there are edge and race conditions which may cause the client to hang until a timeout occurs.

Name

Dropbear — Ssh client support

Synopsis

#include <dropbear.h>

int **cyg_dropbear_ssh_connect**(*handle*, *addr*, *auth*, *command*);

void **cyg_dropbear_ssh_close**(*handle*, *wait*);

Description

The client-side API allows an eCos application to establish a secure connection to a remote ssh server and run commands on the remote machine. This requires that the application authenticate itself as a valid user on that system. Once the remote command is running the eCos application can interact with its stdin/stdout/stderr stream over sockets.

The client-side code has only been tested against openssh running on a Linux server and and as such descriptions of host-side server configuration settings and files in the remainder of this section refer to Linux. Interoperability with other ssh implementations cannot be guaranteed.

Application developers should be aware that establishing an ssh connection is a complicated business. Even if the eCos application is working correctly there are many things completely outside its control that could go wrong and prevent a secure connection from being established. Some of these are: firewalls intercepting and discarding packets to the ssh server; tcp wrappers intercepting and rejecting requests before they even reach the ssh server, courtesy of settings in the `/etc/hosts.allow` and `/etc/hosts.deny` files on the host ssh server; ssh server settings in `/etc/ssh/sshd_config` which are incompatible with the application's requirements; problems with the user account specified by the application; or problems with the ssh keys in the `~/.ssh/authorized_keys2` file of the user's account on the host server. It is recommended that when experiencing connectivity problems from an eCos application the developer first checks the server's setup, for example by using **ssh** or **dbclient** commands on a suitable Linux box on the same network as the eCos system and specifying the same account and keys.

Application developers should also be aware that allowing remote systems running eCos to access an ssh server has security implications. For example if an attacker has physical access to a remote system, that attacker could use technology like jtag to examine the contents of the flash memory and search for plain text passwords or private keys. It is the developers' responsibility to understand the security issues associated with ssh technology and decide whether the risks are acceptable.

API

There are only two functions in the client-side API, one to establish a secure connection and run a command on the remote machine, the other to shut down the connection cleanly. The key data structure is a cyg_dropbear_cli_handle which holds all application-level state relevant to the connection.

```
typedef struct cyg_dropbear_cli_handle {
    int         db_stdin_stdout;
    int         db_stderr;
    int         db_exitcode;
    char        db_error[CYG_DROPBEAR_MAX_ERROR];
    …
} cyg_dropbear_cli_handle;
```

Each ssh connection requires its own instance of this data structure, and the instance must exist for the duration of the connection. All of the fields are managed by the dropbear code and the application should only read them, not modify them in any way. The *`db_stdin_stdout`* and *`db_stderr`* fields are file descriptors corresponding to sockets. Any data written to *`db_stdin_stdout`* will appear on the remote application's stdin stream. Any data written by the remote application to its stdout will appear as input on *db_stdin_stdout*. Any data written to its stderr will appear as input on *db_stderr*. The *db_exitcode* field is only valid once the remote application has exited and hold its exit code, usually 0 for a successful run and non-zero to indicate some kind of error. Most error conditions associated with the ssh connection itself will result in an error message being placed in *db_error*. However error conditions within the remote command will typically be reported via the stderr stream.

A typical client-side application will look like this:

```
void
run_remote_program(…)
{
    cyg_dropbear_cli_handle handle;

    <Fill in a struct sockaddr with the server's network address>

    <Fill in an authentication structure>

    if (!cyg_dropbear_ssh_connect(&handle, …)) {
        <Something has gone wrong during the connect process>
        <If there is a user, report the handle's db_error message>
        return;
    }

    if ( <reading from remote application> ) {
        while (! <EOF detected on db_stdin_stdout> ) {
            <Use read() on db_stdin_stdout>
            <Optionally, for robustness, look for errors on db_stderr>
        }
    } else { // writing to remote application
        while ( <there is data to be written> ) {
            <use write() on db_stdin_stdout>
            <Optionally, for robustness, look for errors on db_stderr>
        }
    }

    cyg_dropbear_ssh_close(&handle, 1);
    <Optionally check the exit code>
}
```

More complicated behaviour is possible, and the `clitest1.c` testcase in the package's `tests` subdirectory provides numerous examples.

Connecting

The `cyg_dropbear_ssh_connect` function takes four arguments:

`handle`

A pointer to a cyg_dropbear_cli_handle structure. This structure will be filled in and managed by the dropbear code, and should only be read by the eCos application. The structure must remain valid for the duration of the ssh connection, until after the call to `cyg_dropbear_ssh_close`.

`addr`

The full address of the ssh server on the remote machine. Typically this will actually be a sockaddr_in or sockaddr_in6 structure (assuming `CYGPKG_NET_INET6` is enabled). The ssh server must be accessible via this address irrespective of any firewall filtering, tcpwrapper settings (`/etc/hosts.allow` and `/etc/hosts.deny`), and ssh server settings (`/etc/ssh/sshd_config` on the host, especially the `AddressFamily`, `ListenAddress` and `Port` settings). Usually the port number will be `htons(22)` but an alternative ssh server listening on a different port may also be used. The dropbear code does not examine the contents of the address, it simply passes the address on to the TCP/IP stack's `connect` function.

`auth`

This structure holds all the authentication information, and is discussed in detail below.

`command` The command to be executed on the remote server. Typically this will be run using the account's default shell with a `-c <command>` option. If `NULL` is passed then the remote ssh server will start an interactive shell.

If the connection attempt succeeds and the remote ssh server starts the remote shell then `cyg_dropbear_ssh_connect` will return 1 and the *`db_stdin_stdout`* and *`db_stderr`* fields in the handle structure will be filled in with suitable sockets. Note that this does not mean that the remote shell has successfully started the requested command. If that part of the operation fails then the shell will output an error message on stderr and exit.

If the connection attempt fails because of a lack of resources, because the remote ssh server is not accessible, or because of an authentication failure, then `cyg_dropbear_ssh_connect` will return 0 and the handle's *`db_error`* field will contain an error message.

Internally, establishing an ssh connection involves starting a separate worker thread and it is the worker thread which runs the main dropbear code. It accepts messages over the network socket from the remote ssh server, decrypts them, and forwards them over local sockets to the application's *`db_stdin_stdout`* and *`db_stderr`*. It also accepts data written to *`db_stdin_stdout`* via a local socket, encrypts it, and passes it on to the remote application via the network socket and the ssh server.

Authentication

The cyg_dropbear_authenticate structure passed to `cyg_dropbear_ssh_connect` holds the information needed to authenticate the connection with the remote ssh server. Most of the fields are optional, as long as at least one valid authentication mechanism is provided. The structure contains the following fields:

```
typedef struct cyg_dropbear_authenticate {
    const char*     db_username;
    const char*     db_host_rsa_key_pub;
    const char*     db_host_dsa_key_pub;
    const char*     db_id_rsa;
    int             db_id_rsa_keylen;
    const char*     db_id_dsa;
    int             db_id_dsa_keylen;
    const char*     db_password;
} cyg_dropbear_authenticate;
```

The structure can be constructed at run-time or statically allocated. The dropbear code only reads the various fields during the call to `cyg_dropbear_ssh_connect`.

The *`db_username`* field must be filled in. It should be a simple string corresponding to a valid account name on the ssh server machine, for example:

```
    struct cyg_dropbear_authenticate auth;
    …
    auth.db_username = "dropbeartest";
```

The account name must also be one allowed by the ssh server, as per the `/etc/ssh/sshd_config` file's `AllowUsers` setting on the host.

The rsa and dsa host keys can be used to validate the identity of the remote ssh server, preventing certain man-in-the-middle attacks. These fields serve much the same purpose as the `~/.ssh/known_hosts` file when using the **ssh** command on a Linux system. During the authentication stage of establishing a connection the remote ssh server will send a signature encrypted using the server's private key, and the public keys can be used to validate this signature. The fields should be initialized using the contents of the `/etc/ssh/ssh_host_dsa_key.pub` and `/etc/ssh/ssh_host_rsa_key.pub` files on the host server, for example:

```
    …
    auth.db_host_rsa_key_pub = "ssh-rsa AAAAB3Nz…rb8=";
    auth.db_host_dsa_key_pub = "ssh-dss AAAABDNz…v7s=";
```

Note that the host's `/etc/ssh/sshd_config` file can specify alternative keys using `HostKey` settings. It is not necessary to supply the public host keys to the dropbear code. If neither host key is supplied then the code will simply not attempt to validate the identity of the remote ssh server and the `known_hosts` protection is not applied.

Specifying the public host keys in the authentication structure has one major disadvantage. If it ever becomes necessary to change the host keys on the ssh server then the eCos boxes will not be able to connect to the remote ssh server until the boxes are updated with a new host key. This behaviour is different from running **ssh** interactively on the Linux command line where the user will be given the choice of accepting the new key and updating the `known_hosts` file.

The *`db_id_rsa`*, *`db_id_rsa_keylen`*, *`db_id_dsa`* and *`db_id_dsakeylen`* fields are used to hold the private keys for public key authentication. If neither key is supplied then the dropbear code will only attempt password authentication. It should be noted that establishing a secure connection using an RSA private key requires many more cpu cycles than using a DSA private key. If both keys are supplied then the dropbear code will try the DSA key first, then the RSA key. The overheads can be reduced by using a smaller keysize, but obviously that has security implications.

The dropbear code requires its private keys in a different format from the Linux **ssh** command, and embedding these keys requires a somewhat convoluted process. One approach involves generating the keys using the host's **ssh-keygen** utility with *`-t rsa`* or *`-t dsa`*. No passphrase must be used, and great care should be taken not to overwrite the user's default private key file. The ssh private key can then be converted into a dropbear key using the **dropbearconvert** utility, either built from the sources or installed via e.g. the standard dropbear package.

Notes

1. **dropbearconvert** requires the private ssh key to be in legacy PEM private key format, while the default format of private keys for OpenSSH's **ssh-keygen** command is its own internal format. The option *`-m PEM`* to **ssh-keygen** may be used to specify the private key format of PEM when creating a new private key, or to convert an existing key from internal to PEM format using the *`-p`* option (traditionally used to remove or change a key's passphrase). For example:

   ```
   ssh-keygen -m PEM -t rsa -C "dropbear@example.com"  # Create new rsa key
   ssh-keygen -m PEM -p -f ~/.ssh/id_rsa               # Convert existing key to PEM format
   ```

2. OpenSSH 7.0 and greater disables the ssh-dss (DSA) public key algorithm by default as it is considered too weak. It's use is not recommended. For additional details see:

   - https://www.openssh.com/legacy.html
   - https://security.stackexchange.com/questions/112802/why-openssh-deprecated-dsa-keys

The dropbear-format `db_id_dsa` file can then be converted into a C array using the **privatekey2c** utility supplied in the package's `misc/hangman` and `misc/shell` directories.

For example, to generate a set of private keys for both dsa and rsa, convert them into dropbear format, and generate a C array for inclusion into an eCos client:

```
ssh-keygen -m PEM -t rsa -C "dropbear@ecoscentric.com"      # Create rsa key
ssh-keygen -m PEM -t dsa -C "dropbear@ecoscentric.com"      # Create dsa key
dropbearconvert openssh dropbear ~/.ssh/id_rsa db_id_rsa    # Convert to dropbear format
dropbearconvert openssh dropbear ~/.ssh/id_dsa db_id_dsa    # Convert to dropbear format
privatekey2c id_rsa db_id_rsa > id_rsa.c                    # Create C code for eCos
privatekey2c id_dsa db_id_dsa > id_dsa.c                    # Create C code for eCos
```

The resulting `id_dsa.c` file will contain code like the following:

```
#define ID_DSA_LEN 457
static const char id_dsa[ID_DSA_LEN] = {
    0x00, 0x00, 0x00, 0x07, \
    … \
    0xd3 \
};
```

The resulting file can be #include'd by the application code and used to fill in the auth structure's *`db_id_dsa`* and *`db_id_dsa_keylen`* fields.

As an alternative to using the **ssh-keygen** and **dropbearconvert** utilities, dropbear's **dropbearkey** can be used to generate the private key files directly in the dropbear format. It will still be necessary to use **privatekey2c** to turn the keys into a C array.

The remote ssh server will use the account's `~/.ssh/authorized_keys` file to validate the private keys supplied by the eCos application. This file must be created or updated with the corresponding public keys. For example:

```
cat ~/.ssh/id_rsa.pub >> ~/.ssh/authorized_keys
cat ~/.ssh/id_dsa.pub >> ~/.ssh/authorized_keys
chmod go-rw ~/.ssh/authorized_keys
```

Note

Prior to version 3 of OpenSSH, public key authentication used the file `authorized_keys` for SSH Protocols 1.3 and 1.5, while `authorized_keys2` was used for SSH protocol 2.0. ersion 3 and above of OpenSSH deprecated the use of `authorized_keys2`, allowing all public keys to be put into `authorized_keys`.

It is also necessary to have `PubkeyAuthentication` enabled in `/etc/ssh/sshd_config` on the ssh server host, and if DSA is to be permitted, `PubkeyAcceptedKeyTypes` must include *`ssh-dss`*.

The final field in the authentication structure is *`db_password`*. Again this should be a C string holding the plaintext password, or NULL if password authentication should not be attempted. The ssh server will only allow plaintext passwords if `PasswordAuthentication` is enabled in the server's configuration file.

I/O with the remote process

Once a secure connection has been established using `cyg_dropbear_ssh_connect` the eCos application code can interact with the remote command using the *`db_stdin_stdout`* and *`db_stderr`* fields in the connection's handle structure. These fields hold file descriptors corresponding to local sockets, and the other ends of these local sockets are managed by an internal worker thread started by the connect operation and running the bulk of the dropbear code. Typically I/O involves the `read`, `write` and `select` calls. Any data written to *`db_stdin_stdout`* will be read by the worker thread, encrypted, forwarded to the remote ssh server over the network connection, decrypted, and can be read by the remote command using its stdin stream. Any data written by the remote command to stdout or stderr will follow the reverse path and can be read by the eCos application code using the *`db_stin_stdout`* and *`db_stderr`* file descriptors.

If the remote command exits while the eCos application is still reading data, this will result in an end-of-file condition on the *`db_stdin_stdout`* file descriptor. In other words a `read` call will return 0. At that point the application should close the connection using `cyg_dropbear_ssh_close`, and not by using the `close` call on the file descriptor. Similarly if the eCos application wants to close the connection while the remote command is still running then it should use `cyg_dropbear_ssh_close`.

Given the complexity of the data flow, details of any error conditions such as broken network connections will not get as far as the application code. Specifically, the value of the `errno` variable will not correspond to the underlying error condition. Instead error conditions are likely to manifest as end-of-file conditions indistinguishable from the command exiting.

Closing a connection

When the eCos application wants to close down the ssh connection it should call `cyg_dropbear_ssh_close`. This takes two arguments, the handle filled in by `cyg_dropbear_ssh_connect` and a flag to indicate whether or not the application wants to wait for the remote command to exit. If the application does not wait then the *`db_exitcode`* field may not be valid, and the internal worker thread will continue to run in the background and consume resources until the remote command has finished.

Configuration

There are no configuration options specific to the client-side API, other than ones related to testing as described below. However there are a number of options common to the server-side and client-side API.

CYGNUM_NET_DROPBEAR_MAX_PAYLOAD_LEN

While establishing a secure connection the client and daemon negotiate an upper limit for the outgoing packet size. This has to be large enough to cope with the initial key exchange and related information. For eCos the default size is set to 1K, which should be sufficient but is still rather smaller than the dropbear default on other platforms. If the application involves transferring large amounts of data over ssh then throughput may be improved by increasing this packet size, at the cost of increased memory usage.

CYGNUM_NET_DROPBEAR_THREAD_PRI

The client-side dropbear code involves an internal worker thread for each secure connection. These worker threads run at the same priority controlled by this configuration option. The ssh protocol involves computationally intensive operations such as encrypting and decrypting packets, so these threads may have a significiant impact on the number of cpu cycles available to the rest of the system. It may be necessary to manipulate the thread priority to achieve an acceptable balance between overall system performance and the achievable ssh bandwidth.

CYGNUM_NET_DROPBEAR_THREAD_STACKSIZE

This configuration option controls the size of the stacks allocated for internal worker threads. Fairly large stacks are needed to implement the ssh protocol, and in addition the various application callback functions will also run on these stacks. The default value should suffice for all architectures, but this can be checked by using a debug build with stack checking enabled. If the stack sizes are reduced to save memory then it is strongly recommended that the system be tested with stack checking enabled.

Testing

The client-side code comes with an extensive testcase tests/clitest1.c. However this testcase is not built by default. It requires information about the testing environment such as the address of a suitable ssh server, as well as authentication information such as private keys and plain-text passwords. Embedding that kind of information directly into readily-available source code would have obvious security implications. Instead it is necessary to set a variety of configuration options before the testcase can be built.

Not all relevant configurations options need to be set. For example if the booldata option CYGTST_NET_DROPBEAR_TESTS_CLI_PASSWORD is not enabled then the testcase will not attempt any tests related to plain-text passwords. Details of the authentication mechanisms and relevant server settings can be found in the authentication section above.

Some of the configuration values are long, for example complete private ssh keys. Entering these using the graphical configuration tool may be problematical. Instead the ecos.ecc savefile can be edited directly. Alternatively the dropbear package comes with a file misc/clitest1.ecm, containing the configuration options related to testing. This file can be edited and then imported into the eCos configuration. Where appropriate the testcase will turn the configuration values into C strings automatically, so there is no need to add extra quotes to the values. The relevant options are:

CYGPKG_NET_DROPBEAR_TESTS_CLI

Unless this option is enabled the client-side testcase will not be built.

CYGTST_NET_DROPBEAR_TESTS_CLI_SERVER_ADDR

This should be the address of the remote ssh server in a format acceptable to the standard inet_pton function, for example 192.168.0.42.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_SERVER_ADDR {
    user_value 192.168.0.42
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_SERVER_PORT

This should be the tcp port number for the remote ssh server. It should be 22 when interacting with the system's standard ssh server.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_SERVER_PORT {
#    user_value 22
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_AF

This should be the address family, `AF_INET` for IPv4 testing or `AF_INET6` for IPv6 testing.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_AF {
#    user_value AF_INET
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_USERNAME

This should be the name of the testing account on the ssh server machine.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_USERNAME {
     user_value dropbeartest
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_HOST_RSA_KEY_PUB

The public RSA host key for the remote ssh daemon. On a modern debian Linux systems, this can be found in `/etc/ssh/ssh_host_rsa_key.pub`. Note that the trailing comment, normally the hostname, should be ommitted.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_HOST_RSA_KEY_PUB {
    user_value 1 "ssh-rsa AAAA…rb8="
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_HOST_DSA_KEY_PUB

The public DSA host key for the remote ssh daemon. On a modern debian Linux systems, this can be found in `/etc/ssh/ssh_host_dsa_key.pub`. Note that the trailing comment, normally the hostname, should be ommitted.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_HOST_DSA_KEY_PUB {
    user_value 1 "ssh-dss AAAA…v7s="
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_ID_RSA

This value should be the contents of a private RSA key. This can be obtained using the **privatekey2c** utility as described above in the authentication section. The contents of the C array in the resulting source file can then be copied and pasted into the .ecm or .ecc file.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_ID_RSA {
    user_value 1 " \
    0x00, 0x00, 0x00, 0x07, 0x73, 0x73, 0x68, 0x2d, \
    … \
    0x76, 0xfe, 0x15"
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_ID_DSA

This value should be the contents of a private DSA key. This can be obtained using the **privatekey2c** utility as described above in the authentication section. The contents of the C array in the resulting source file can then be copied and pasted into the .ecm or .ecc file.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_ID_DSA {
    user_value 1 " \
    0x00, 0x00, 0x00, 0x07, 0x73, 0x73, 0x68, 0x2d, \
    … \
    0x1d"
};
```

CYGTST_NET_DROPBEAR_TESTS_CLI_PASSWORD

This value should be the plain-text password used for authenticating the user.

```
cdl_option CYGTST_NET_DROPBEAR_TESTS_CLI_PASSWORD {
    user_value 1 opensesame
};
```

SSH Server Host Configuration

Modern Linux hosts are normally tightly configured with respect to ssh access so as to minimise risk of being compromised. When using an OpenSSH server on Linux as the test host, you may wish to ensure access to the host is not compromised and is restricted. For example, you may only wish to permit access by the dropbear clitest1 and scptest1 tests to the user specified in CYGTST_NET_DROPBEAR_TESTS_CLI_USERNAME from internal network addresses used by the test hardware. For example, if the test hardware were located on the internal IPv4 segment 192.168.8.0/24 and internal IPv6 segment fd54:5cd1:6fc7:1619::/64, the configuration file /etc/ssh/sshd_config could contain the following configuration extract that permits password and DSA autentication for the user dropbeartest from either network:

```
# Permit dropbear test user to connect from internal test networks and use password authentication
Match User dropbeartest Address 192.168.8.0/24,fd54:5cd1:6fc7:1619::/64
        PasswordAuthentication yes
        PubkeyAcceptedKeyTypes=+ssh-dss
```

When testing the user account from another Linux server using ssh, the user file ~/.ssh/config also should contain the following line to permit DSA private key authentication as that client host may likely have such authentication prohibited:

```
PubkeyAcceptedKeyTypes +ssh-dss
```

Name

Dropbear — scp client support

Synopsis

#include <dropbear.h>

int **cyg_dropbear_scp_open**(*handle*, *addr*, *auth*, *path*, *flags*, *len*, *mode*);

ssize_t **cyg_dropbear_scp_write**(*handle*, *buf*, *len*);

ssize_t **cyg_dropbear_scp_read**(*handle*, *buf*, *len*);

void **cyg_dropbear_scp_close**(*handle*);

Description

The scp client support allows eCos applications to read and write files on a remote server over a secure channel. It is implemented as a thin layer over the generic client-side support and the same caveats regarding security implications etc. are applicable. The package comes with a testcase `tests/scptest1.c` which can serve as example code.

API

The scp API consists of just four functions. `cyg_dropbear_scp_open` is used to establish a secure connection to a remote ssh server, run the scp command on that server to handle the remote file I/O. and perform some initial protocol operations. The data can then be transferred using repeated calls to `cyg_dropbear_scp_read` and `cyg_dropbear_scp_write`. Finally `cyg_dropbear_scp_close` can be used to shut down the connection. All calls make use of a handle structure to hold per-connection state:

```
typedef struct cyg_dropbear_scp_handle {
    cyg_dropbear_cli_handle     db_cli_handle;
    …
} cyg_dropbear_scp_handle;
```

The main field of interest is *`db_cli_handle.db_error`* which will contain a suitable error message if a connect operation fails. Typical code to write to a remote file would look like this:

```
<global sockaddr_storage structure containing a suitable address>

<global cyg_dropbear_authenticate structure appropriately filled in>

void
write_remote_file(char* buf, int len)
{
    cyg_dropbear_scp_handle  handle;
    int                      xfrd;

    if (!cyg_dropbear_scp_open(&handle, <addr>, <auth>,
                               "/tmp/out", O_WRONLY, &len,
                               S_IRUSR | S_IWUSR)) {
        <report handle.db_cli_handle.db_error to the user>
        return
    }

    for (xfrd = 0; xfrd < len; ) {
        <use cyg_dropbear_scp_write to send a chunk to the remote server>
    }

    cyg_dropbear_scp_close(&handle);
}
```

The code for reading a remote file is very similar:

```
void
read_remote_file(char* buf, int maxlen)
{
    cyg_dropbear_scp_handle handle;
    int len;

    if (!cyg_dropbear_scp_open(&handle, <addr>, <auth>,
                               "/tmp/in", O_RDONLY, &len, 0)) {
        <report handle.db_cli_handle.db_error to the user>
        return
    }
    if (len > maxlen) {
        <decide what to do>
    }

    for (xfrd = 0; xfrd < len; ) {
        <use cyg_dropbear_scp_read to read a chunk from the remote server>
    }

    cyg_dropbear_scp_close(&handle);
}
```

Connecting

The function cyg_dropbear_scp_open is used to establish a secure connection to a remote server and to open a file on that remote system. It takes seven arguments:

handle
: A pointer to a cyg_dropbear_scp_handle structure. This will be filled in and managed by the dropbear code, and should only be read by the eCos application. The structure must remain valid for the duration of the scp operation, until after the call to cyg_dropbear_scp_close.

addr
: The full address of the ssh server on the remote machine. Typically this will actually be a sockaddr_in or sockaddr_in6 structure (assuming CYGPKG_NET_INET6 is enabled). The ssh server must be accessible via this address irrespective of any firewall filtering, tcpwrapper settings (/etc/hosts.allow and /etc/hosts.deny, if enabled), and ssh server settings (/etc/ssh/sshd_config, especially the AddressFamily, ListenAddress and Port settings). Usually the port number will be htons(22) but it is possible to connect to an alternative ssh server listening on a different port, if desired. The dropbear code does not examine the contents of the address, it simply passes the address on to the TCP/IP stack's connect function.

auth
: This structure holds all the authentication information and is discussed in detail in the documentation for the Ssh client support.

path
: The full path of a file on the remote system.

flags
: This should be O_RDONLY to read a file on the remote system, or O_WRONLY to write a file.

len
: The scp protocol requires that the total amount of data to be transferred is known at the start of the transfer. len should be a pointer to an ssize_t variable. For a write operation the application should initialize that variable with the total transfer size before calling cyg_dropbear_scp_open. For a read operation the dropbear code will set that variable to the file size, thus letting the application know how much data it should read.

mode
: This field is only relevant when writing a file, and is used to set the access mask for the file on the remote system as per e.g. the Linux chmod system call. It will be some combination of the S_IRUSR, S_IWUSR, S_IXUSR, S_IRGRP, S_IWGRP, S_IXGRP, S_IROTH,

S_IWOTH, and S_IXOTH constants defined in the <sys/stat.h> header file. Note that the application should use the eCos values for these constants and the dropbear code will automatically translate them to the Linux equivalents. Also note that the settings are subject to the account's umask value on the remote server.

The cyg_dropbear_scp_open function will attempt to make a secure connection to the remote server, start the **scp** on that server, and perform the initial protocol operations. If it returns successfully then the application can proceed with the data transfers using cyg_dropbear_scp_write or cyg_dropbear_scp_read. If it fails for any reason then an error message will be written to the *db_cli_handle.db_error* field of the handle. Due to the complexity of the operation and the implementation's need for a background worker thread that runs the bulk of the dropbear code, the value in errno may not give an accurate indication of the error(s) that occurred.

Transferring Data

Once an scp connection has been established the application can transfer data using cyg_dropbear_scp_write if the remote file was opened with O_WRONLY, or cyg_dropbear_scp_read if O_RDONLY was used. In addition to transferring the data these functions catch certain error conditions and manage the scp protocol, so their use is preferable to any attempt to read or write the data directly over sockets.

cyg_dropbear_scp_read will return the amount of data actually read during this call, which may be less than the amount requested because of buffering effects. Typically this function will be called in a loop until all required data has been transferred. A return value of 0 indicates an end-of-file condition, usually because the transfer is complete but possibly because the connection has been broken. A return value of -1 indicates some unexpected and indeterminate error condition.

cyg_dropbear_scp_write will return the amount of data actually written during this call. Usually this will be the amount requested, but may be less because of buffering effects. Typically this function will be called in a loop until all required data has been transferred. For large transfers it may be desirable to split the transfer into a number of smaller chunks, effectively spreading the cpu cycle and buffering costs over a longer period of time. A return value of 0 or -1 indicates an unexpected and indeterminate error condition.

Closing a Connection

At the end of a transfer cyg_dropbear_scp_close should be used to shut down the connection. The handle structure will no longer be needed after this call returns.

Normally the application should transfer exactly the amount of data requested. For a write this is the size specified during the open call. For a read this is the size filled in by the dropbear code during the open call. It is possible to call cyg_dropbear_scp_close before the transfer has completed. For a read this is harmless. For a write, some or all of the data transferred so far may be discarded by the remote scp command, and the exact behaviour is unpredictable.

Configuration

There are no configuration options specific to the client-side scp support. However this support is built on top of the generic ssh client-side API so all configuration options relevant to that also affect scp operations.

Testing

The dropbear package comes with a testcase tests/scptest1.c. However this testcase is not built by default. It will only be built if the configuration enables the building of the generic client-side testcase tests/clitest1.c, and will use the same configuration options to identify the remote server and to provide the authentication information.

Part L. FTP Client for eCos TCP/IP Stack

The ftpclient package provides an FTP (File Transfer Protocol) client for use with the TCP/IP stack in eCos. It supports both IPv4 and IPv6 and will use the DNS client, when its is part of the eCos configuration. The API allows for active (server->client) or passive (client->server) transfer connections to be used.

The data operations support binary mode transfers only. The supplied filename paths only support Unix-style '/, directory separators.

The API provides support for either direct buffer transfers, or for call-back routines to be used to copy data as required. Care must be taken, especially when receiving files, since the direct buffer support calls are limited to handling files that will fit within the single buffer passed through the API. The API call-back based implementation can avoid this limitation by allowing the client to control the data reception and buffering as appropriate.

By default the data transfer operations will initially attempt a connection using the newer “extended” (IPv6 capable) FTP commands (`EPRT` or `EPSV` as appropriate). If those commands are not supported by the FTP server then the client will fallback to using the original FTP connection commands (`PORT` or `PASV` respectively).

Table of Contents

Chapter 184. FTP Client API and Configuration

FTP Client API

The FTP Client API is provided by the include file `install/include/ftpclient.h` and it can be used thus:

```
#include <network.h>
#include <ftpclient.h>
```

Note

The reason for the following variety of API operations performing the `get` and `put` operations is for backwards compatibility with earlier releases of the FTP Client package. Existing API parameter requirements have not been changed, with new features adding new API calls as required.

Support API

Support functions are available irrespective of the type of data transfer operations used.

ftp_delete

```
int ftp_delete(char * hostname,
               char * username,
               char * passwd,
               char * filename,
               ftp_printf_t ftp_printf);
```

Delete a file from the FTP server. The *`filename`* should be the full pathname of the file to be deleted.

ftpclient_printf

```
void ftpclient_printf(unsigned error, const char *fmt, …);
```

The `get` and `put` API operations take a pointer to a function to use for printing out diagnostic and error messages. This is a sample implementation which can be used if you don't want to implement the function yourself. *`error`* will be true when the message to print is an error message. Otherwise the message is diagnostic, eg. the commands sent and received from the server.

Basic FTP Client API

The basic API only supports active connections, and is provided for backwards compatability with earlier releases. It is superceded by the extended API described below, which provides greater control and extra features not available with the original basic API. The basic API consists of the following exported functions:

ftp_get

```
int ftp_get(char * hostname,
            char * username,
            char * passwd,
            char * filename,
            char * buf,
            unsigned buf_size,
            ftp_printf_t ftp_printf);
```

Use the FTP protocol to retrieve a file from a server. Only binary mode is supported. The filename can include a directory name. Only use unix style ’/, file separators, not ’\,. The file is placed into *`buf`*. *`buf`* has maximum size *`buf_size`*. If the file is bigger than this, the transfer fails and FTP_TOOBIG is returned. Other error codes listed in the header can also be returned. If the transfer is successful the number of bytes received is returned.

ftp_put

```
int ftp_put(char * hostname,
            char * username,
            char * passwd,
            char * filename,
            char * buf,
            unsigned buf_size,
            ftp_printf_t ftp_printf);
```

Use the FTP protocol to send a file to a server. Only binary mode is supported. The filename can include a directory name. Only use unix style ’/, file separators, not ’\,. The contents of *`buf`* are placed into the file on the server. If an error occurs one of the codes listed will be returned. If the transfer is successful zero is returned.

ftp_get_var

```
int ftp_get(char * hostname,
            char * username,
            char * passwd,
            char * filename,
            ftp_write_t ftp_write,
            void * ftp_write_priv,
            ftp_printf_t ftp_printf);
```

Use the FTP protocol to retrieve a file from a server. Only binary mode is supported. The filename can include a directory name. Only use unix style ’/, file separators, not ’\,. The *`ftp_write`* function is called as data arrives, using the supplied *`ftp_write_priv`* private context. If the transfer is successful the total number of bytes received is returned.

ftp_put_var

```
int ftp_put(char * hostname,
            char * username,
            char * passwd,
            char * filename,
            ftp_read_t ftp_read,
            void * ftp_read_priv,
            ftp_printf_t ftp_printf);
```

Use the FTP protocol to send a file to a server. Only binary mode is supported. The filename can include a directory name. Only use unix style ’/, file separators, not ’\,. The *`ftp_read`* function is called to fetch data to be written, using the supplied *`ftp_read_priv`* private context. The call returns the total amount of data written, or a negative error indication.

Extended FTP Client API

The extended FTP Client API provides for more control of the FTP connection, including passive mode selection and timeout configuration. The extended API uses the `ftp_extended_info` structure to pass information into the handler functions. The use of a structure allows the data to be re-used, or individual fields modified, between calls using the API. The extended API also provides a boolean `passive` that if `true` causes the relevant API call to use a passive FTP connection, with `false` indicating an active FTP connection (as per the original API).

The extended API also allows for RX and TX timeouts (specified as a number of seconds) to be used for connection and data transfers. If either of the timeout fields is set to 0 then the respective CDL configuration option

`CYGNUM_NET_FTPCLIENT_TIMEOUT_RX` and `CYGNUM_NET_FTPCLIENT_TIMEOUT_TX` will be used by the API operation instead.

The structure contains the following fields, which mostly mirror the individual parameter functions as used by the older (active-only) API:

```
struct ftp_extended_info {
  cyg_bool passive;
  char *hostname;
  char *username;
  char *passwd;
  char *filename;
  ftp_printf_t ftp_printf;
  unsigned int rx_timeout;
  unsigned int tx_timeout;
};
```

The extended API consists of the following functions:

ftp_get_extended

```
int ftp_get_extended(struct ftp_extended_info * info,
                     char * buf,
                     unsigned buf_size);
```

Use the FTP protocol to retrieve a file from a server. Only binary mode is supported. The filename can include a directory name. Only use unix style '/, file separators, not '\,. The *`info`* parameter provides the server connection and credentials information, as well as indicating the type of connection to establish, the diagnostic and error output routine and the RX and TX timeouts. The file is placed into *`buf`*. *`buf`* has maximum size *`buf_size`*. If the file is bigger than this, the transfer fails and FTP_TOOBIG is returned. Other error codes listed in the header can also be returned. If the transfer is successful the number of bytes received is returned.

ftp_put_extended

```
int ftp_put_extended(struct ftp_extended_info * info,
                     char * buf,
                     unsigned buf_size);
```

Use the FTP protocol to send a file to a server. Only binary mode is supported. The filename can include a directory name. Only use unix style '/, file separators, not '\,. The *`info`* parameter provides the server connection and credentials information, as well as indicating the type of connection to establish, the diagnostic and error output routine and the RX and TX timeouts. The contents of *`buf`* are placed into the file on the server. If an error occurs one of the codes listed will be returned. If the transfer is successful zero is returned.

ftp_get_extended_var

```
int ftp_get_extended_var(struct ftp_extended_info * info,
                         ftp_write_t ftp_write,
                         void * ftp_wrote_priv);
```

Use the FTP protocol to retrieve a file from a server. Only binary mode is supported. The filename can include a directory name. Only use unix style '/, file separators, not '\,. The *`info`* parameter provides the server connection and credentials information, as well as indicating the type of connection to establish, the diagnostic and error output routine and the RX and TX timeouts. The *`ftp_write`* function is called as data arrives, using the supplied *`ftp_write_priv`* private context. If the transfer is successful the total number of bytes received is returned.

ftp_put_extended_var

```
int ftp_put_extended_var(struct ftp_extended_info * info,
                         ftp_read_t ftp_read,
                         void * ftp_read_priv);
```

Use the FTP protocol to send a file to a server. Only binary mode is supported. The filename can include a directory name. Only use unix style ’/, file separators, not ’\,. The *`info`* parameter provides the server connection and credentials information, as well as indicating the type of connection to establish, the diagnostic and error output routine and the RX and TX timeouts. The *`ftp_read`* function is called to fetch data to be written, using the supplied *`ftp_read_priv`* private context. The call returns the total amount of data written, or a negative error indication.

FTP Client Configuration

The FTP Client provides some CDL configuration items that can be used to tune the performance and behaviour of the client.

CYGNUM_NET_FTPCLIENT_BUFSIZE

> The FTP data transfer functions buffer the data as it passes between systems and this option controls the size of the dynamically allocated buffer. The buffers are allocated using the standard `malloc()` interface.

CYGNUM_NET_FTPCLIENT_TIMEOUT_RX

> This option controls the default timeout in seconds used when waiting for connection or data reception. It is used to set the `SO_RCVTIMEO` for the overall control and data socket connections, as well as the individual `read()` operations. The CDL value can be over-ridden by a run-time supplied value when using the extended API.

CYGNUM_NET_FTPCLIENT_TIMEOUT_TX

> This option controls the default timeout in seconds used when waiting for data transmissions to complete. It is used to set the `SO_SNDTIMEO` for the overall control and data socket connections, as well as the individual `write()` operations. The CDL value can be over-ridden by a run-time supplied value when using the extended API.

Part LI. FTP Server Support

Name

eCosPro Support FTP Service — Overview

Description

The ftpserver package provides an FTP (File Transfer Protocol) server for use with the TCP/IP stack in eCos. It is currently restricted to IPv4 networks only and can only use the BSD IP stack.

The server implements a restricted subset of the FTP protocol, sufficient to transfer binary files to and from an eCos system. Only passive mode transfers are supported. Directory creation ('**mkdir**'), changing ('**cd**') or listing ('**ls**') are not supported. User and password authentication is supported if the user supplies a means of checking these, otherwise access is permitted to all clients. As authentication is not securely encrypted, it is recommended that the FTP server is only used on an internal trusted network.

The server has been tested against the default Linux **ftp** command for both storing and retrieving files. It has also been tested with **wget** and **Firefox** for retrieving files. The server should work with any command-line based FTP client. Graphical clients are less likely to work since these will want to fetch file listings, which the server does not currently support.

Name

FTP Server API — describe FTP server API, callback and configuration

FTP Server API

The FTP server provides a single entry point:

```
    #include <ftpserver.h>

     __externC int cyg_ftpserver_start( cyg_ftpserver *server );
```

This function starts an FTP server running using parameters defined in the *server* argument. It should be called from a thread with a stack with at least CYGNUM_NET_FTPSERVER_STACK_SIZE bytes available. Under normal circumstances this function will not return, so the application should create a thread dedicated to the server. There are examples of this in the test programs.

The *server* argument contains a number of fields that the user may set to control the behaviour of the FTP server.

const char *address

> This is a string giving the IP address on which the server will listen. If not set this will default to listening on all network interface, which is usually what is wanted. This option is only useful if a target has more than one network interface and the FTP server should only listen on one of them.

int port

> This defines the port number on which the server will listen. Leaving this value unset, zero, will cause the server to choose the default FTP port of 21.

const char *greeting

> This is the string that the server will use in its initial response to a client connection. Leaving this NULL will cause the server to use a default message: "Welcome to eCosPro FTP service.".

const char *root

> This string defines a filesystem pathname to the root directory of the FTP server. Files will only be transferred to and from this directory or any subdirectories. A NULL pointer here will cause the server to use "/" as the root.

int data_port

> This defines the first port at which the server will create passive data connections. It will try successive ports from this value until a free port is found, limited to the following 20 ports. Leaving this value NULL will cause the server to start from port 5000.

The normal idiom for use of the FTP server is to define the cyg_ftpserver structure statically and to then call cyg_ftpserver_start() with a pointer to that. The following is a somewhat contrived example:

```
#include <ftpserver.h>

//==========================================================================

static cyg_ftpserver ftp_server =
{
    .port       = 2121,                            // Listen on port 2121
    .root       = "/fatfs/ftp",                    // FTP to/from here
    .greeting   = "Welcome to Fubar FTP service.", // Welcome string
    .data_port  = 40000                            // Move data ports to 40000+
};

//==========================================================================
static void ftpd(CYG_ADDRWORD p)
{
    init_all_network_interfaces();

    cyg_ftpserver_start( &ftp_server );
}

//==========================================================================

#define STACK_SIZE CYGNUM_NET_FTPSERVER_STACK_SIZE
static char stack[STACK_SIZE] CYGBLD_ATTRIB_ALIGN_MAX;
static cyg_thread thread_data;
static cyg_handle_t thread_handle;

void start_ftpd_thread(void)
{
    cyg_thread_create(10,               // Priority
                    ftpd,               // entry
                    0,                  // entry parameter
                    "FTP test",         // Name
                    &stack[0],          // Stack
                    STACK_SIZE,         // Size
                    &thread_handle,     // Handle
                    &thread_data        // Thread data structure
                    );
  cyg_thread_resume(thread_handle);  /* Start it */
}
```

The defaults for the configuration parameters are such that leaving them all zero or NULL will cause the server to configure itself on the standard port serving files to/from the root of the filesystem.

Callback Interface

The default server operates to and from a directory in a filesystem, in the same way that most FTP servers operate. However, not all embedded systems have filesystem support. To allow such systems to provide an FTP service, all file access operations go through a set of callback functions in the cyg_ftpserver structure. The user can define these to redirect file I/O operations to other devices such as memory buffers or flash memory regions.

The callback interface defines a type, ftpserver_cookie that is passed to the callback functions. It is a word or pointer sized value and is typically used by the callback functions to contain a data structure pointer, or an index into a table that uniquely identifies an open file.

The callbacks for a notional *example* interface are defined as follows:

`int example_open( const char *path, cyg_bool write, ftpserver_cookie *cookie );`

> Called to open a file for data transfer. The *path* is a fully rooted path formed from the *root* field of the server configuration plus the client supplied path. The *write* argument is true if the file is to be opened for writing and false if for reading. If successful the function may store a private value to **cookie*.
>
> If the file is opened successfully this function should return FTPSERVER_OK. If the file cannot be opened for reading it should return FTPSERVER_NO_FILE. If the file cannot be written to or created it should return FTPSERVER_NOT_ALLOWED.

`int example_write( ftpserver_cookie cookie, const cyg_uint8 *buf, cyg_uint32 size );`

> Called to write data to the file. The *cookie* argument is the value stored by the open callback. Arguments *buf* and *size* define the data to be written.
>
> If the data is successfully written this function should return FTPSERVER_OK. If any error occurs it should return FTPSERVER_WRITE_FAIL.

int example_read(ftpserver_cookie cookie, cyg_uint8 *buf, cyg_uint32 *size);

Called to read data from the file. The cookie argument is the value stored by the open callback. Arguments buf and *size define a buffer into which the data should be stored, *size should be updated with the amount of data written to the buffer. If no more data is available, *size should be set to zero.

If the function is successful it should return FTPSERVER_OK. If any error occurs it should return FTPSERVER_READ_FAIL.

int example_close(ftpserver_cookie cookie);

Called to close the file for further data transfer. The cookie argument is the value stored by the open callback. After this call the cookie value will not be used in further calls.

This function should return FTPSERVER_OK under all circumstance, there are no error conditions of interest to the FTP server.

int example_auth(const char *user, const char *passwd);

This function is called to authenticate a user ID and password supplied by the client. The FTP server will only request a password, by returning a 331 response, if a user supplied authentication function is installed.

If the user and password are accepted, this function should return FTPSERVER_LOGIN_OK; it should return FTPSERVER_BADUSER if they do not.

int example_delete(const char *path);

Called to delete a file. The path is a fully rooted path formed from the root field of the server configuration plus the client supplied path.

If the file is deleted successfully this function should return FTPSERVER_OPDONE. If the file cannot be deleted or is not found, FTPSERVER_NO_FILE should be returned.

Extending the previous example, the cyg_ftpserver might look like this:

```
static cyg_ftpserver ftp_server =
{
    .port       = 2121,                           // Listen on port 2121
    .root       = "/fatfs/ftp",                   // FTP to/from here
    .greeting   = "Welcome to Fubar FTP service.", // Welcome string
    .data_port  = 40000,                          // Move data ports to 40000+

    .open       = example_open,
    .read       = example_read,
    .write      = example_write,
    .close      = example_close,
    .auth       = example_auth,
    .delete     = example_delete,

};
```

Configuration Options

The FTP server package contains a number of configuration options:

CYGNUM_NET_FTPSERVER_BUFFER_SIZE

This option defines the size of the buffer used for data transfers. Buffer size is a tradeoff between memory use and transfer speed. The default should be a reasonable compromise between these two.

CYGNUM_NET_FTPSERVER_USER_SIZE

This option defines the size of the buffer used for storing the user name supplied by the client.

`CYGNUM_NET_FTPSERVER_PASSWD_SIZE`

This option defines the size of the buffer used for storing the password supplied by the client. The default reflects the habit of using a user's email address as a password for anonymous FTP.

`CYGNUM_NET_FTPSERVER_CONTROL_TIMEOUT`

This option defines the timeout applied to control streams. If after this number of seconds the client has not interacted with the server, the connection is closed down. Since the server only allows a single client at a time, any client that fails to close a control stream down will block it for others.

`CYGNUM_NET_FTPSERVER_DATA_TIMEOUT`

This option defines the timeout applied to data streams. If after this number of seconds the client has not transferred data to or from the server, the connection is closed down. Clients are expected to use a data connection immediately after it is created so this timeout can be considerably smaller than the control timeout.

Name

FTP Server Test Programs — describe the test programs and their host-side support

Test Programs

There are three test programs in the `tests` subdirectory of this package that exercise the FTP server and do duty as examples of its use. These are supported by an eCos configuration and **expect** scripts in the `misc` subdirectory which call the standard linux **ftp** client to exercise the FTP server.

To build an eCos library suitably configured to support the test programs, import the `ftpserver.ecm` minimal configuration located in the `misc` subdirectory of this package (at `packages/net/ftpserver/`*`VERSION`* within your eCos package repository) into your target configuration. This minimal configuration loads the `CYGPKG_NET`, `CYGPKG_IO`, `CYGPKG_NET_FTPSERVER` and `CYGPKG_FS_RAM` packages, enables the building of the test programs as well as increases the sizes of `CYGPKG_NET_MAXSOCKETS`, `CYGNUM_FILEIO_NFILE` and `CYGNUM_FILEIO_NFD` from their default values to values large enough to allow the test scripts to operate in a reasonable amount of time.

When each test program is executed it will output on either the **gdb** console, or a debug channel, the filename of a corresponding **expect** script to be executed on your development PC, along with any additional parameters to provide the script. This **expect** script is used to exercise each FTP server test application. The script name and parameter will be contained within angle braces prefixed by `CMD:`. Each script can be executed on a suitable Linux host which has **expect** and the standard Linux text-mode **ftp** client installed and on the PATH. For example, the output below suggests that the script `ftpserver1.exp` is executed with the argument `192.168.1.54`.

```
  INFO:<Create file1>
  CMD:<ftpserver1.exp 192.168.1.54>
  INFO:<Start FTP server>
```

These scripts are located within the `misc` subdirectory of the FTP server package and on its completion will terminate the ftp test program on the target.

Note

All tests can be stopped manually by logging onto the target platform running the test with a standard ftp client using the user ID "shutdown" and password "now".

ftpserver1

The `ftpserver1.c` test creates a default FTP server using the RAM filesystem. A default file, `file1`, is created that can be retrieved, and further files can be uploaded, retrieved or overwritten.

ftpserver2

The `ftpserver2.c` test uses the callback interface to serve files in memory. It creates a read-only file, `text`, and a 32KB read/write buffer, `buffer`.

ftpserver3

The `ftpserver3.c` test is identical to `ftpserver1.c` except that it expects a specific user and password, "test" and "barnwell", to be supplied before it permits access.

Part LII. Embedded HTTP Server

Table of Contents

Chapter 185. Embedded HTTP Server

Introduction

The *eCos* HTTPD package provides a simple HTTP server for use with applications in eCos. This server is specifically aimed at the remote control and monitoring requirements of embedded applications. For this reason the emphasis is on dynamically generated content, simple forms handling and a basic CGI interface. It is *not* intended to be a general purpose server for delivering arbitrary web content. For these purposes a port of the GoAhead web server is available from www.goahead.com.

This server is also capable of serving content using IPv6 when the eCos configuration contains IPv6.

Server Organization

The server consists of one or more threads running in parallel to any application threads and which serve web pages to clients. Apart from defining content, the application does not need to do anything to start the HTTP server.

The HTTP server is, by default, started by a static constructor. This simply creates an initial thread and sets it running. Since this is called before the scheduler is started, nothing will happen until the application calls `cyg_scheduler_start()`. The server thread can also be started explicitly by the application, see the `CYGNUM_HTTPD_SERVER_AUTO_START` option for details.

When the thread gets to run it first optionally delays for some period of time. This is to allow the application to perform any initialization free of any interference from the HTTP server. When the thread does finally run it creates a socket, binds it to the HTTP server port, and puts it into listen mode. It will then create any additional HTTPD server threads that have been configured before becoming a server thread itself.

Each HTTPD server thread simply waits for a connection to be made to the server port. When the connection is made it reads the HTTP request and extracts the filename being accessed. If the request also contains form data, this is also preserved. The filename is then looked up in a table.

Each table entry contains a filename pattern string, a pointer to a handler function, and a user defined argument for the function. Table entries are defined using the same link-time table building mechanism used to generate device tables. This is all handled by the `CYG_HTTPD_TABLE_ENTRY()` macro which has the following format:

```
#include <cyg/httpd/httpd.h>

CYG_HTTPD_TABLE_ENTRY( __name, __pattern, __handler, __arg )
```

The `__name` argument is a variable name for the table entry since C does not allow us to define anonymous data structures. This name should be chosen so that it is unique and does not pollute the name space. The `__pattern` argument is the match pattern. The `__handler` argument is a pointer to the handler function and `__arg` the user defined value.

The link-time table building means that several different pieces of code can define server table entries, and so long as the patterns do not clash they can be totally oblivious of each other. However, note also that this mechanism does not guarantee the order in which entries appear, this depends on the order of object files in the link, which could vary from one build to the next. So any tricky pattern matching that relies on this may not always work.

A request filename matches an entry in the table if either it exactly matches the pattern string, or if the pattern ends in an asterisk, and it matches everything up to that point. So for example the pattern "/monitor/threads.html" will only match that exact filename, but the pattern "/monitor/thread-*" will match "/monitor/thread-0040.html", "/monitor/thread-0100.html" and any other filename starting with "/monitor/thread-".

When a pattern is matched, the hander function is called. It has the following prototype:

```
cyg_bool cyg_httpd_handler(FILE *client,
                           char *filename,
                           char *formdata,
                           void *arg);
```

The *client* argument is the TCP connection to the client: anything output through this stream will be returned to the browser. The *filename* argument is the filename from the HTTP request and the *formdata* argument is any form response data, or NULL if none was sent. The *arg* argument is the user defined value from the table entry.

The handler is entirely responsible for generating the response to the client, both HTTP header and content. If the handler decides that it does not want to generate a response it can return `false`, in which case the table scan is resumed for another match. If no match is found, or no handler returns true, then a default response page is generated indicating that the requested page cannot be found.

Finally, the server thread closes the connection to the client and loops back to accept a new connection.

Server Configuration

The HTTP server has a number of configuration options:

`CYGNUM_HTTPD_SERVER_PORT`

> This option defines the TCP port that the server will listen on. It defaults to the standard HTTP port number 80. It may be changed to a different number if, for example, another HTTP server is using the main HTTP port.

`CYGDAT_HTTPD_SERVER_ID`

> This is the string that is reported to the client in the "Server:" field of the HTTP header.

`CYGNUM_HTTPD_THREAD_COUNT`

> The HTTP server can be configured to use more than one thread to service HTTP requests. If you expect to serve complex pages with many images or other components that are fetched separately, or if any pages may take a long time to send, then it may be useful to increase the number of server threads. For most uses, however, the connection queuing in the TCP/IP stack and the speed with which each page is generated, means that a single thread is usually adequate.

`CYGNUM_HTTPD_THREAD_PRIORITY`

> The HTTP server threads can be run at any priority. The exact priority depends on the importance of the server relative to the rest of the system. The default is to put them in the middle of the priority range to provide reasonable response without impacting genuine high priority threads.

`CYGNUM_HTTPD_THREAD_STACK_SIZE`

> This is the amount of stack to be allocated for each of the HTTPD threads. The actual stack size allocated will be this value plus the values of `CYGNUM_HAL_STACK_SIZE_MINIMUM` and `CYGNUM_HTTPD_SERVER_BUFFER_SIZE`.

`CYGNUM_HTTPD_SERVER_BUFFER_SIZE`

> This defines the size of the buffer used to receive the first line of each HTTP request. If you expect to use particularly long URLs or have very complex forms, this should be increased.

`CYGNUM_HTTPD_SERVER_AUTO_START`

> This option causes the HTTP Daemon to be started automatically during system initialization. If this option is not set then the application must start the daemon explicitly by calling `cyg_httpd_startup()`. This option is set by default.

`CYGNUM_HTTPD_SERVER_DELAY`

> This defines the number of system clock ticks that the HTTP server will wait before initializing itself and spawning any extra server threads. This is to give the application a chance to initialize properly without any interference from the HTTPD.

Support Functions and Macros

The emphasis of this server is on dynamically generated content, rather than fetching it from a filesystem. To do this the handler functions make calls to `fprintf()` and `fputs()`. Such handler functions would end up a mass of print calls, with the actual structure of the HTML page hidden in the format strings and arguments, making maintenance and debugging very difficult. Such an approach would also result in the definition of many, often only slightly different, format strings, leading to unnecessary bloat.

In an effort to expose the structure of the HTML in the structure of the C code, and to maximize the sharing of string constants, the `cyg/httpd/httpd.h` header file defines a set of helper functions and macros. Most of these are wrappers for predefined print calls on the *`client`* stream passed to the hander function. For examples of their use, see the System Monitor example.

Note

All arguments to macros are pointers to strings, unless otherwise stated. In general, wherever a function or macro has an *`attr`* or *`__attr`* parameter, then the contents of this string will be inserted into the tag being defined as HTML attributes. If it is a NULL or empty string it will be ignored.

HTTP Support

```
void cyg_http_start( FILE *client, char *content_type, int content_length );
void cyg_http_finish( FILE *client );
#define html_begin(__client)
#define html_end( __client )
```

The function `cyg_http_start()` generates a simple HTTP response header containing the value of `CYGDAT_HTTPD_SERVER_ID` in the "Server" field, and the values of *`content_type`* and *`content_length`* in the "Content-type" and "Content-length" field respectively. The function `cyg_http_finish()` just adds an extra newline to the end of the output and then flushes it to force the data out to the client.

The macro `html_begin()` generates an HTTP header with a "text/html" content type followed by an opening "<html>" tag. `html_end()` generates a closing "</html>" tag and calls `cyg_http_finish()`.

General HTML Support

```
void cyg_html_tag_begin( FILE *client, char *tag, char *attr );
void cyg_html_tag_end( FILE *client, char *tag );
#define html_tag_begin( __client, __tag, __attr )
#define html_tag_end( __client, __tag )
#define html_head( __client, __title, __meta )
#define html_body_begin( __client, __attr )
#define html_body_end( __client )
#define html_heading( __client, __level, __heading )
#define html_para_begin( __client, __attr )
#define html_url( __client, __text, __link )
#define html_image( __client, __source, __alt, __attr )
```

The function `cyg_html_tag_begin()` generates an opening tag with the given name. The function `cyg_html_tag_end()` generates a closing tag with the given name. The macros `html_tag_begin()` and `html_tag_end` are just wrappers for these functions.

The macro `html_head()` generates an HTML header section with *`__title`* as the title. The *`__meta`* argument defines any meta tags that will be inserted into the header. `html_body_begin()` and `html_body_end` generate HTML body begin and end tags.

`html_heading()` generates a complete HTML header where *`__level`* is a numerical level, between 1 and 6, and *`__heading`* is the heading text. `html_para_begin()` generates a paragraph break.

`html_url()` inserts a URL where `__text` is the displayed text and `__link` is the URL of the linked page. `html_image()` inserts an image tag where `__source` is the URL of the image to be included and `__alt` is the alternative text for when the image is not displayed.

Table Support

```
#define html_table_begin( __client, __attr )
#define html_table_end( __client )
#define html_table_header( __client, __content, __attr )
#define html_table_row_begin( __client, __attr )
#define html_table_row_end( __client )
#define html_table_data_begin( __client, __attr )
#define html_table_data_end( __client )
```

`html_table_begin()` starts a table and `html_table_end()` end it. `html_table_header()` generates a simple table column header containg the string `__content`.

`html_table_row_begin()` and `html_table_row_end()` begin and end a table row, and similarly `html_table_data_begin()` and `html_table_data_end()` begin and end a table entry.

Forms Support

```
#define html_form_begin( __client, __url, __attr )
#define html_form_end( __client )
#define html_form_input( __client, __type, __name, __value, __attr )
#define html_form_input_radio( __client, __name, __value, __checked )
#define html_form_input_checkbox( __client, __name, __value, __checked )
#define html_form_input_hidden( __client, __name, __value )
#define html_form_select_begin( __client, __name, __attr )
#define html_form_option( __client, __value, __label, __selected )
#define html_form_select_end( __client )
void cyg_formdata_parse( char *data, char *list[], int size );
char *cyg_formlist_find( char *list[], char *name );
```

`html_form_begin()` begins a form, the `__url` argument is the value for the `action` attribute. `html_form_end()` ends the form.

`html_form_input()` defines a general form input element with the given type, name and value. `html_form_input_radio` creates a radio button with the given name and value; the `__checked` argument is a boolean expression that is used to determine whether the `checked` attribute is added to the tag. Similarly `html_form_input_checkbox()` defines a checkbox element. `html_form_input_hidden()` defines a hidden form element with the given name and value.

`html_form_select_begin()` begins a multiple choice menu with the given name. `html_form_select_end()` end it. `html_form_option()` defines a menu entry with the given value and label; the `__selected` argument is a boolean expression controlling whether the `selected` attribute is added to the tag.

`cyg_formdata_parse()` converts a form response string into an `NULL`-terminated array of "name=value" entries. The `data` argument is the string as passed to the handler function; note that this string is not copied and will be updated in place to form the list entries. `list` is a pointer to an array of character pointers, and is `size` elements long. `cyg_formlist_find()` searches a list generated by `cyg_formdata_parse()` and returns a pointer to the value part of the string whose name part matches `name`; if there is no match it will return `NULL`.

Predefined Handlers

```
cyg_bool cyg_httpd_send_html( FILE *client, char *filename, char *request, void *arg );

typedef struct
{
    char        *content_type;
    cyg_uint32  content_length;
    cyg_uint8   *data;
} cyg_httpd_data;
#define CYG_HTTPD_DATA( __name, __type, __length, __data )

cyg_bool cyg_httpd_send_data( FILE *client, char *filename, char *request, void *arg );
```

The HTTP server defines a couple of predefined handers to make it easier to deliver simple, static content.

`cyg_httpd_send_html()` takes a `NULL`-terminated string as the argument and sends it to the client with an HTTP header indicating that it is HTML. The following is an example of its use:

```
char cyg_html_message[] = "<head><title>Welcome</title></head>\n"
                          "<body><h2>Welcome to my Web Page</h2></body>\n"

CYG_HTTPD_TABLE_ENTRY( cyg_html_message_entry,
                       "/message.html",
                       cyg_httpd_send_html,
                       cyg_html_message );
```

`cyg_httpd_send_data()` Sends arbitrary data to the client. The argument is a pointer to a cyg_httpd_data structure that defines the content type and length of the data, and a pointer to the data itself. The `CYG_HTTPD_DATA()` macro automates the definition of the structure. Here is a typical example of its use:

```
static cyg_uint8 ecos_logo_gif[] = {
    …
};

CYG_HTTPD_DATA( cyg_monitor_ecos_logo_data,
                "image/gif",
                sizeof(ecos_logo_gif),
                ecos_logo_gif );

CYG_HTTPD_TABLE_ENTRY( cyg_monitor_ecos_logo,
                       "/monitor/ecos.gif",
                       cyg_httpd_send_data,
                       &cyg_monitor_ecos_logo_data );
```

System Monitor

Included in the HTTPD package is a simple System Monitor that is intended to act as a test and an example of how to produce servers. It is also hoped that it might be of some use in and of itself.

The System Monitor is intended to work in the background of any application. Adding the network stack and the HTTPD package to any configuration will enable the monitor by default. It may be disabled by disabling the `CYGPKG_HTTPD_MONITOR` option.

The monitor is intended to be simple and self-explanatory in use. It consists of four main pages. The thread monitor page presents a table of all current threads showing such things as id, state, priority, name and stack dimensions. Clicking on the thread ID will link to a thread edit page where the thread's state and priority may be manipulated. The interrupt monitor just shows a table of the current interrupts and indicates which are active. The memory monitor shows a 256 byte page of memory, with controls to change the base address and display element size. Note: Accessing invalid memory locations can cause memory exceptions and the program to crash. The network monitor page shows information extracted from the active network interfaces and protocols. Finally, if kernel instrumentation is enabled, the instrumentation page provides some controls over the instrumentation mechanism, and displays the instrumentation buffer.

Part LIII. SNMP

Table of Contents

Chapter 186. SNMP for *eCos*

Version

This is a port of UCD-SNMP-4.1.2

Originally this document said: See http://ucd-snmp.ucdavis.edu/ for details. And send them a postcard.

The project has since been renamed “net-snmp” and re-homed at http://net-snmp.sourceforge.net/ where various new releases (of the original, not *eCos* ports) are available.

The original source base from which we worked to create the *eCos* port is available from various archive sites such as ftp://ftp.freesnmp.com/mirrors/net-snmp/ generally with this filename and details:

```
        ucd-snmp-4.1.2.tar.gz. . . . . . Nov  2  2000   1164k
```

SNMP packages in the *eCos* source repository

The SNMP/eCos package consists of two eCos packages; the SNMP library and the SNMP agent.

The sources are arranged this way partly for consistency with the original release from UCD, and so as to accommodate possible future use of the SNMP library without having an agent present. That could be used to build an eCos-based SNMP client application.

The library contains support code for talking SNMP over the net - the SNMP protocol itself - and a MIB file parser (ASN-1) which is not used in the agent case.

The agent contains the application specific handler files to get information about the system into the SNMP world, together with the SNMP agent thread (`snmpd` in `UNIX` terms).

MIBs supported

The standard set in MIB-II, together with the Ether-Like MIB, are supported by default. The MIB files used to compile the handlers in the agent and to “drive” the testing (**snmpwalk** *et al* under `LINUX`) are those acquired from that same UCD distribution.

These are the supported MIBs; all are below mib2 == 1.3.6.1.2.1:

```
system        { mib2 1 }
interfaces    { mib2 2 }
              [ address-translation “at” { mib2 3 } is deprecated ]
ip            { mib2 4 }
icmp          { mib2 5 }
tcp           { mib2 6 }
udp           { mib2 7 }
              [ exterior gateway protocol “egp” { mib2 8 } not supported ]
              [ cmot { mib2 9 } is “historic”, just a placeholder ]
dot3          { mib2 10 7 } == { transmission 7 } “EtherLike MIB”
snmp          { mib2 11 }
```

On inclusion of SNMPv3 support packages, the following MIBs are added to the default set of MIBs enumerated above :

```
snmpEngine    { snmpFrameworkMIBObjects 1 }  SNMP-FRAMEWORK-MIB, as described in
                                             RFC-2571 for support of SNMPv3
                                             framework.

usmStats      {           usmMIBObjects 1 }  SNMP-USER-BASED-SM-MIB, as
usmUser       {           usmMIBObjects 2 }  specified in RFC-2574 for support
                                             of user based security model in
                                             SNMPv3 management domains.
```

Note

Not every MIB variable is necessarily supported - some don't really apply to eCos, some are simply not yet implemented, and some would be overly complex to implement to be worth it in an embedded system. Similarly writing to some variables may be permitted by the MIB definition, but may not produce any effect. For example trying to set an interface administratively up or down with IF-MIB::ifAdminStatus at present has no effect.

Changes to eCos sources

Small changes were made in three areas to accomodate SNMP originally:

1. Various hardware-specific ethernet drivers.
2. The generic ethernet device driver.
3. The OpenBSD TCP/IP networking package (Deprecated and removed from current eCosPro releases).

These changes were made in order to export information about the driver and the network that the SNMP agent must report. The changes were trivial in the case of the network stack, since it was already SNMP-friendly. The generic ethernet device driver was re-organized to have an extensive header file and to add a couple of APIs to extract statistics that the hardware-specific device drivers keep within themselves.

There may be a performance hit for recording that data; disabling a config option named something like `CYGDBG_DEVS_ETH_xxxx_xxxx_KEEP_STATISTICS` depending on the specific device driver will prevent that.

Not all platform ethernet device drivers export complete SNMP statistical information; if the exported information is missing, SNMP will report zero values for such data (in the dot3 MIB).

The interface chipset has an ID which is an OID; not all the latest greatest devices are listed in the available database, so new chipsets may need to be added to the client MIB, if not defined in those from UCD.

Starting the SNMP Agent

A routine to instantiate and start the SNMP agent thread in the default configuration is provided in `PACKAGES/net/snmp/agent/current/src/snmptask.c`

It starts the snmpd thread at priority `CYGPKG_NET_THREAD_PRIORITY+1` by default, ie. one step less important than the TCP/IP stack service thread. It also statically creates and uses a very large stack of around 100 KiloBytes. To use that convenience function, this code fragment may be copied (in plain C).

```
#ifdef CYGPKG_SNMPAGENT
{
                extern void cyg_net_snmp_init(void);
                cyg_net_snmp_init();

}
#endif
```

In case you need to perform initialization, for example setting up SNMPv3 security features, when the snmp agent starts and every time it restarts, you can register a callback function by simply writing the global variable:

```
externC void (*snmpd_reinit_function)( void );
```

with a suitable function pointer.

The entry point to the SNMP agent is:

```
externC void snmpd( void (*initfunc)( void ) );
```

so you can of course easily start it in a thread of your choice at another priority instead if required, after performing whatever other initialization your SNMP MIBs need. A larger than default stacksize is required. The `initfunc` parameter is the callback function mentioned above — a NULL parameter there is safe and obviously means no callback is registered.

Note that if you call `snmpd();` yourself and do *not* call `cyg_net_snmp_init();` then that routine, global variable, and the default large stack will not be used. This is the recommended way control such features from your application; create and start the thread yourself at the appropriate moment.

Other APIs from the `snmpd` module are available, specifically:

```
void SnmpdShutDown(int a);
```

which causes the `snmpd` to restart itself — including the callback to your init function — as soon as possible.

The parameter *a* is ignored. It is there because in `snmpd`'s “natural environment” this routine is a `UNIX` signal handler.

The helper functions in the network stack for managing `DHCP` leases will call `SnmpdShutDown()` when necessary, for example if network interfaces go down and/or come up again.

Configuring eCos

To use the SNMP agent, the SNMP library and agent packages must be included in your configuration. To incorporate the stack into your configuration select the SNMP library and SNMP agent packages in the eCos Configuration Tool, or at the command line type:

```
$ ecosconfig add snmplib snmpagent
```

After adding the networking, common ethernet device drivers, snmp library and snmp agent packages, there is no configuration required. However there are a number of configuration options that can be set such as some details for the System MIB, and disabling SNMPv3 support (see below).

Starting the SNMP agent is not integrated into network tests other than `snmpping` below, nor is it started automatically in normal eCos startup - it is up to the application to start the agent when it is ready, at least after the network interfaces are both ’up,.

Version usage (v1, v2 or v3)

The default build supports all three versions of the SNMP protocol, but without any dispatcher functionality (rfc 2571, section 3.1.1.2). This has the following implications :

1. There is no community authentication for v1 and v2c.

2. Security provided by v3 can be bypassed by using v1/v2c protocol.

To provide the dispatcher with rfc 2571 type functionality, it is required to set up security models and access profiles. This can be provided in the normal Unix style by writing the required configurations in `snmpd.conf` file. Application code may setup profiles in `snmpd.conf` and optionally set the environment variable `SNMPCONFPATH` to point to the file if it is not in the usual location. The whole concept works in the usual way as with the standard UCD-SNMP distribution.

Traps

The support of the `trapsink` command in the snmpd.conf file is not tested and there may be problems for it working as expected. Moreover, in systems that do not have filesystem support, there is no way to configure a trap-session in the conventional way.

For reasons mentioned above, applications need to initialize their own trap sessions and pass it the details of trap-sink. The following is a small sample for initializing a v1 trap session :

```
typedef struct trap {
        unsigned char ip [4];
        unsigned int  port;
        unsigned char community [256];
}

trap            trapsink;
unsinged char   sink [16];

…
…

if (trapsink.ip != 0) {
        sprintf (sink, "%d.%d.%d.%d",
                 trapsink[0], trapsink[1], trapsink[2], trapsink[3]);
        if (create_trap_session (sink,
                trapsink.port,
                (char *)trapsink.community,
                SNMP_VERSION_1,
                SNMP_MSG_TRAP) == 0) {
                log_error ("Creation of trap session failed \n");
        }
}
```

`snmpd.conf` file

Using snmpd.conf requires the inclusion of one of the file-system packages (eg. CYGPKG_RAMFS) and CYGPKG_FILEIO. With these two packages included, the SNMP sub-system will read the snmpd.conf file from the location specified in `SNMPCONFPATH`, or the standard builtin locations, and use these profiles. Only the profiles specified in the `ACCESS-CONTROL` section of snmpd.conf file have been tested and shown to work. Other profiles which have been implemented in `UCD-SNMP-4.1.2`'s `snmpd.conf` may not work because the sole purpose of adding support for the snmpd.conf file has been to set up `ACCESS-CONTROL` models.

At startup, the SNMP module tries to look for file `snmp.conf`. If this file is not available, the module successively looks for files `snmpd.conf`, `snmp.local.conf` and `snmpd.local.conf` at the locations pointed to by `SNMPCONFPATH` environment variable. In case `SNMPCONFPATH` is not defined, the search sequence is carried out in default directories. The default directories are :`/usr/share/snmp`, `/usr/local/share/snmp` and `$(HOME)/.snmp`. The configurations read from these files are used to control both, SNMP applications and the SNMP agent; in the usual UNIX fashion.

The inclusion of snmpd.conf support is enabled by default when suitable filesystems and FILEIO packages are active.

Test cases

Currently only one test program is provided which uses SNMP.

"snmpping" in the SNMP agent package runs the ping test from the TCPIP package, with the snmpd running also. This allows you to interrogate it using host tools of your choice. It supports MIBs as documented above, so eg. **snmpwalk <*`hostname`*> public dot3** under Linux/UNIX should have the desired effect.

For serious testing, you should increase the length of time the test runs by setting CYGNUM_SNMPAGENT_TESTS_ITERATIONS to something big (e.g., 999999). Build the test (**make -C net/snmp/agent/current tests**) and run it on the target.

Then start several jobs, some for pinging the board (to make the stats change) and some for interrogating the snmpd. Set $IP to whatever IP address the board has:

```
# in a root shell, for flood ping
while(1)
date
ping -f -c 3001 $IP
sleep 5
ping -c 32 -s 2345 $IP
end
```

```
# have more than one of these going at once
```

```
setenv MIBS all
while (1)
snmpwalk -OS $IP  public
date
end
```

Leave to run for a couple of days or so to test stability.

The test program can also test snmpd.conf support. It tries to build a minimal snmpd.conf file on a RAM filesystem and passes it to the snmp sub-system. With this profile on target, the following snmp[cmd] (cmd=walk, get, set) should work :

```
snmp[cmd] -v1 $IP crux $OID
snmp[cmd] -v2 $IP crux $OID
snmp[cmd] -v3 $IP -u root -L noAuthNoPriv $OID
snmp[cmd] -v3 $IP -u root -L authNoPriv -A MD5 -a md5passwd $OID
```

The following commands would however fail since they violate the access model :

```
snmp[cmd] $IP public $OID
snmp[cmd] -v1 $IP public $OID
snmp[cmd] -v2c $IP public $OID
snmp[cmd] -v3 $IP -u no_user -L noAuthNoPriv $OID
snmp[cmd] -v3 $IP -u root -L authNoPriv -A MD5 -a badpasswd $OID
```

SNMP clients and package use

SNMP clients may use these packages, but this usage is currently untested: the reason why this port to eCos exists is to acquire the SNMP agent. The fact that that the SNMP API (for clients) exists is a side-effect. See the standard man page SNMP_API(3) for details. There are further caveats below about client-side use of the SNMP library.

All of the SNMP header files are installed beneath .../include/ucd-snmp in the install tree. The SNMP code itself assumes that directory is on its include path, so we recommend that client code does the same. Further, like the TCP/IP stack, compiling SNMP code requires definition of _KERNEL and __ECOS, and additionally IN_UCD_SNMP_SOURCE.

Therefore, add all of these to your compile lines if you wish to include SNMP header files:

```
-D_KERNEL
-D__ECOS
-DIN_UCD_SNMP_SOURCE=1
-I$(PREFIX)/include/ucd-snmp
```

Unimplemented features

Currently, the filesystem and persistent storage areas are left undone, to be implemented by the application.

The SNMP library package is intended to support client and agent code alike. It therefore contains lots of assumptions about the presence of persistent storage ie. a filesystem. Currently, by default, eCos has no such thing, so those areas have been simply commented out and made to return empty lists or say “no data here.”

Specifically the following files have omitted/unimplemented code :

`PACKAGES/net/snmp/lib/current/src/parse.c`

contains code to enumerate MIB files discovered in the system MIB directories (“`/usr/share/snmp/mibs`”), and read them all in, building data structures that are used by client programs to interrogate an agent. This is not required in an agent, so the routine which enumerates the directories returns an empty list.

`PACKAGES/net/snmp/lib/current/src/read_config.c` contains two systems:

The first tries to read the configuration file as described in the snmpd.conf file section and the second system contains code to record persistent data as files in a directory (typically `/var/ucd-snmp`) thus preserving the state permanently.

The first part is partially implemented to support multiple profiles and enables dispatcher functionality as discussed in the section called "Version usage (v1, v2 or v3)". The second part is not supported at all in the default implementation. As required, a cleaner interface to permit application code to manage persistent data will be developed in consultation with customers.

MIB Compiler

In the directory `/snmp/agent/current/utils/mib2c`, there are the following files:

```
README-eCos              notes about running with a nonstandard
                         perl path.
README.mib2c             the README from UCD; full instructions on
                         using mib2c
mib2c                    the perl program
mib2c.conf               a configuration file altered to include the
                         eCos/UCD
mib2c.conf-ORIG          copyright and better #include paths; and
                         the ORIGinal.
mib2c.storage.conf       other config files, not modified.
mib2c.vartypes.conf
```

mib2c is provided BUT it requires the SNMP perl package SNMP-3.1.0, and that in turn requires perl nsPerl5.005_03 (part of Red Hat Linux from 6.0, April 1999).

These are available from the CPAN ("the Comprehensive Perl Archive Network") as usual; http://www.cpan.org/ and links from there. Specifically:

- PERL itself: http://people.netscape.com/kristian/nsPerl/

(note that the .tar.gz files are not browsable)

For documentation on the files produced, see the documentation available at http://ucd-snmp.ucdavis.edu/ in general, and file `AGENT.txt` in particular.

It is likely that the output of mib2c will be further customized depending on eCos customer needs; it,s easy to do this by editing the mib2c.conf file to add or remove whatever you need with the resulting C sources.

The UCD autoconf-style configuration does not apply to eCos. So if you add a completely new MIB to the agent, and support it using mib2c so that the my_new_mib.c file contains a init_my_new_mib() routine to register the MIB handler, you will also need to edit a couple of control files; these claim to be auto-generated, but in the eCos release, they,re not, don,t worry.

```
PACKAGES/net/snmp/agent/current/include/mib_module_includes.h
```

contains a number of lines like

```
#include "mibgroup/mibII/interfaces.h"
```

so add your new MIB thus:

```
#include "mibgroup/mibII/my_new_mib.h"
```

```
PACKAGES/net/snmp/agent/current/include/mib_module_inits.h
```

contains a number of lines like

```
init_interfaces();
init_dot3();
```

and so on; add your new MIB as follows:

```
init_my_new_mib();
```

and this should work correctly.

snmpd.conf

```
SNMPD.CONF(5)                                       SNMPD.CONF(5)

NAME
       share/snmp/snmpd.conf  -  configuration  file for the ucd-
       snmp SNMP agent.

DESCRIPTION
       snmpd.conf is the configuration file which defines how the
       ucd-smnp SNMP agent operates.  These files may contain any
       of the directives found in the DIRECTIVES  section  below.
       This  file  is  not  required for the agent to operate and
       report mib entries.

PLEASE READ FIRST
       First, make sure you have read the  snmp_config(5)  manual
       page  that  describes how the ucd-snmp configuration files
       operate, where they are located  and  how  they  all  work
       together.

EXTENSIBLE-MIB
       The  ucd-snmp  SNMP  agent reports much of its information
       through queries to the 1.3.6.1.4.1.2021 section of the mib
       tree.   Every  mib in this section has the following table
       entries in it.

       .1 -- index
              This is the table's index numbers for each  of  the
              DIRECTIVES listed below.

       .2 -- name
              The  name of the given table entry.  This should be
              unique, but is not required to be.

       .100 -- errorFlag
              This is a flag returning either the integer value 1
              or  0 if an error is detected for this table entry.

       .101 -- errorMsg
              This is a DISPLAY-STRING describing any error trig-
              gering the errorFlag above.

       .102 -- errorFix
              If  this entry is SNMPset to the integer value of 1
              AND the errorFlag defined above is indeed  a  1,  a
              program  or script will get executed with the table
              entry name from above as the argument.  The program
              to  be  executed is configured in the config.h file
              at compile time.

   Directives
       proc NAME

       proc NAME MAX

       proc NAME MAX MIN
```

```
              Checks to see if the NAME'd processes  are  running
              on  the  agent's  machine.  An error flag (1) and a
              description  message  are  then   passed   to   the
              1.3.6.1.4.1.2021.2.100  and  1.3.6.1.4.1.2021.2.101
              mib tables (respectively) if the NAME'd program  is
              not  found  in  the  process  table  as reported by
              "/bin/ps -e".

              If MAX and MIN are not specified, MAX is assumed to
              be infinity and MIN is assumed to be 1.

              If  MAX  is specified but MIN is not specified, MIN
              is assumed to be 0.

       procfix NAME PROG ARGS
              This registers a command  that  knows  how  to  fix
              errors   with   the   given   process  NAME.   When
              1.3.6.1.4.1.2021.2.102 for a given NAMEd program is
              set to the integer value of 1, this command will be
              called.  It defaults to a compiled value set  using
              the PROCFIXCMD definition in the config.h file.

       exec NAME PROG ARGS

       exec MIBNUM NAME PROG ARGS

              If  MIBNUM is not specified, the agent executes the
              named PROG with arguments of ARGS and  returns  the
              exit status and the first line of the STDOUT output
              of   the   PROG   program   to   queries   of   the
              1.3.6.1.4.1.2021.8.100  and  1.3.6.1.4.1.2021.8.101
              mib  tables  (respectively).   All  STDOUT   output
              beyond the first line is silently truncated.

              If  MIBNUM  is  specified,  it  acts  as  above but
              returns the exit status  to  MIBNUM.100.0  and  the
              entire  STDOUT  output to the table MIBNUM.101 in a
              mib table.  In this case, the MIBNUM.101  mib  con-
              tains the entire STDOUT output, one mib table entry
              per line of output (ie, the first line is output as
              MIBNUM.101.1,  the second at MIBNUM.101.2, etc…).

              Note:  The MIBNUM must be specified in dotted-inte-
                     ger  notation  and  can  not be specified as
                     ".iso.org.dod.internet…"  (should  instead
                     be

              Note:  The  agent caches the exit status and STDOUT
                     of the executed program for 30 seconds after
                     the  initial  query.   This  is  to increase
                     speed and maintain consistency  of  informa-
                     tion  for  consecutive  table  queries.  The
                     cache can be flushed by a  snmp-set  request
                     of  integer(1)  to 1.3.6.1.4.1.2021.100.VER-
                     CLEARCACHE.

       execfix NAME PROG ARGS
              This registers a command  that  knows  how  to  fix
              errors  with  the  given  exec  or  sh  NAME.  When
              1.3.6.1.4.1.2021.8.102 for a given NAMEd  entry  is
              set to the integer value of 1, this command will be
              called.  It defaults to a compiled value set  using
              the EXECFIXCMD definition in the config.h file.

       disk PATH

       disk PATH [ MINSPACE | MINPERCENT% ]
```

```
              Checks  the  named disks mounted at PATH for avail-
              able disk space.  If the disk space  is  less  than
              MINSPACE  (kB) if specified or less than MINPERCENT
              (%) if a  %  sign  is  specified,  or  DEFDISKMINI-
              MUMSPACE  (kB)  if  not  specified,  the associated
              entry in the 1.3.6.1.4.1.2021.9.100 mib table  will
              be  set to (1) and a descriptive error message will
              be returned to queries of 1.3.6.1.4.1.2021.9.101.

       load MAX1

       load MAX1 MAX5

       load MAX1 MAX5 MAX15

              Checks the load average of the machine and  returns
              an error flag (1), and an text-string error message
              to   queries   of    1.3.6.1.4.1.2021.10.100    and
              1.3.6.1.4.1.2021.10.101   (respectively)  when  the
              1-minute, 5-minute, or  15-minute  averages  exceed
              the associated maximum values.  If any of the MAX1,
              MAX5, or MAX15 values are unspecified, they default
              to a value of DEFMAXLOADAVE.

       file FILE [MAXSIZE]
              Monitors  file sizes and makes sure they don't grow
              beyond a certain size.  MAXSIZE defaults  to  infi-
              nite  if  not specified, and only monitors the size
              without reporting errors about it.

   Errors
       Any errors in obtaining the above information are reported
       via    the    1.3.6.1.4.1.2021.101.100    flag   and   the
       1.3.6.1.4.1.2021.101.101 text-string description.

SMUX SUB-AGENTS
       To enable and SMUX based sub-agent, such as gated, use the
       smuxpeer configuration entry

       smuxpeer OID PASS
              For gated a sensible entry might be

       .1.3.6.1.4.1.4.1.3 secret

ACCESS CONTROL
       snmpd  supports the View-Based Access Control Model (vacm)
       as defined in RFC 2275.  To this end,  it  recognizes  the
       following  keywords  in  the  configuration file: com2sec,
       group, access, and view  as  well  as  some  easier-to-use
       wrapper   directives:  rocommunity,  rwcommunity,  rouser,
       rwuser.

       rocommunity COMMUNITY [SOURCE] [OID]

       rwcommunity COMMUNITY [SOURCE] [OID]
              These create read-only and  read-write  communities
              that  can  be used to access the agent.  They are a
              quick method of using the following com2sec, group,
              access,  and view directive lines.  They are not as
              efficient either, as groups aren't created  so  the
              tables  are possibly larger.  In other words: don't
              use these if you have complex situations to set up.

              The  format  of the SOURCE is token is described in
              the com2sec directive section below.  The OID token
              restricts  access  for that community to everything
              below that given OID.

       rouser USER [noauth|auth|priv] [OID]

       rwuser USER [noauth|auth|priv] [OID]
              Creates a  SNMPv3  USM  user  in  the  VACM  access
              configuration  tables.   Again,  its more efficient
              (and powerful) to use the combined com2sec,  group,
              access, and view directives instead.

              The minimum level of authentication and privacy the
              user must use  is  specified  by  the  first  token
              (which  defaults  to  "auth").   The  OID parameter
              restricts access for that user to everything  below
              the given OID.

       com2sec NAME SOURCE COMMUNITY
              This   directive   specifies  the  mapping  from  a
              source/community pair to a  security  name.  SOURCE
              can be a hostname, a subnet, or the word "default".
              A subnet can be specified as  IP/MASK  or  IP/BITS.
              The first source/community combination that matches
              the incoming packet is selected.

       group NAME MODEL SECURITY
              This directive defines the mapping  from  security-
              model/securityname  to  group.  MODEL is one of v1,
              v2c, or usm.

       access NAME CONTEXT MODEL LEVEL PREFX READ WRITE NOTIFY
              The  access  directive  maps  from   group/security
              model/security  level  to  a view.  MODEL is one of
              any, v1, v2c, or usm.   LEVEL  is  one  of  noauth,
              auth,  or priv.  PREFX specifies how CONTEXT should
              be matched against the context of the incoming pdu,
              either  exact  or  prefix.   READ, WRITE and NOTIFY
              specifies the view to be used for the corresponding
              access.   For  v1  or  v2c  access,  LEVEL  will be
              noauth, and CONTEXT will be empty.

       view NAME TYPE SUBTREE [MASK]
              The defines the named view. TYPE is either included
              or  excluded.   MASK is a list of hex octets, sepa-
              rated by '.' or ':'.  The MASK defaults to "ff"  if
              not specified.

              The  reason  for the mask is, that it allows you to
              control access to one row in a table,  in  a  rela-
              tively  simple  way.  As  an example, as an ISP you
              might consider giving each customer access  to  his
              or her own interface:

              view cust1 included interfaces.ifTable.ifEntry.ifIndex.1 ff.a0
              view cust2 included interfaces.ifTable.ifEntry.ifIndex.2 ff.a0

              (interfaces.ifTable.ifEntry.ifIndex.1 == .1.3.6.1.2.1.2.2.1.1.1,
              ff.a0 == 11111111.10100000. which nicely covers up and including
              the row index, but lets the user vary the field of the row)

       VACM Examples:
              #       sec.name  source          community
              com2sec local     localhost       private
              com2sec mynet     10.10.10.0/24   public
              com2sec public    default         public

              #             sec.model  sec.name
              group mygroup v1         mynet
              group mygroup v2c        mynet
              group mygroup usm        mynet
              group local   v1         local
              group local   v2c        local
              group local   usm        local
              group public  v1         public
              group public  v2c        public
              group public  usm        public

              #           incl/excl subtree                          mask
              view all    included  .1                               80
              view system included  system                           fe
              view mib2   included  .iso.org.dod.internet.mgmt.mib-2 fc

              #              context sec.model sec.level prefix read   write notify
              access mygroup ""      any       noauth    exact  mib2   none  none
              access public  ""      any       noauth    exact  system none  none
              access local   ""      any       noauth    exact  all    all   all

       Default VACM model
              The default configuration of the agent, as shipped, is functionally
              equivalent to the following entries:
              com2sec   public    default   public
              group     public    v1   public
              group     public    v2c  public
              group     public    usm  public
              view      all  included  .1
              access    public    ""   any  noauth    exact     all  none none

SNMPv3 CONFIGURATION
       engineID STRING
              The  snmpd  agent  needs  to  be configured with an
              engineID to be able to respond to SNMPv3  messages.
              With  this  configuration  file  line, the engineID
              will be configured from STRING.  The default  value
              of  the  engineID  is  configured with the first IP
              address found for the hostname of the machine.

       createUser username (MD5|SHA) authpassphrase [DES]  [priv-
       passphrase]
              This directive should be placed into the "/var/ucd-
              snmp"/snmpd.conf  file  instead of the other normal
              locations.  The reason is that the  information  is
              read  from  the  file  and then the line is removed
              (eliminating the storage of the master password for
              that  user)  and  replaced  with  the  key  that is
              derived from it.  This key is a localized  key,  so
              that  if  it is stolen it can not be used to access
              other agents.  If the password is stolen,  however,
              it can be.

              MD5  and  SHA  are the authentication types to use,
              but you must have built the  package  with  openssl
              installed  in  order  to use SHA.  The only privacy
              protocol currently supported is DES.  If  the  pri-
              vacy  passphrase is not specified, it is assumed to
              be the same as the authentication passphrase.  Note
              that  the users created will be useless unless they
              are also added to the VACM  access  control  tables
              described above.

              Warning:  the minimum pass phrase length is 8 char-
              acters.

              SNMPv3 users can be created at  runtime  using  the
              snmpusm command.
```

```
SETTING SYSTEM INFORMATION
       syslocation STRING

       syscontact STRING

              Sets the system location and the system contact for
              the agent.  This information  is  reported  by  the
              'system' table in the mibII tree.

       authtrapenable NUMBER
              Setting  authtrapenable  to 1 enables generation of
              authentication failure traps. The default value  is
              2 (disable).

       trapcommunity STRING
              This  defines  the  default  community string to be
              used when sending traps.  Note  that  this  command
              must  be  used  prior to any of the following three
              commands  that  are  intended  use  this  community
              string.

       trapsink HOST [COMMUNITY [PORT]]

       trap2sink HOST [COMMUNITY [PORT]]

       informsink HOST [COMMUNITY [PORT]]
              These  commands  define  the hosts to receive traps
              (and/or inform notifications). The daemon  sends  a
              Cold  Start  trap when it starts up. If enabled, it
              also sends traps on authentication failures.   Mul-
              tiple  trapsink, trap2sink and informsink lines may
              be specified to specify multiple destinations.  Use
              trap2sink  to  send  SNMPv2 traps and informsink to
              send inform notifications.   If  COMMUNITY  is  not
              specified,  the  string from a preceding trapcommu-
              nity directive will be used. If PORT is not  speci-
              fied,  the  well known SNMP trap port (162) will be
              used.

PASS-THROUGH CONTROL
       pass MIBOID EXEC
              Passes entire control of MIBOID to  the  EXEC  pro-
              gram.   The  EXEC  program  is called in one of the
              following three ways:

              EXEC -g MIBOID

              EXEC -n MIBOID

                     These call lines match to SNMP get and  get-
                     next requests.  It is expected that the EXEC
                     program will take the arguments passed to it
                     and  return the appropriate response through
                     it's stdout.

                     The first line of stdout should be  the  mib
                     OID of the returning value.  The second line
                     should be the TYPE of value returned,  where
                     TYPE  is  one  of  the text strings: string,
                     integer,  unsigned,   objectid,   timeticks,
                     ipaddress,  counter,  or  gauge.   The third
                     line of stdout should be  the  VALUE  corre-
                     sponding with the returned TYPE.

                     For  instance, if a script was to return the
                     value integer value "42" when a request  for
                     .1.3.6.1.4.100  was  requested,  the  script
                     should return the following 3 lines:
                       .1.3.6.1.4.100
                       integer
                       42

                     To indicate that the  script  is  unable  to
                     comply with the request due to an end-of-mib
                     condition or an invalid request, simple exit
                     and  return  no  output to stdout at all.  A
                     snmp error will be  generated  corresponding
                     to the SNMP NO-SUCH-NAME response.

              EXEC -s MIBOID TYPE VALUE

                     For SNMP set requests, the above call method
                     is used.  The TYPE passed to the  EXEC  pro-
                     gram  is  one  of the text strings: integer,
                     counter, gauge, timeticks, ipaddress, objid,
                     or  string,  indicating  the  type  of value
                     passed in the next argument.

                     Return nothing to stdout, and the  set  will
                     assumed to have been successful.  Otherwise,
                     return one of the following error strings to
                     signal an error: not-writable, or wrong-type
                     and the appropriate error response  will  be
                     generated instead.

                      Note:  By   default,   the  only  community
                             allowed to  write  (ie  snmpset)  to
                             your  script  will  be the "private"
                             community,or community #2 if defined
                             differently by the "community" token
                             discussed above.  Which  communities
                             are  allowed  write  access are con-
                             trolled by the RWRITE definition  in
                             the snmplib/snmp_impl.h source file.

EXAMPLE
       See the EXAMPLE.CONF file in the top level  source  direc-
       tory for a more detailed example of how the above informa-
       tion is used in real examples.

RE-READING snmpd.conf and snmpd.local.conf
       The ucd-snmp agent can be forced to re-read its configura-
       tion files.  It can be told to do so by one of two ways:

       1.     An       snmpset       of       integer(1)       to
              1.3.6.1.4.1.2021.100.VERUPDATECONFIG.

       2.     A "kill -HUP" signal sent to the snmpd  agent  pro-
              cess.

FILES
       share/snmp/snmpd.conf

Part LIV. mDNS Responder and DNS-SD

Important

This eCosPro-mDNS Middleware package is STRICTLY LICENSED FOR NON-COMMERCIAL PURPOSES ONLY. It may not be used for Commercial purposes in full or in part in any format, including source code, binary code and object code format.

A Commercial eCosPro License version 3 (or above) which explicity includes this Middleware Package is required for Commercial use.

Table of Contents

Chapter 187. mDNS overview

Introduction

eCosPro-mDNS is eCosCentric's commercial name for the `CYGPKG_NET_MDNS` package. The `CYGPKG_NET_MDNS` package implements a small, lightweight, link-local scope mDNS Responder designed to provide Service Discovery (DNS-SD) support for services announced to the network. It optionally provides a DNS-SD API to allow network services to be discovered by the client application. The current mDNS implementation makes use of the lwIP TCP/IP stack.

mDNS Responder Features:

- Probing and Announcement of the local hostname and of registered services.

  These are repeated as necessary on cable change, mDNS naming conflict, and so on.

- Configuration of local DNS records, and responding to external mDNS queries for the local hostname and registered services.

  ### Note

  Only the class IN "the Internet" is supported.

- Support for both IPv4 and IPv6 addressing.

  ### Note

  Only link-local scope.

The goal of the mDNS Responder support is to have as small a dynamic memory footprint as possible, whilst still being flexible enough for a variety of real-world scenarios. The mDNS Responder currently has a simple single-packet probe/announce scheme. This limits the number of services that can be registered depending on the lwIP heap available and the limitations that lwIP imposes on individual UDP packet transmissions. It is important that the mDNS configuration matches the client application expectations as regards number of services, and the resources available (and configured) for the target platform.

DNS-SD Features:

- Simple, low resource footprint, callback mechanism for Resource Record processing.
- Ability to generate network queries for specific Resource Record types, to trigger responses.

Similar to the goal for the mDNS Responder, the DNS-SD API allows for clients to be coded with as small a dynamic memory footprint as possible, whilst not limiting the possibilities for resource-rich applications.

The mDNS implementation is based on the Multicast DNS RFC6762 and DNS-Based Service Discovery RFC6763 standards.

These in turn reference many other RFCs, for example RFC2782 for DNS SRV records, and RFC1035 covering DNS TXT entries.

The MCASTDNS section 16 "Multicast DNS Character Set" explicitly states that all names in mDNS MUST be encoded as precomposed UTF-8 [RFC3629] "Net-Unicode" [RFC5198] text. When an application provides strings to the mDNS Responder it should ensure that they conform to the standard naming requirements.

A good introduction to the features and benefits of Bonjour/Zeroconf can be found in the O'Reilly book "Zero Configuration Networking - The Definitive Guide" written by Stuart Chesire and Daniel H. Steinberg.

Chapter 188. API

The main mDNS API provides a serialisation layer between the low-level (lwIP) networking based operations and client application threads.

API

Name

cyg_mdns_init — Initialise mDNS Responder

Synopsis

#include <mdns.h>

```
cyg_bool cyg_mdns_init();
```

Description

This initialises the common mDNS support. It will normally be called from the application shortly after lwIP initialisation, and performs the basic "start-of-day" initialisation.

Note

All of the required lwIP network interfaces should have been added (normally via a call to the `init_all_network_interfaces()`) prior to initialising the mDNS Responder. If network interfaces are subsequently removed then the mDNS daemon should be disabled and re-enabled with the functions `cyg_mdns_disable()` and `cyg_mdns_enable()` to ensure the correct interface configurations are used. If network interfaces are subsequently added, it is sufficient to call solely `cyg_mdns_enable()` so that it configures the new interface for mDNS requests.

Once initialised, it is possible to register services with `cyg_mdns_service_register()`, and then allow the mDNS responder to respond to incoming requests with `cyg_mdns_enable()`.

Return value

Boolean `true` if the mDNS sub-system has initialised OK, or `false` on failure.

Name

cyg_mdns_terminate — Terminate mDNS Responder

Synopsis

#include <mdns.h>

```
void cyg_mdns_terminate();
```

Description

Provides clean soft-shutdown of the mDNS Responder. In reality most deeply embedded systems will never actually need to call this routine, since they will be CPU-reset-restart systems.

This call will unregister all attached service vectors before disabling enabled interfaces. So any leaving (TTL=0) announcements will be transmitted and IGMP/MLD filtering will be removed prior to disabling the mDNS packet reception.

Name

cyg_mdns_enable — Enable mDNS

Synopsis

#include <mdns.h>

```
cyg_bool cyg_mdns_enable();
```

Description

Start the mDNS Responder listening on all of the network interfaces. This function enables the listener “daemon” to respond to mDNS queries. Usually, this call does nothing if the mDNS Responder is already enabled, except in the case where new network interfaces have been added, in which case this function is called in order to receive mDNS requests on the new interfaces.

Return value

Boolean `true` if mDNS successfully initialised. On error `false` is returned.

Name

cyg_mdns_disable — Disable mDNS

Synopsis

#include <mdns.h>

```
cyg_bool cyg_mdns_disable();
```

Description

This function stops the mDNS Responder from listening on the network interfaces. This function does nothing if the mDNS Responder is not enabled.

Return value

Boolean `true` if mDNS successfully disabled. On error `false` is returned.

Name

cyg_mdns_service_register — Register set of services

Synopsis

#include <mdns.h>

cyg_bool **cyg_mdns_service_register**(*count*, *vector*);

Description

This function registers the set of service(s) in the supplied *vector* array. *count* gives the number of vector entries. If any of the referenced services were already registered for a different service then an error is returned and none of the services in the supplied *vector* are registered. If there are no free (CDL CYGNUM_MDNS_NUM_SERVICE_VECTORS controlled) vector slots available then an error is returned.

A unique 3-tuple will be used to identify services registered. The tuple consists of the UTF-8 *service* and *proto* strings, plus the 16-bit service *port* number. A simple descriptor structure is defined to hold these values, along with the “Weight” and “Priority” values (which are not considered part of the unique identification). It is the responsibility of the caller to ensure the lifetime of the string objects referenced, and that they are immutable when registered with the mDNS Responder; similarly that the passed service descriptors in *vector* are immutable.

If all of the *vector* tuples match an already registered *vector* then the held pointer is updated. This allows the application to supply new “Priority” and “Weight” values.

Or to put it another way, you can update the “Priority” and “Weight” values for a service *only* if you pass in a vector that replaces all the same services as the vector that was used to previously register that service.

Note

Furthermore, since the API requires that the registered *vector* is immutable this updating of “Weight” and “Priority” can only happen when the supplied *vector* pointer is different. This ensures that the application client code is not tempted to update the registered services data (which should be immutable) under-the-feet of the mDNS world.

We do not need to return a handle when registering services since the service tuple is used to uniquely identify each service.

Normally, for simple systems, the application will just have a single cyg_mdns_service_register() call with the fixed, hardwired, vector of service descriptors to be announced for the application.

The cyg_mdns_service structure is used to define a service tuple. It is the responsibility of the client application to ensure valid data is passed to the mDNS sub-system.

```
typedef struct cyg_mdns_service {
  const struct cyg_mdns_service_identity *id;
  const cyg_uint8 *default_label;
  const cyg_mdns_txt_record *txt_vector;
  cyg_uint16 priority;
  cyg_uint16 weight;
  cyg_uint8 txt_count;
} cyg_mdns_service;
```

The service descriptor *id* field is a pointer to a cyg_mdns_service_identity structure descriptor.

```
typedef struct cyg_mdns_service_identity {
  const cyg_uint8 *service;
  const cyg_uint8 *proto;
  cyg_uint16 port;
} cyg_mdns_service_identity;
```

The *service* and *proto* fields are pointers to a vector containing the 1-byte label length followed by 1..`MDNS_MAX_LABEL` UTF-8 characters. The client *must* ensure that the labels are prefixed with the '_' character. Defining these vectors using constant literal strings in C is unlikely to be appropriate as strings will include an additional NUL terminator character.

Note

For simplicity, and to avoid having to maintain an internal database, it is the responsibility of the client application to ensure the correct service and protocol label assignments.

The mDNS system exports the `cyg_mdns_label_tcp` and `cyg_mdns_label_udp` labels since they are common and are likely to be needed by most applications. They also avoid the cost associated with the developer having to provide duplicate string definitions in the application when defining their service vectors. In fact, for DNS-SD conforming worlds, only the “_tcp” and “_udp” protocol specifiers should be used.

If the *txt_vector* pointer is NULL then whenever a TXT field is required then a single 1-byte NUL character TXT response will be provided. If it is non-NULL then the *txt_count* field specifies the number of `cyg_mdns_txt_record` TXT table entries provided.

```
typedef struct cyg_mdns_txt_record {
  const cyg_uint8 *table;
  cyg_uint8 len;
} cyg_mdns_txt_record;
```

The *table* field of each TXT descriptor references a sequence of 1-byte length followed by 1…`MDNS_MAX_LABEL` UTF-8 character strings. The *len* field specifies the overall individual table length. The mDNS standard does NOT require the table to be terminated by a zero-length (`NUL`) indicator, since the TXT resource record contains the length. The following is an incomplete service example, but does show the provision of two TXT records (though, in reality, this simple example would be merged into a single TXT entry). Due to the use of the type `cyg_uint8` for the *len* field individual TXT tables are limited to a maximum of 255-bytes in length. Care must also be taken if registering services with multiple, large, TXT tables that the resulting data will fit within the memory available to the mDNS packet transmission code.

```
static const cyg_uint8 txttab_example_1[] = {
  0x09,'t','x','t','v','e','r','s','=','1',
  0x0B,'O','p','t','i','o','n','s','=','o','n','e'
};

static const cyg_uint8 txttab_example_2[] = {
  0x09,'F','e','a','t','u','r','e','O','n'
};

static const cyg_mdns_txt_record txt_records[] = {
  {
    .table = txttab_example_1,
    .len = sizeof(txttab_example_1)
  },
  {
    .table = txttab_example_2,
    .len = sizeof(txttab_example_2)
  }
};

static const cyg_mdns_service services[] = {
  {
    .txt_vector = txt_records,
    .txt_count = (sizeof(txt_records) / sizeof(txt_records[0])),
    // ... other fields as required
  }
};
```

Return value

Boolean `true` on success, and `false` on error.

Name

cyg_mdns_service_unregister — Remove registered services

Synopsis

#include <mdns.h>

`cyg_bool` **`cyg_mdns_service_unregister`**`(`*`count`*`, `*`vector`*`);`

Description

This function removes the services listed in *`vector`* from the set of registered services. *`vector`* must be a service vector previously passed to `cyg_mdns_service_register()`. An error is returned if the *`vector`* does not match a complete held vector. In other words, when a list of services is registered by a vector, they may only be de-registered together with that same vector.

In reality (due to the API restriction on immutable “vector”s being registered), the *`vector`* and *`count`* parameters are validated by checking that the *`vector`* matches a previously registered vector, and *`count`* matches the count of vectors previously passed when that vector was registered.

If the vector is indeed valid, then mDNS announcements are sent immediately to advertise to attached networks that the service has been removed (Resource Records with TTL of 0).

Return value

Boolean `true` on success, and `false` on error.

Name

cyg_mdns_sethostname — Set base hostname

Synopsis

#include <mdns.h>

```
cyg_bool cyg_mdns_sethostname(hostname);
```

Description

Request that the given NUL terminated UTF-8 string be used as the device hostname. This is only a request and depending on the external network devices the name may not be available. The hostname callback function interface provides, if required, application control over the alternative naming strategy when a hostname is not available, or becomes (due to external network changes) unavailable.

Return value

Boolean `true` on success, and `false` on error.

Name

cyg_mdns_hostname_callback_register — Register hostname generation callback

Synopsis

#include <mdns.h>

void **cyg_mdns_hostname_callback_register**(*fn*, *private*);

Description

This function is used to attach a hostname callback handler function. By default the mDNS sub-system provides a callback handler which attempts to acquire a unique hostname via monotonically increasing a suffix appended to the base hostname value, and automatically trying to claim the amended hostname. e.g. “ecospro” -> “ecospro-1”, “ecospro-2”, … “ecospro-999”, … etc. The application can over-ride this default behaviour by registering an alternative handler function using this API.

The DNS-SD standard Appendix D “Choice of Factory-Default Names” recommends that names are user-friendly, instead of, for example, having something like the 24-bit (non-OUI) MAC address appended. This however means that when a device is first connected to a network containing multiple similarly CDL configured devices then it can take some time to negotiate a unique name. It is the responsibility of the application, using whatever persistant storage schemes it has access to, to ideally store any claimed unique name for subsequent restarts of the device.

If the passed *fn* is `NULL` then the code reverts to the default mDNS callback handler.

```
typedef void (*cyg_mdns_hostname_callback_fn)(void *private, cyg_bool success,
                                              const cyg_uint8 *hostname, cyg_uint8 len);
```

The callback function is executed from the main lwIP networking thread and should be implemented like an eCos DSR and must *NEVER* block, and should run for as little time as possible (for example by waking other threads to perform lengthier tasks).

The hostname callback function is called with *success* set to `true` when the name given has been successfully claimed. At this point an application that has provided its own callback handler can, if desired, record the new name in its persistent storage. The ability for the application to track the last allocated name over reboots, and to use a stored name with a call to the `cyg_mdns_sethostname()` on startup will minimise subsequent delays claiming a name.

Note

The lifetime of the UTF-8 *hostname* pointer is for the active call to the callback function only, and if required for later application use the contents should be copied into a suitable thread-safe buffer accordingly.

If *success* is `false` then the callback indicates that the given *hostname* is not valid and an alternative name should be requested (via another call to `cyg_mdns_sethostname()` from a different thread as appropriate). NOTE: The callback handler may be called at *any* point whilst registered if the hostname is no longer valid (e.g. due to a device appearing on the network and claiming the hostname that was being used). If the callback is no longer required it should be released by attaching a new callback, or by passing NULL for the default handler to be re-instated. The callback function is executed similarly to an eCos DSR and is limited in the operations it can perform and must never block. If higher level processing is required by an application due to a *hostname* conflict then suitable eCos primitives should be used to notify such code.

Note

The callback is implemented as described above (instead of, for example, returning an alternative name to its caller) so that the DSR-like nature of the function is made clear, and that any slow operations should (and can) be performed by higher application layers as needed. It is envisaged that application specific hostname conflict handlers will signal a controlling thread, which when re-scheduled will subsequently call `cyg_mdns_sethostname()` with the next name to be tried.

Name

cyg_mdns_gethostname — Get current hostname value

Synopsis

#include <mdns.h>

cyg_bool **cyg_mdns_gethostname**(*dstbuf*, *len*);

Description

This function provides access to the currently configured mDNS UTF-8 hostname (shared across all mDNS configured lwIP network interfaces) and is intended for debug or UI usage. The active hostname is copied into the supplied buffer, where the passed `*len` specifies the valid buffer length of *dstbuf*. Normally the referenced *dstbuf* should have at least `MDNS_MAX_LABEL` available space, and `*len` set accordingly. The return boolean state indicates success or failure, with `*len` updated with the number of bytes written/required. On failure the contents of *dstbuf* are undefined. If *dstbuf* is `NULL` then the call can be used with a valid *len* pointer to ascertain the amount of storage required to hold the name.

Note

It is possible due to a dynamically changing external network that any returned hostname may already be invalid by the time the call returns the filled buffer to the application. For normal real-world operations the hostname callback function should be tracked by the application to cope with the actual active/current state with suitable cross-thread synchronisation implemented as required.

Return value

If a non-null *len* is supplied then the referenced location is updated with the hostname length at the time of the function call. Boolean `true` is returned if *dstbuf* is NULL or is a pointer to a `*len` buffer large enough to hold the hostname at the time of the call, which is filled with the hostname. On error boolean `false` is returned.

Name

cyg_mdns_setservicelabel — Set service label

Synopsis

#include <mdns.h>

```
cyg_bool cyg_mdns_setservicelabel(id, label);
```

Description

Request that the given NUL terminated UTF-8 string be used as the label for the service specified by *`id`*. This is only a request and depending on the external network devices the name may not be available. The servicelabel callback function interface provides, if required, application control over the alternative naming strategy used when the complete <label>.<service>.<proto>.local name is not available.

Note

This function is not available if the system is configured with `CYGFUN_MDNS_COMMON_NAME` enabled.

Return value

Boolean `true` on success, and `false` on error.

Name

cyg_mdns_getservicelabel — Get current service label value

Synopsis

#include <mdns.h>

```
cyg_bool cyg_mdns_getservicelabel(id, dstbuf, len);
```

Description

This function provides access to the currently configured mDNS UTF-8 label for the specified *`id`* service descriptor. This function is intended for debug or non-time critical UI usage. The active label is copied into the supplied buffer, where the passed *`*len`* specifies the valid buffer length of *`dstbuf`*. Normally the referenced *`dstbuf`* should have at least `MDNS_MAX_LABEL` available space, and *`*len`* set accordingly. The return boolean state indicates success or failure, with *`*len`* updated with the number of bytes written/required. On failure the contents of *`dstbuf`* are undefined. If *`dstbuf`* is `NULL` then the call can be used with a valid *`len`* pointer to ascertain the amount of storage required to hold the name.

Note

It is possible due to a dynamically changing external network that any returned label may already be invalid by the time the call returns the filled buffer to the application. For normal real-world operations the servicelabel callback function should be tracked by the application to cope with the actual active/current state with suitable cross-thread synchronisation implemented as required.

Note

This function is not available if the system is configured with `CYGFUN_MDNS_COMMON_NAME` enabled.

Return value

If a non-null *`len`* is supplied then the referenced location is updated with the label length at the time of the function call. Boolean `true` is returned if *`dstbuf`* is NULL or is a pointer to a *`*len`* buffer large enough to hold the service label at the time of the call, which is filled with the service label. On error boolean `false` is returned.

Name

cyg_mdns_servicelabel_callback_register — Register service label generation callback

Synopsis

#include <mdns.h>

```
void cyg_mdns_servicelabel_callback_register(fn, private);
```

Description

This function is used to attach a servicelabel callback handler function. By default the mDNS sub-system provides a callback handler which attempts to acquire a unique label via monotonically increasing a suffix appended to the current label value, and then automatically attempting to claim the amended <label>.<service>.<proto>.local name.

Note

This function is not available if the system is configured with `CYGFUN_MDNS_COMMON_NAME` enabled.

The application can over-ride this default behaviour by registering an alternative handler function using this API. If the passed *fn* is `NULL` then the code reverts to the default mDNS callback handler.

The same limitations for the callback handler apply as for the hostname callback interface as documented by cyg_mdns_hostname_callback_register.

Name

cyg_mdns_hinfo_register — Register HINFO record data

Synopsis

#include <mdns.h>

`cyg_bool` **`cyg_mdns_hinfo_register`**`(`*`data`*`, `*`len`*`);`

Description

This optional function (controlled by the CDL option `CYGFUN_MDNS_HINFO_OVERRIDE`) allows the application to supply an immutable data vector to be used as the HINFO record data when announcing that a hostname has been claimed. The passed *`len`* parameter specifies the length of the valid data from the supplied *`data`* pointer. Passing the `NULL` pointer allows the application to restore the default mDNS HINFO response.

The passed *`data`* vector should consist of two (2) length-prefixed strings conforming to the mDNS HINFO rules:

- Each length-prefixed string must start with a letter.
- Only upper-case letters, digits, hyphen and forward slash characters are permitted.

The following is a very simple fixed data example:

```
static const cyg_uint8 record_hinfo[] = {
  /* CPU */
  0x09,'C','O','R','T','E','X','-','M','3',
  /* OS */
  0x07,'E','C','O','S','P','R','O',
};

if (!cyg_mdns_hinfo_register(record_hinfo,sizeof(record_hinfo))) {
  /* generate error */
}
```

In some systems the CPU information may need to be derived dynamically at run-time (if multiple platforms are being supported by the application source) and so a RAM structure would be used that is then filled with the CPU and OS fields. The `tests/mdns_example.c` source, located in this package in the eCos source repository, provides an example dynamic implementation.

Return value

The boolean `true` is returned when the referenced data has been registered successfully. If an invalid HINFO data structure is supplied then boolean `false` is returned and the current mDNS HINFO state is not updated.

Name

cyg_mdns_discovery_callback_register — Register DNS-SD response callback

Synopsis

#include <mdns.h>

`cyg_mdns_discovery_context *`**`cyg_mdns_discovery_callback_register`**`(`*`name`*`, `*`fn`*`, `*`private`*`);`

Description

This function is used to attach a callback handler function to be called when (by default) ANSWER, and optionally ADDITIONAL, responses matching the supplied *`name`* are received. The `cyg_mdns_discovery_callback_flags()` function can be used to update the control flags from the default ANSWERS-only configuration once the callback has been registered.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

The *`name`* is an encoded string-table specifying the name that will be matched against mDNS responses when deciding if the registered callback function *`fn`* should be called. For example to match “_http._tcp.local”:

```
const cyg_uint8 label_http[] = { 0x05,'_','h','t','t','p' };
const cyg_uint8 * const services_http[] = { label_http, cyg_mdns_label_tcp, cyg_mdns_label_local, NULL };
```

The *`private`* value is used to pass data (if needed) to the callback function, and is never interpreted by the callback API.

The `<mdns.h>` header defines the function prototype for the callback *`fn`* function:

```
typedef void (*cyg_mdns_discovery_callback_fn)( void *private, cyg_uint32 state, const cyg_mdns_resource *phrr,
                                                struct pbuf *p, cyg_uint16 offname, cyg_uint16 offdata );
```

The *`private`* is the same value as supplied when registering the callback function, and is used by the client to hold any state needed to implement any interaction between the DSR-alike callback function and the application foreground client code.

The *`state`* parameter is a bitmask of flags and are used by the callback to determine what processing is required. The currently defined flags are:

`MDNS_DISCOVERY_CB_NOMORE`

Set to indicate no more data available for the active mDNS response being processed. When this flag is set *NO* actual Resource Record is actually being supplied. This call allows application that require, for example, a U/I update to be notified that a complete response has been processed and no more records are available for the callback. It may be used by a callback that has been caching information whilst constructing a “complete” image of a service to pass the data gathered to another client component.

`MDNS_DISCOVERY_CB_ADDITIONAL`

Set when the callback is being passed an Additional record, and not a direct Answer record.

`MDNS_DISCOVERY_CB_FLUSH`

Informational flag indicating whether this is a “unique” response and any cache should be flushed. See RFC 6762 section 10.2 for more information.

The *`phrr`* pointer references a structure containing, primarily, the type of Resource Record that the callback is being passed, and the TTL (Time-To-Live) of the record, where a TTL value of zero indicates a service is no longer available.

```
typedef struct cyg_mdns_resource {
    cyg_uint16 type;
    cyg_uint16 class;
    cyg_uint32 ttl;
    cyg_uint16 rdlength;
} cyg_mdns_resource;
```

The *`p`* pointer references the lwIP packet buffer containing the Resource Record entry to be processed by the callback, with the *`offname`* and *`offdata`* indices referencing, respectively, the offsets to the resource name and Resource Record type (`phrr->type`) specific data if relevant. The callback should *NEVER* modify the referenced lwIP packet buffer, and should use the available Support API routines to extract the (possibly) compressed data from the lwIP packet buffer for local processing/caching as required. This is because the packet buffer may be shared by multiple Resource Record responses, and other callbacks may also be executed as a result of a single mDNS response as well as the mDNS Responder requirements.

By default only ANSWER records are passed through, but if needed the `cyg_mdns_discovery_callback_flags()` function can be used to manipulate the control flags used to decide which response records are passed to the callback.

When the callback is no longer required it can be detached by using the `cyg_mdns_discovery_callback_unregister()` function. It is the responsibility of the controlling application to ensure that any resources owned by the callback routine are in a safe state prior to unregistering the callback.

Note

The callback function registered should *NEVER* block and should be treated like a DSR function. The function is called within the context of the mDNS lwIP handler as the result of low-level mDNS packet processing.

Return value

A non-`NULL` pointer to an abstract *`handle`* used for subsequent interaction with the successfully registered callback, or `NULL` on failure. For example, the call may fail if all the available callback slots are currently in use.

Note

The number of concurrently registered callbacks is controlled by the `CYGNUM_MDNS_DNSSD_NUM_CALLBACKS` configuration option.

Name

cyg_mdns_discovery_callback_unregister — Unregister DNS-SD response callback

Synopsis

#include <mdns.h>

```
cyg_bool cyg_mdns_discovery_callback_unregister(handle);
```

Description

This function is used to detach a previously registered callback handler function using its abstract *handle*.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

This will ensure that the callback function is no longer called by the mDNS response processing, and makes the callback slot available for re-use.

Return value

Boolean `true` if the operation has completed OK, or `false` on failure.

Name

cyg_mdns_discovery_callback_flags — Read/Modify DNS-SD response callback control flags

Synopsis

#include <mdns.h>

cyg_bool **cyg_mdns_discovery_callback_flags**(*handle*, *and*, *eor*, *flags*);

Description

This function is used to read or modify the control flags used by the mDNS code to decide which received response records are passed to the registered callback function referenced by the abstract *handle*.

Note

This function is not available if the system is not configured with CYGIMP_NET_MDNS_DNSSD enabled.

For simplicity, and code size, this function uses the standard AND/EOR scheme to allow the function to be used for non-destructive interrogation, as well as for flag modification. First the supplied “*and*” value is used as a mask to select the bits to be preserved, prior to the supplied “*eor*” parameter being used to modify specific flag bits. For example, to read the current state without affecting the flags:

```
cyg_mdns_discovery_callback_flags(handle,0xFF,0x00,&current); // READ
```

Whereas the following will ignore the existing flag state and only set the MDNS_DISCOVERY_ADDITIONAL flag value:

```
cyg_mdns_discovery_callback_flags(handle,0x00,MDNS_DISCOVERY_ADDITIONAL,&explicit); // SET
```

The following example explicitly clears the single MDNS_DISCOVERY_ALL flag:

```
cyg_mdns_discovery_callback_flags(handle,~MDNS_DISCOVERY_ALL,0,&modified); // CLEAR FLAG
```

The use of the AND/EOR scheme allows for a single operation to be used to read some flags, explicitly set/clear some flags and toggle other flags all in a single operation if required.

The full set of flags available are:

```
#define MDNS_DISCOVERY_ANSWER     (1 << 0) // Callback will be passed Answer records (default)
#define MDNS_DISCOVERY_ADDITIONAL (1 << 1) // Callback will be passed Additional records
#define MDNS_DISCOVERY_ALL        (1 << 2) // Callback will be passed ALL Additional records if
                                           //   ANSWER callback executed
```

Return value

Boolean true if the operation has completed OK, or false on failure. On success the location referenced by the passed *flags* parameter is updated with the current (as optionally modified) flag state.

Name

cyg_mdns_discovery_query — Issue a DNS-SD query

Synopsis

#include <mdns.h>

`cyg_bool` **`cyg_mdns_discovery_query`**`(`*`name`*`, `*`cnetif`*`, `*`type`*`);`

Description

This function is used to transmit a query to the selected lwIP network interface. The *`name`* should reference a `NULL` terminated set of pointers to the individual field entries for the query name. The *`type`* should be a RFC1035 defined resource record value. If the supplied *`cnetif`* is `NULL` then the code will transmit the query to all active interfaces. An IPv4 query will always be generated, and if lwIP IPv6 is configured than the code will also generate an IPv6 query.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

The following example source fragment demonstrates the “vector of pointers” structure used to hold the *`name`* to be used for the query. This example will issue a query across all interfaces asking for HTTP server information:

```
static const cyg_uint8 label_http[] = { 0x05,'_','h','t','t','p' };

static const cyg_uint8 * const services_http[] = {
    label_http,cyg_mdns_label_tcp,cyg_mdns_label_local,NULL
};

if (cyg_mdns_discovery_query(services_http,NULL,MDNS_RRTYPE_PTR)) {
    // success
} else {
    // failed
}
```

The `<mdns.h>` header file contains manifests (prefixed `MDNS_RRTYPE_`) for the main RFC1035 defined Resource Record types. Though, for DNS-SD use, normally only the `MDNS_RRTYPE_PTR`, `MDNS_RRTYPE_SRV`, `MDNS_RRTYPE_A` and `MDNS_RRTYPE_AAAA` types would be used during network service discovery.

Note

As discussed previously the process of generating queries is distinct from the system for registering callbacks to process responses. It is perfectly possible to generate requests when no callbacks are in place to handle responses (though this would not be of much use), and similarly it is expected that a callback may be registered for the lifetime of the application, with it asynchronously processing relevant responses that may have been triggered by the use of this query function.

Return value

Boolean `true` if the operation has completed OK, or `false` on failure. A failure may result if the operation cannot be posted to the lwIP layer for processing (this will trigger an assert when an `ASSERT` enabled configuration is being used), or (more likely) if there are no active (“link up”) network interfaces on which to send the query.

Example Responder

The `tests/mdns_example.c` source file included in the package provides a complete, simple, real-world example of the mDNS Responder usage. It registers two services, a dummy (port 9) service `_workstation._tcp.local` and a HTTP daemon using service `_http._tcp.local` on port 80.

Normally the first task after the lwIP networking has been initialised is to call the C function:

```
cyg_bool cyg_mdns_init();
```

This initialises the core of the mDNS support. After the mDNS Responder has been initialised, services can be registered, and the network interfaces enabled as required.

The following is a very simple example of declaring a `<hostname>._http._tcp.local` service for the `<hostname>.local` address, where `<hostname>` is the default as configured by the `CYGDAT_NET_MDNS_HOSTNAME` CDL option.

```
static const cyg_uint8 label_http[] = { 0x05,'_','h','t','t','p' };

static const cyg_mdns_service_identity httpd80 = {
  .service = label_http,
  .proto = cyg_mdns_label_tcp,
  .port = 80
};

static const struct cyg_mdns_service httpd80_service = {
  .id = &httpd80,
  .txt_vector = NULL,
  .txt_count = 0,
};

…

if (cyg_mdns_init()) {
  if (cyg_mdns_service_register(1,(struct mdns_service *)&httpd80_service)) {
    if (cyg_mdns_enable()) {
      // other application processing as needed ...
    } else {
      (void)cyg_mdns_service_unregister(1,(struct mdns_service *)&httpd80_service);
      // report error
    }
  } else {
    cyg_mdns_terminate();
    // report error
  }
} else {
  // report error
}
```

Example DNS-SD Queries

The `tests/dnssd_example.c` source file included in the package provides a complete, simple, real-world example of the DNS-SD API usage. See the section called “DNS-SD Example” for more detail.

Chapter 189. Support API

Some support functions are provided by the mDNS code for use by client applications. These functions do not by themselves affect the mDNS state and are thread-safe. Some functions are only present when `CYGIMP_NET_MDNS_DNSSD` support is configured.

Support API

Name

cyg_mdns_strlen — Calculate uncompressed length of (possibly compressed) string

Synopsis

#include <mdns.h>

```
cyg_uint16 cyg_mdns_strlen(p, index, raw);
```

Description

This function is used to calculate the space needed to hold an uncompressed copy of a Resource Record encoded string. The *p* pointer references the lwIP packet buffer containing the original string structure, with the *index* specifying the starting offset within the lwIP packet for the string.

The boolean *raw* flag is used to control the style of uncompressed string for which a length is being calculated.

Return value

The return value depends on the supplied boolean *raw* flag parameter. When *raw*=`true` the return value is the size needed for an uncompressed “raw” copy of the string still using the mDNS encoding style (length byte followed by UTF-8 character data). When *raw*=`false` is specified then the function returns the size needed to hold a final string representation using '.' to separate fields, and also including the terminating `NUL` character. If invalid parameters, or data, are given then the error limit value `0xFFFF` is returned.

Name

cyg_mdns_name_uncompress — Uncompress encoded string

Synopsis

#include <mdns.h>

cyg_uint16 **cyg_mdns_name_uncompress**(*dst*, *dstlimit*, *p*, *index*, *raw*);

Description

This function is used to build a copy of the Resource Record encoded string in the supplied destination buffer. The *p* pointer references a lwIP packet buffer containing the encoded string to be processed at the given *index* offset within the packet. If the supplied *dst* pointer is `NULL` then the function does not copy the data, but can be used to step over an encoded string. When *dst* is not-`NULL` then the *dstlimit* value defines the amount of space available in the destination buffer. When copying the function will not copy more than *dstlimit* characters.

When the boolean *raw* parameter is `true`, the function will copy the uncompressed individual fields to the destination buffer, still using the encoded string style (length byte followed by UTF-8 character data). Whereas *raw*=`false` will build a '.' separated name in the destination buffer.

Return value

The return value is the lwIP packet buffer index for the first data byte after the encoded string.

Name

cyg_mdns_strlen_vector — Calculate uncompressed length of string vector

Synopsis

#include <mdns.h>

```
cyg_uint16 cyg_mdns_strlen_vector(iname, raw);
```

Description

This function is used to calculate the space needed to hold an uncompressed copy of an encoded string described by the *iname* vector. The last entry of the *iname* vector must be `NULL`.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

When *raw*=`true` the function counts the space needed to hold a copy of all the vector entries in an uncompressed form (for supporting “compressed->uncompressed” copying in the original “string-table” format, i.e. length byte followed by UTF-8 character data). The returned value is the space for the referenced encoded strings, and is not the size of the vector describing the name.

When *raw*=`false` we are counting the space needed to hold the “final” string representation with '.' inserted to separate fields.

Return value

Number of bytes needed to hold the uncompressed string in the selected boolean parameter *raw* style.

Name

cyg_mdns_strlen_uncompressed — Length of uncompressed encoded string

Synopsis

#include <mdns.h>

`cyg_uint16` **`cyg_mdns_strlen_uncompressed`**`(`*`us`*`);`

Description

This function is used to calculate the length of an uncompressed, encoded string terminated by a zero-length (`NUL`) field.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

```
static const cyg_uint8 encoded_string[] = {
  0x08,'t','e','s','t','n','a','m','e',
  0x05,'_','h','t','t','p',
  0x00
};

…

cyg_uint16 elen = cyg_mdns_strlen_uncompressed(encoded_string);
// elen == ((1 + 8) + (1 + 5) + 1) == 16
```

Return value

The number of bytes occupied by the encoded string.

Name

cyg_mdns_name — Convert encoded name into dot-notation

Synopsis

#include <mdns.h>

cyg_uint16 **cyg_mdns_name**(*dst*, *dstlimit*, *strtab*);

Description

This function is used to convert an encoded name into a “simple” dot-notation `NUL`-terminated string.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

If the passed *dst* pointer is `NULL` then the routine can be used to calculate the space needed to hold the converted name.

Pseudo-code example:

```
cyg_uint16 needed = cyg_mdns_name(NULL,0,hostname);
char buffer[needed];
cyg_uint16 used = cyg_mdns_name(buffer,needed,hostname);
if (used == needed) {
  diag_printf("  http://%s:%u/\n",buffer,port);
}
```

The routine will not write more than the passed *dstlimit* number of characters, and as such if the passed buffer is too small then the string will *not* be `NUL` terminated.

Return value

The number of characters needed to hold the converted string (when *dst*=`NULL`), or the number of characters used in the supplied *dst* destination buffer.

Name

cyg_mdns_build_txt_vector — Build vector of pointers to individual TXT Record fields

Synopsis

#include <mdns.h>

`cyg_uint8` **`cyg_mdns_build_txt_vector`**`(`*`txt`*`, `*`txtlen`*`, `*`txtkeys`*`, `*`vlen`*`);`

Description

This helper function is used to construct a vector of the individual TXT Resource Record fields for easier client processing.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

The *`txt`* parameter should reference a contiguous buffer containing a TXT Record string-table - length byte followed by character data, possibly followed by another length byte and more character data and so on. NOTE: An empty TXT string-table is marked with a `NUL` character, so *`txtlen`* should always be `1` or more, but a string-table containing entries does *NOT* have a terminating `NUL`, which is why the *`txtlen`* parameter is required.

If the passed *`txtkeys`* value is `NULL` then the function counts the number of entries needed to hold the individual `key[=value]` entries within the TXT Record, so can be used to ascertain the size of vector needed for a specific TXT Record. When *`txtkeys`* is non-`NULL` it points to the beginning of an array of cyg_uint8 pointers. The *`vlen`* parameter specifies the number of vector slots available in this array to receive pointers into the *`txt`* buffer for the individual entries (which for TXT Records will be in the form `key` or `key=value`). When populating the supplied *`txtkeys`* vector a terminating `NULL` pointer is added if the supplied *`vlen`* indicates the supplied vector is larger than the number of TXT fields found.

For example:

```
static const cyg_uint8 example_txt[] = {
  0x04,'a','b','c','d',
  0x0C,'s','o','m','e','k','e','y','=','d','a','t','a'
};
cyg_uint16 txtlen = (cyg_uint16)sizeof(example_txt);

cyg_uint8 entries = cyg_mdns_build_txt_vector(example_txt,txtlen,NULL,0);
cyg_uint8 *txtkeys[entries + 1]; // extra “+1” for terminating NULL

(void)cyg_mdns_build_txt_vector(example_txt,txtlen,txtkeys,(entries + 1));
diag_printf("  TXT-%u contains %u entr%s\n",ti,entries,((entries == 1) ? "y" : "ies"));

unsigned int idx;
for (idx = 0; (idx < entries); idx++) {
  cyg_uint8 klen = txtkeys[idx][0];
  if (klen) {
    cyg_uint8 key[klen + 1];
    memcpy(key,&txtkeys[idx][1],klen);
    key[klen] = '\0';
    diag_printf("    [%u]=\"%s\"\n",idx,key);
  } else {
    diag_printf("    [%u]={EMPTY}\n",idx);
  }
}
```

Return value

Returns a count of the number of `key[=value]` entries in the referenced TXT Record.

Name

cyg_mdns_build_strtab_vector — Build vector of pointers to individual encoded string fields

Synopsis

#include <mdns.h>

`cyg_uint8` **`cyg_mdns_build_strtab_vector`**`(`*`strtab`*`, `*`labels`*`, `*`vlen`*`);`

Description

This helper function is used to construct a vector of the individual label fields present in the supplied, uncompressed, contiguous *`strtab`* string-table.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

If the passed *`labels`* value is `NULL` then the function counts the number of entries needed to hold pointers to the individual label field entries within the `NUL`-terminated string-table, so can be used to ascertain the size of vector needed for a specific encoded string. When *`labels`* is non-`NULL` the *`vlen`* parameter specifies the number of vector slots available to receive pointers into the *`strtab`* buffer for the individual label field entries. When populating the supplied *`labels`* vector a terminating `NULL` pointer is added.

This function is similar in operation to the `cyg_mdns_build_txt_vector()` function, so a similar approach it its example can be used to build and subsequently process a vector of pointers.

Return value

Returns a count of the number of fields within the referenced uncompressed encoded string.

Name

cyg_mdns_strcasecmp_strtab — Compare two encoded string-tables ignoring case

Synopsis

#include <mdns.h>

`int` **`cyg_mdns_strcasecmp_strtab`**`(`*`t1`*`, `*`t2`*`);`

Description

This function allows a field-by-field comparison of two encoded string-table buffers to be performed.

Note

This function is not available if the system is not configured with `CYGIMP_NET_MDNS_DNSSD` enabled.

The referenced string-table parameters should be pointers to uncompressed, contiguous, `NUL`-terminated encoded strings of the form:

```
static const cyg_uint8 encoded_string_example[] = {
  0x08,'t','e','s','t','n','a','m','e',
  0x05,'_','h','t','t','p',
  0x00
};
```

Return value

Returns an integer value equal to zero if *`t1`* is found to exactly match *`t2`* (ignoring case), otherwise a non-zero value is returned on a failure to match.

Chapter 190. Configuration

This chapter shows how to include the mDNS support into an eCos configuration, and how to configure it once installed.

Configuration Overview

The mDNS Responder is contained in a single eCos package `CYGPKG_NET_MDNS`. However, it depends on the services of a collection of other packages for complete functionality. Currently the mDNS Responder implementation is tightly bound with the lwIP TCP/IP networking stack provided by the `CYGPKG_NET_LWIP` package. The lwIP package provides the packet buffer support (allocation and access routines) as well as the underlying multicast UDP transport support.

Quick Start

Incorporating the mDNS Responder into your application is straightforward. The essential starting point is to incorporate the mDNS eCos package (`CYGPKG_NET_MDNS`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Alternatively, as a convenience, minimal configuration files (`.ecm` files) have been provided to permit an easy starting point for creating a configuration incorporating the mDNS Responder. Two configuration files, `mdns_bct` and `mdns_minimal`, are provided for those intending to use the Bonjour Conformance Test (BCT), and these can be found in the directory *`ECOSPRO`*`/packages/net/mdns/`*`VERSION`*`/misc` where *`ECOSPRO`* is the base directory of the eCosPro installation, and *`VERSION`* is the eCosPro (or package) version. The `mdns_minimal.ecm` file is provided as an example of a low footprint configuration for resource limited target platforms. These files may be used either by providing the configuration file name with the command line **ecosconfig import**; or with the **File->Import…** menu item within the eCos Configuration Tool. Both these files are basic, incorporating only those packages which are essential for mDNS operation.

> **Note**
>
> When building the tests for a limited RAM platform it may be necessary to build only the mDNS tests. The tests for some standard packages may require too much RAM to successfully link. For example to build the mDNS tests for a low resource platform:
>
> ```
> $ mkdir minimal_bct
> $ cd minimal_bct
> $ ecosconfig new PLATFORM
> [ … ecosconfig output elided … ]
> $ ecosconfig import $ECOS_REPOSITORY/net/mdns/VERSION/misc/mdns_minimal.ecm
> [ … ecosconfig output elided … ]
> $ ecosconfig resolve
> $ ecosconfig tree
> $ make
> [ … make output elided … ]
> $ cd net/mdns/current
> $ make tests
> [ … make output elided … ]
> ```

Configuring the mDNS Responder

Once added to the eCos configuration, the mDNS Responder package has a number of configuration options.

`CYGDAT_NET_MDNS_HOSTNAME`

The default mDNS *`hostname`* used when announcing services is provided as part of the standard eCos CDL, but it is expected that real-world applications will manage (via whatever means is appropriate for the target application/platform) their own default `hostname` configuration, and will then use the mDNS API as required to configure the required `hostname` prior to enabling a network interface.

The mDNS `hostname` is, when assigned, shared across all the active mDNS network interfaces. This is to ensure that a named service is common across all the configured interfaces.

Note

The actual `hostname` in use may change asynchronously as part of the handling of mDNS name conflicts and rejections. It is possible for another device to attach to the network and cause a new `hostname` to be chosen. The `hostname` callback support allows for application control of the namespace used. By default the mDNS Responder provides a simple conflict resolution approach of appending a suffix with a monotonically increasing number.

The DNS-SD standard Appendix D “Choice of Factory-Default Names” suggests that the starting name is a simple, user-friendly, human-decipherable, name; and is not automatically derived from some unique identification (e.g. the OUI MAC address).

`CYGNUM_MDNS_NUM_SERVICE_VECTORS`

The number of “sets of service vectors” that can be supported. Each service vector specifies one or more services. To minimise the memory footprint required to support mDNS, the service descriptors are provided by the controlling application as a set of immutable contiguous descriptors. This option controls the number of such sets (minimum 1) that can be held by the mDNS instance.

The CDL configuration should match the target application requirements, and this setting relates to the number of distinct cyg_mdns_service_register calls that can be made. For most embedded applications a value of `1` should suffice since the services to be advertised are known and fixed. However, if an application needs to register and de-register differing sets of services dynamically then this configuration value needs to reflect the number of distinct service sets required.

`CYGNUM_MDNS_MAX_SERVICE_COUNT`

This option specifies the number (count) of service descriptors allowed in an individual service vector. To minimise the memory footprint required to support mDNS this option allows the number of services per vector to be tuned to reflect the requirements of the application.

`CYGFUN_MDNS_COMMON_NAME`

If enabled this option will use the claimed hostname for all registered services. This requires a much smaller RAM footprint than allowing for per-service labels, and may be required for deeply-embedded, low memory, targets if more than a few services are registered. In some environments it may be sufficient to have a single name used for the host and all the announced services.

Note

If this feature is enabled then the mDNS Responder will *NOT* pass the Bonjour Conformance Test (BCT) since it explicitly requests a service label containing spaces, which will pass but then the BCT it then subsequently raises a FAILURE when it sees the hostname label contain spaces.

`CYGFUN_MDNS_HINFO_OVERRIDE`

By default the mDNS Responder provides an HINFO record using the CPU name “CPU” and the operating system name “ECOSPRO” when announcing the claimed hostname. If this option is enabled then support is provided to allow the application to provide its own simple HINFO record data structure.

`CYGNUM_MDNS_ANNOUNCE_COUNT`

The mDNS standard allows for between 2 and 8 announcement packets (with increasing inter-packet delays) to be transmitted when a hostname or service is claimed. Since mDNS is based on UDP multicasts it is possible in a congested system, or for limited bandwidth targets, for packets to be missed. This option allows an increased number of packets to be transmitted to minimise the chances of remote systems missing an announcement.

`CYGNUM_MDNS_TTL_SERVICE`

This option specifies the default “time to live” (TTL) value in seconds that is published for registered services.

`CYGNUM_MDNS_TTL_ANNOUNCEMENT`

This option specifies the default “time to live” (TTL) value in seconds for announcements.

`CYGFUN_MDNS_STATS`

If enabled then this option adds code to track information that may be useful when ascertaining the resources required for a configuration or when debugging the mDNS Responder.

The information is held in the exported structure object *`cyg_mdns_statistics`*. This allows the contents to be manually inspected via a debug tool, or for the application to access the data using the structure definition as provided by the header file `mdns.h`.

See the the section called “Statistics” section for more information on use of this configuration option.

`CYGDBG_MDNS_DEBUG`

If this option is enabled then it provides access to individually controlled CDL debug options for various sub-systems or package features. This allows the detail and amount of debug information to be controlled.

Configuring the mDNS DNS-SD support

Optional support for the DNS-SD API can be enabled in a configuration by enabling the `CYGIMP_NET_MDNS_DNSSD` option. By default, for backwards compatibility, this option is disabled. This ensures the extra memory footprint required to support the DNS-SD API does not impact existing configurations unless explicitly enabled.

`CYGIMP_NET_MDNS_DNSSD`

If this feature is enabled then the DNS-SD API is provided to allow client applications to perform service discovery.

`CYGNUM_MDNS_DNSSD_NUM_CALLBACKS`

This option controls the number of active, concurrent, application callbacks supported by the DNS-SD API. A lower value will help minimise the memory footprint required by the mDNS implementation. The value should be tuned to the application requirements. It is possible for an application to be written requiring only a single active callback handler, though multiple handlers may allow different application sub-systems to be maintaining their own “view” of the specific network services or hosts that the particular sub-system is interested in.

Tuning

Footprint

The current implementation relies on the lwIP heap for allocating the response packets. This requires that lwIP has been configured with a large enough `CYGNUM_LWIP_MEM_SIZE` heap size. If ASSERTS are enabled for the build then failure to allocate the required response packet space will trigger an assert failure, otherwise the packet transmission operation will be dropped in that hope that subsequent operations will succeed once some lwIP heap has become available.

Service Labels

The `CYGFUN_MDNS_COMMON_NAME` controls whether a single, common, name is used to announce the host and all registered services. This option reduces the RAM footprint required, at the expense of not supporting per-service labels.

For very simple target applications, where maybe only a single service is being announced, it may be deemed that it is not an issue if the hostname and service-label are the same. However, a conflict with either causing a renaming will therefore affect both the hostname and service-label.

Statistics

The `CYGFUN_MDNS_STATS` option can be enabled to allow for information counts and sizes to be gathered during execution. These statistics can help with the tuning of the mDNS world during development, since monitoring the minimum and maximum usage counts of resources along with the error counts can indicate resource starvation issues.

For the network packet memory tracking, a common *`cyg_mdns_statistics_memory`* structure is defined and used for each of the packet size records being tracked:

```
struct cyg_mdns_statistics_memory {
  cyg_uint32 count; // number of tracked items
  cyg_uint16 min; // minimum size seen
  cyg_uint16 max; // maximum size seen
};
```

For example the basic statistics structure is defined as:

```
struct cyg_mdns_statistics {
    struct cyg_mdns_statistics_memory errors; // failed packet allocation information
    struct cyg_mdns_statistics_memory hostname; // hostname probe/announce packets
    struct cyg_mdns_statistics_memory service; // service probe/announce packets
    struct cyg_mdns_statistics_memory responses; // query response packets
    struct cyg_mdns_statistics_memory tx; // packets transmitted
};
```

The *`errors`* information records the number of failures to allocate a packet buffer, along with the smallest allocation attempt that failed reported in the *`min`* field and the largest allocation attempt that failed in the *`max`* field.

The *`hostname`*, *`service`* and *`responses`* elements record the number of buffer allocations made for each of the respective mDNS packet type generators along with the minimum and maximum sizes seen.

The *`tx`* field tracks the actual generated packet size as transmitted for all of the packet generators. The maximum recorded by this statistic will normally be smaller than the largest of the packet generator maximums since it tracks the size of packet actually transmitted after any name compression has been applied.

Real-World Example

As an example, with careful tuning, it is possible to implement a simple mDNS Responder and webserver with a very small RAM footprint.

For a Cortex-M3 (STM32F207x) based platform, the default mDNS Responder configuration occupies ~14K of code and requires less than 512-bytes of RAM for the mDNS Responder specific state. If `CYGFUN_MDNS_COMMON_NAME` is enabled then the code occupies less than 14K and requires less than 300-bytes of RAM to hold the mDNS specific context.

The code (normally ROM) and RAM footprint for a complete application will be higher depending on the eCos features configured and application code requirements (e.g. number and size of thread stacks, network buffers, etc.).

Chapter 191. Debug and Test

Debugging

Asserts

If the target platform resources allow, the first step in debugging should be to enable ASSERTs. The inclusion of assert checking will increase the code footprint and lower the performance, but does allow the code to catch internal errors from unexpected data values. e.g. when the application/client is not able to guarantee the validity of data passed into the mDNS Responder.

The mDNS Responder asserts are controlled via the standard eCos Infrastructure CYGPKG_INFRA package CYGDBG_USE_ASSERTS option. If enabled, then run-time assertion checks are performed by the mDNS Responder.

If assertions are enabled, and a debugger is being used it is normally worthwhile setting a breakpoint on the cyg_assert_fail symbol so that the debugger will stop prior to entering the default busy-loop processing.

Diagnostic Output

In conjunction with the CYGDBG_MDNS_DEBUG CDL configuration setting, the header-file src/mdns_debug.h implements the mDNS specific debug control.

When CYGDBG_MDNS_DEBUG is enabled a set of individually selectable sub-systems are available to control the diagnostic output generated.

However, when developing or debugging the mDNS Responder implementation, it may be simpler (with fewer build side-effects) to control the debugging output via uncommenting the necessary manifests at the head of the src/mdns_debug.h source file than re-configuring the complete eCos configuration via the CDL. That way only the mDNS package will be re-built.

Note

Some diagnostic output, if enabled, may adversely affect the operation of the mDNS Responder as seen by 3rd-party code. For example, “slow” serial diagnostic output of the packet parsing and response generation could mean that a significant amount of time passes, such that the mDNS Responder no longer adheres to the timings as specified by the mDNS/DNS-SD standards.

Testing

If the configuration option CYGPKG_NET_MDNS_TESTS is enabled then a set of simple tests are built.

Note

If the target platform has limited memory and is unable to execute the tests then the eCos synthetic Linux target can be used to execute tests and verify the behaviour of the mDNS implementation when debugging, assertions or large test executables are required.

mdns_example

The mdns_example provides a very basic HTTP daemon, with enough functionality to pass the Bonjour Conformance Test (see the section called “Bonjour Conformance Test”).

On startup the application initialises a HTTP daemon listening on port 80, and registers and enables the mDNS announcing that service. A `HTTP GET` request for the default root page will return an HTML page listing the sub-pages provided. The application is manually terminated by requesting the `exit` page. The `config` page has specific support for the features needed for the BCT.

The mdns_example is, however, a simple example of announcing a DNS-SD service, as well as a simple lwIP HTTP daemon demonstration.

dnssd_example

The dnssd_example application demonstrates the use of the DNS-SD API to discover network services (see the section called “DNS-SD Example” for more detail). The application will enumerate local services being announced to the network, before performing specific queries for “_http” and “_ipp” services to ascertain server and TXT information.

mdns_testp

The mdns_testp uses dummy network interfaces to monitor the responses generated by the mDNS Responder in a known clean environment. The physical network connection is not used after the startup initialisation. The test application controls the packets injected into the networking stack and provides its own artificial `driver` layer for packet transmission. This allows for specific mDNS Responder features to be tested without the noise and interference of a real network setup, and without specifying a stand-alone, closed, network like the 3rd-party Bonjour conformance testing.

mdns_farm

The mdns_farm test is primarily for use in the eCosCentric® automated testfarm. It can however be manually executed by starting the application, and then manually executing the simple bash test script `misc/mdnstest1.sh` on a suitable host, passing the network address of the target executing the mdns_farm executable. For example:

```
$ ./misc/mdnstest1.sh 192.168.7.165
```

Note

The host used to execute the script should have a suitable avahi configuration.

Bonjour Conformance Test

If the configuration option `CYGPKG_NET_MDNS_TESTS_STANDALONE` is enabled then the mdns_example is built. This implements a simple mDNS application providing, by default, a limited functionality HTTP daemon on port 80. This test program, when used with a suitable eCos system configuration, can be used for execution against the Bonjour Conformance Test (BCT).

Note

For the full BCT test, which includes link-local address verification, the eCos configuration should have the lwIP IPv4 AutoIP (`CYGFUN_LWIP_AUTOIP`) support enabled and the network interface being used for the Ethernet connection configured to obtain its network address using AutoIP (`CYGOPT_LWIP_ETH_DEV_ADDR_AUTOIP#`).

For the BCT to function, a very specific closed network setup is required. For the mDNS Responder package testing the following equipment was used:

- Unit-Under-Test (UUT)

  The target platform being tested, executing a suitable eCosPro configuration.

- MacBookPro (OS: 10.8.2)

  Executing the BonjourConformanceTest v1.2.8 in a Terminal shell window, and the Safari v6.0.1 web-browser.

- Airport Extreme (HW: A1408 FW: 7.6.1)

  10base-T (wired) Ethernet connections to the UUT and the MacBookPro.

The HTTP daemon provided by the mdns_example application provides support for the necessary BCT interaction using specific CGI parameters to the `/config` page.

The BCT initially tests the IPv4 link-local address support before starting the mDNS Responder interaction.

The following example URLs are based on the BCT v1.2.8 interaction with a default mDNS configuration. If the application being tested uses a different starting hostname, or later BCT executables change the processing, then the target address will need to be modified to suit the state reached at the specific point in the BCT sequence.

For the `MANUAL NAME CHANGE` component the unit-under-test (UUT) needs to be supplied with a specific service label. The `config?service=` option allows a new service-label to be specified for the registered HTTP daemon.

```
ecospro-21.local./config?service=New - Bonjour Service Name
```

Note

The mdns_example provides the HTTP daemon as the first registered service, and the simple `config?service=` option interacts with that specific service in the knowledge that the BCT uses the first announced service as its test `SRV`.

For the `Mixed-Network Interoperability Test` `ROUTABLE TO LINK-LOCAL COMMUNICATION` component the UUT needs to be configured with a routable IP address. The `config?ip=` option allows an IPv4 address to be specified. This will re-configure the default network interface to the specified IPv4 address with an explicit netmask of `255.255.255.0`. For example:

```
ecospro-42.local./config?ip=17.1.1.1
```

For the final `CHATTINESS` component of the BCT the UUT needs to be re-configured with a link-local address. The `config?ll=` option allows an IPv4 link-local address to be supplied, explicitly setting the netmask `255.255.0.0`. For example:

```
ecospro-42.local./config?ll=169.254.1.0
```

Note

For the final `CHATTINESS` component of the BCT, after changing the UUT IPv4 address to a link-local address described above it is important to exit the Safari web-browser being executed on the test host to avoid its Bonjour support interfering with the BCT execution.

When the BCT execution finishes it prompts the operator regarding the generation of an execution report. When applying for Bonjour Conformance the report should be created, and in conjunction with the generated `debug.log` file, sent to Apple for validation as documented in their procedures.

The results for an actual BCT run using the `mdns_example`, executing on a STM32F207xx (Cortex-M3) based platform, are available in the Example 191.1, “ `doc/bct_stm32f207_result.txt` ” and `doc/bct_stm32f207_debug.log` files. These files are original, as produced by the BCT application. For reference, the `doc/bct_stm32f207_terminal.txt` file contains the execution output captured from the MacOS Terminal.

The following is a listing of the `doc/bct_result.txt` file as provided in the package.

Note

The BCT actually finished its testing at 18:05 on Tue Nov 20th, but the `Completed` timestamp reflects when the report was written and does not reflect the time taken for the actual BCT run.

Example 191.1. `doc/bct_stm32f207_result.txt`

DNS-SD Example

If required the dnssd_example application can be used as a starting point for a real-world application. The test starts a thread which performs some DNS-SD operations, as likely to be needed by an application that needs to search for mDNS announced network services. The test is contained within the function:

void **thread_dnssd**(*arg*);

Since the callback function (as described in cyg_mdns_discovery_callback_register()) must *NEVER* block, this example uses the eCos mailbox and fixed-size-memory-allocator functionality as the mechanism to communicate between the callback (which was registered with the mDNS world with the aforementioned function) and the application code. It uses the non-blocking functionality of these core eCos features to ensure the callback will not block.

The core of the foreground functionality is performed in the function:

void **example_browse**(*tag*, *services*, *cflags*, *waitsecs*, *cb_hostport*);

which performs a `PTR` service browse operation, and then waits for callback events to the function registered against the specific *services* name. As documented, a query can result in multiple registered callbacks being called since the queries are common, and not specific to a registered *services* name. The *waitsecs* just specifies how long (in seconds) the example code will wait for responses before returning. The code currently waits a relatively long time after issuing the single query, whereas a real-world application would more likely have its own control loop to re-issue periodic queries if needed; and to maintain whatever data structures for discovered services it needs to track. However, whilst the callback is active, any matching mDNS response will be passed through the callback, irrespective of whether that response is the result of a query generated by this “host”, or another network device. Another example in the function:

service_table_entry ***example_query**(*query*, *type*, *ctx*);

implements functionality where the query is re-issued every second, but the function completes as soon as a valid result is received (which would normally be a very short time after the initial query is transmitted to the network).

The example callback is provided by the `cb_service()` function, and is coded to support both the basic service browsing, but also the individual specific queries. Simpler applications could implement a simpler function just responding to the information they need. Fundamentally the callback implements two phases: Processing records, and marking the end of a “set” of responses:

```
void cb_service(void *priv, cyg_uint32 state, const cyg_mdns_resource *phrr,
                struct pbuf *p, u16_t offname, u16_t offdata)
{
  if (state & MDNS_DISCOVERY_CB_NOMORE) { // No record for this callback
    /* If required notify foreground.
```

```
       This could trigger a U/I update with recently acquired data, or
       just be the point at which captured data is passed through. */
  } else { // Process record
    switch (phrr->type) {
      …
    }
  }

  return;
}
```

A fundamental task of the callback is to extract the encoded information from the referenced lwIP packet buffer. The following example fragment shows how the referenced response name can be copied into a local buffer. This example uses `raw=true` so that the result is an uncompressed version in the mDNS encoded string format (length byte followed by the field data, with the set of fields terminated by a `0x00` byte indicating a zero-length field):

```
cyg_uint16 nlen = cyg_mdns_strlen(p,offname,true);
cyg_uint8 name[nlen];
u16_t endindex;

endindex = cyg_mdns_name_uncompress((char *)name,sizeof(name),p,offname,true);
CYG_ASSERT((endindex <= offdata),"Name length mismatch");
```

Note

The callback should *NEVER* modify the passed lwIP packet buffer. A mDNS response may contain multiple records that are relevant to more than one callback as well as to the internal mDNS Responder operation. Also mDNS responses may be compressed, where data is shared between records. This is why a DNS-SD query client that needs to preserve information needs to make its own uncompressed copies without changing the referenced mDNS response data.

Back at the application foreground level, the first substantial operation performed within `thread_dnssd()` is to use the specific DNS-SD “wildcard” query to ascertain what service types are being announced to the network. This uses the `cyg_mdns_name_services_dnssd_udp_local` variable (built-in to the mDNS package) to reference the standard “_services._dns-sd._udp.local” name. The function outputs each service type discovered, for example:

```
INFO:<Browsing for “Local services” (wait 4-seconds)>
Service: _http._tcp.local
Service: _pdl-datastream._tcp.local
Service: _ipp._tcp.local
Service: _printer._tcp.local
Service: _udisks-ssh._tcp.local
Service: _ssh._tcp.local
Service: _sftp-ssh._tcp.local
Service: _workstation._tcp.local
Service: _http-alt._tcp.local
Service: _scanner._tcp.local
PASS:<Service Browse>
```

The example then performs three passes each against the “_http” and “_ipp” local service names, with each pass allowing more records to be passed to the registered callback for processing.

The first pass uses the default control flags, which will pass only the explicit matching ANSWER records for any active PTR answers. The application will output a line for each specific service type that provides a response:

```
INFO:<Browsing for “_http” (wait 4-seconds)>
Service: Officejet Pro 8500 A910 [D0220F]._http._tcp.local
Service: Xerox Phaser 6280DN (ac:a8:0d)._http._tcp.local
PASS:<Service Browse>
```

The second pass explicitly adds the `MDNS_DISCOVERY_ADDITIONAL` flag to have the callback supplied with matching ADDITIONAL records, and not just the matching ANSWER record. For example, this now results in the server name, port and TXT records being recorded if they are supplied:

```
INFO:<Browsing for “_http” ADDITIONAL (wait 4-seconds)>
INFO:<Callback flags now 03>
Service: Officejet Pro 8500 A910 [D0220F]._http._tcp.local
  http://hp8500.local:80/
  TXT-0 contains 0 entries
Service: Xerox Phaser 6280DN (ac:a8:0d)._http._tcp.local
  http://XRX0000AAACA80D.local:80/
  TXT-0 contains 9 entries
    [0]=“qtotal=5”
    [1]=“ty=Xerox Phaser 6280DN”
    [2]=“product=(Phaser 6280DN)”
    [3]=“pdl=application/postscript”
    [4]=“adminurl=http://.local./”
    [5]=“usb_MFG=Xerox”
    [6]=“usb_MDL=Xerox Phaser 6280DN”
    [7]=“Binary=T”
    [8]=“TBCP=T”
PASS:<Service Browse>
```

The third pass adds the `MDNS_DISCOVERY_ALL` flag requesting that the callback is supplied all ADDITIONAL records in the response if an ANSWER was previously passed for the response being processed. This can be used to allow the callback to gather network address information (from `A` or `AAAA` records as appropriate) so that the callback can supply complete service information in a single result. As can be seen from the following example output, the IPv4 and IPv6 addresses are now provided in the result passed through the mailbox from the callback processing to the foreground client code:

```
INFO:<Browsing for “_http” ALL ADDITIONAL (wait 4-seconds)>
INFO:<Callback flags now 07>
Service: Officejet Pro 8500 A910 [D0220F]._http._tcp.local
  http://hp8500.local:80/
  IPv4 192.168.7.6
  IPv6 2001:4D48:AD00:5A17:6AB5:99FF:FED0:220F
  IPv6 FE80::6AB5:99FF:FED0:220F
  TXT-0 contains 0 entries
Service: Xerox Phaser 6280DN (ac:a8:0d)._http._tcp.local
  http://XRX0000AAACA80D.local:80/
  IPv4 192.168.7.25
  TXT-0 contains 9 entries
    [0]=“qtotal=5”
    [1]=“ty=Xerox Phaser 6280DN”
    [2]=“product=(Phaser 6280DN)”
    [3]=“pdl=application/postscript”
    [4]=“adminurl=http://.local./”
    [5]=“usb_MFG=Xerox”
    [6]=“usb_MDL=Xerox Phaser 6280DN”
    [7]=“Binary=T”
    [8]=“TBCP=T”
PASS:<Service Browse>
```

As mentioned, the example will then perform the same queries for the “_ipp” service name outputting suitable results for the discovered service (if any are actually present on the connected network).

Finally the example performs some explicit queries as would be performed by a simple application that needs to enumerate a (previously discovered, or hardwired) service. The code uses the first valid “_http” service response, and directs specific queries to this service name (unlike the “wildcard” `PTR` queries used to discover services). It uses the `example_query()` to request the `SRV`, and then the `A`/`AAAA` address records as appropriate. The output would be similar to the following.

```
INFO:<Request specific records>
Instance: Officejet Pro 8500 A910 [D0220F]
Service: Officejet Pro 8500 A910 [D0220F]._http._tcp.local
  Host: hp8500.local (Port 80)
  IPv6 2001:4D48:AD00:5A17:6AB5:99FF:FED0:220F
  IPv6 FE80::6AB5:99FF:FED0:220F
  IPv4 192.168.7.6
```

Part LV. NTP Client Support

Name

eCosPro Support for NTP — Overview

Description

The ntpclient package provides an NTP (Network Time Protocol) client for use with the TCP/IP stack in eCos. The client supports Version 3 of the NTP specification as defined in RFC 1305 and supports only unicast messages. It is currently restricted to IPv4 networks only and can only use the BSD IP stack.

The client is based on OpenNTPD 4.6 and implements a subset of the NTP protocol Version 3, sufficient to synchronize the eCos system clock with one or more NTP servers.

The client has been tested against the default Linux **ntpd** server on local hosts and public servers from the UK NTP pool.

Name

NTP Client API — NTP client API and configuration

NTP Client API

The NTP client provides two main entry points:

```
#include <ntpclient.h>

 __externC void cyg_ntpclient_start( cyg_ntpclient_config *config );

 __externC void cyg_ntpclient_stop( void );

__externC void cyg_ntpclient_status( cyg_ntpclient_status *status );

__externC void cyg_ntpclient_log( int log_mask );
```

The `cyg_ntpclient_start()` function starts the NTP client running using parameters defined in the *`config`* argument. The `cyg_ntpclient_stop()` stops the NTP client, after which it can be restarted with a new configuration.

The *`config`* argument contains the following fields that the user may set to control the behaviour of the NTP client. The config structure and its contents must remain accessible until `cyg_ntpclient_stop()` is called, as the NTP client stores a reference to it rather than copying it. Therefore it is likely it will want to be allocated persistently, typically as a static or global.

`const char *server[]`

A list of server IP addresses to access. These are specified as strings in standard dot notation. Unused slots should be set to NULL. The size of this array is controlled by `CYGNUM_NET_NTPCLIENT_SERVER_MAX`.

`int settime`

If non-zero this will force the NTP client to set the system time immediately from the NTP servers. Otherwise it will wait for the time to stabilize before doing this. This is useful on targets that do not have a built-in battery-backed real time clock. Note that by taking the first server time supplied, the initial time set may be less accurate than one would normally expect, it will be adjusted to track the server times more closely as the client accumulates samples.

If this option is set, then the call to `cyg_ntpclient_start()` will not return until the initial time has been set.

The `cyg_ntpclient_status_get()` function returns some information on the state of the client and the NTP peers it is communicating with. On return the *`status`* argument is filled in with the following information.

`double *last_adjustment`

This records the last adjustment made to the clock expressed as a whole number plus fraction of seconds.

`peer[]`

A structure for each peer. The size of this array is controlled by `CYGNUM_NET_NTPCLIENT_SERVER_MAX`. Each entry contains the following fields:

`const char *addr`

The IP address of the peer expressed as a string. This is actually just a pointer to the string passed to `cyg_ntpclient_start()` in the configuration. If the value is NULL then this peer table entry is invalid.

`int trustlevel`

The level of trust the client has in this peer. This is a value between 0 and 10. For a good peer, this will be near the upper end of this range.

`int lasterror`

If non-zero this records the last communication error raised by this peer.

`double delay` The most recent smallest communication delay to the peer.

`double offset` The offset between the local and the remote clock for the same transaction as the *`delay`* field.

The `cyg_ntpclient_log()` function sets some logging option in the NTP client. These are output on the standard output using printf(). The *`log_mask`* is a bitwise OR of the following values: `CYG_NTPCLIENT_LOG_DEBUG`, `CYG_NTPCLIENT_LOG_INFO` and `CYG_NTPCLIENT_LOG_CRIT` which generate debug, information and critical error messages respectively. The value `CYG_NTPCLIENT_LOG_ALL` enables all flags. All flags can be cleared by calling this function with a zero parameter.

The normal idiom for use of the NTP client is to define the cyg_ntpclient structure statically and to then call `cyg_ntpclient_start()` with a pointer to that. The following is a somewhat contrived example:

```
#include <ntpclient.h>

//==========================================================================

static cyg_ntpclient_config ntp_config =
{
    .server             = { "10.0.1.1", "149.255.102.233", NULL },
    .settime            = 1,
};

//==========================================================================

void start_ntp(void)
{
    cyg_ntpclient_start( &ntp_config );
}
```

Configuration Options

The NTP client is enabled by including the `CYGPKG_NET_NTPCLIENT` together with the `CYGPKG_CLOCK_COMMON` package. It also needs the FreeBSD network stack, POSIX and the C library; therefore, it is best to start from the `net` template. The NTP client package contains a number of configuration options:

`CYGNUM_NET_NTPCLIENT_PORT`

This option defines the port number to which the client will direct NTP packets. This should normally be the standard NTP port number of 123, but for testing it may be useful to change it to a non-standard value.

`CYGNUM_NET_NTPCLIENT_STACK_SIZE`

This option defines the size of the stack used by the NTP client thread. This value defines how much more stack than the value given by CYGNUM_HAL_STACK_SIZE_TYPICAL is used. The default of 4KiB should be sufficient for most purposes.

`CYGNUM_NET_NTPCLIENT_THREAD_PRIORITY`

This option defines the priority at which the NTP thread will run. If it is important that the client maintains synchronization with the servers, then this value should be small, giving the client thread a high priority. The default value is 2, making the thread one of the higher priority threads in the system.

`CYGNUM_NET_NTPCLIENT_SERVER_MAX`

This option defines the maximum number of NTP servers the client can access. This controls the number that can be passed in the configuration and the size and number of various data structures allocated statically in the code.

Name

NTP Client Test Programs — Describe the test programs and their host-side support

Test Programs

There are four test programs in the `tests` subdirectory of this package that exercise the NTP client and do duty as examples of its use. These are supported by a test NTP server in the `hosts` directory. There is a `README.TXT` file in that directory describing how to build and run the test server.

ntp_basic

The `ntp_basic.c` test performs no actual tests. Instead it just starts the NTP client and then prints the current time, in the form of seconds since the UNIX epoch, every 10s for some number of iterations before shutting down. The main purpose of this test is to check the basic functionality of the client. With access to a suitable host clock, this can also serve as a manual verification that the client is correctly tracking the server.

ntp_accuracy

The `ntp_accuracy.c` test attempts to check the accuracy of the local clock against the test server. After starting the NTP client and allowing it to synchronize it queries the time on the test server via its control interface and compares the result with local time. It takes a number of samples and if more than 80% of these are within 10ms then the test is considered a pass. It repeats this test a number of times at 10s intervals to look for any clock drift.

ntp_date

The `ntp_date.c` test attempts to check that the client can handle crossing various pathological dates. These include handling leap seconds, the UNIX 32 bit time_t sign overflow in 2038, the UNIX 32 bit unsigned overflow in 2106 and the NTP timestamp era ends in 2036 and 2172. It does this by using the test server's control interface to change its idea of the current data and then watching the local clock as the NTP client resynchronizes to the new date.

ntp_adjtime

The `ntp_adjtime.c` test attempts to check that the underlying clock adjustment subsystem correctly handles various time adjustments. It does this by changing the test server's idea of time by some amount and watching the NTP client resyncronize to the new time. It has the option for each test of either delaying until the adjustment is made, or polling the current time, checking that time continues to increse monotonically.

Part LVI. Simple Network Time Protocol Client

The SNTP package provides implementation of a client for RFC 2030, the Simple Network Time Protocol (SNTP). The client listens for broadcasts or IPv6 multicasts from an NTP server and uses the information received to set the system's time of day clock. This will be either the POSIX CLOCK_REALTIME clock or the wallclock device, or both, depending on the configuration. It can also be configured to send SNTP time requests to specific NTP servers using SNTP's unicast mode.

Note that this package predates the existence of the Common Clock Services and has not yet been adapted to use that package's services. Also this implementation is wholly separate to that of the NTP Client.

Table of Contents

Chapter 192. The SNTP Client

Starting the SNTP client

The sntp client is implemented as a thread which listens for NTP broadcasts and IPv6 multicasts, and optionally sends SNTP unicast requests to specific NTP servers. This thread may be automatically started by the system if it receives a list of (S)NTP servers from the DHCP server and unicast mode is enabled. Otherwise it must be started by the user application. The header file `cyg/sntp/sntp.h` declares the function to be called. The thread is then started by calling the function:

```
void cyg_sntp_start(void);
```

It is safe to call this function multiple times. Once started, the thread will run forever.

What it does

The SNTP client listens for NTP IPv4 broadcasts from any NTP servers, or IPv6 multicasts using the address fe0x:0X::101, where X can be 2 (Link Local), 5 (Site-Local) or 0xe (Global). Such packets contain a timestamp indicating the current time. The packet also contains information about where the server is in the hierarchy of time servers. A server at the root of the time server tree normally has an atomic clock. Such a server is said to be at stratum 0. A time server which is synchronised to a stratum 0 server is said to be at stratum 1 etc. The client will accept any NTP packets from servers using version 3 or 4 of the protocol. When receiving packets from multiple servers, it will use the packets from the server with the lowest stratum. However, if there are no packets from this server for 10 minutes and another server is sending packets, the client will change servers.

If SNTP unicast mode is enabled via the CYGPKG_NET_SNTP_UNICAST option, the SNTP client can additionally be configured with a list of specific NTP servers to query. The general algorithm is as follows: if the system clock has not yet been set via an NTP time update, then the client will send out NTP requests every 30 seconds to all configured NTP servers. Once an NTP time update has been received, the client will send out additional NTP requests every 30 minutes in order to update the system clock. These requests are resent every 30 seconds until a response is received.

The system clock in eCos is accurate to 1 second. The SNTP client will change the system clock when the time difference with the received timestamp is greater than 2 seconds. The change is made as a step.

Configuring the unicast list of NTP servers

If SNTP unicast mode is enabled via the CYGPKG_NET_SNTP_UNICAST option, the SNTP client can be configured with a list of NTP servers to contact for time updates.

By default, this list is configured with NTP server information received from DHCP. The number of NTP servers that are extracted from DHCP can be configured with the CYGOPT_NET_SNTP_UNICAST_MAXDHCP option. This option can also be used to disable DHCP usage entirely.

The list of NTP servers can be manually configured with the following API function. Note that manual configuration will override any servers that were automatically configured by DHCP. But later reconfigurations by DHCP will override manual configurations. Hence it is not recommended to manually configure servers when CYGOPT_NET_SNTP_UNICAST is enabled.

```
#include <cyg/sntp/sntp.h>

void cyg_sntp_set_servers(struct sockaddr *server_list, cyg_uint32 num_servers);
```

This function takes an array of sockaddr structures specifying the IP address and UDP port of each NTP server to query. Currently, both IPv4 and IPv6 sockaddr structures are supported. The num_servers argument specifies how many sockaddr's are contained in the array. The server_list array must be maintained by the caller. Once the array is registered with this function, it must not be modified by the caller until it is replaced or unregistered by another call to this function.

Calling this function with a server_list of NULL and a num_servers value of 0 unregisters any previously configured server_list array.

Finally, note that if this function is called with a non-empty server list, it will implicitly start the SNTP client if it has not already been started (i.e. it will call cyg_sntp_start()).

Warning: timestamp wrap around

The timestamp in the NTP packet is a 32bit integer which represents the number of seconds after 00:00 01/01/1970. This 32bit number will wrap around at 06:28:16 Feb 7 2036. At this point in time, the eCos time will jump back to around 00:00:00 Jan 1 1970 when the next NTP packet is received.

YOU HAVE BEEN WARNED!

The SNTP test program

The SNTP package contains a simple test program. Testing an SNTP client is not easy, so the test program should be considered as more a proof of concept. It shows that an NTP packet has been received, and is accurate to within a few days.

The test program starts the network interfaces using the standard call. It then starts the SNTP thread. A loop is then entered printing the current system time every second for two minutes. When the client receives an NTP packet the time will jump from 1970 to hopefully the present day. Once the two minutes have expired, two simple tests are made. If the time is still less than 5 minutes since 00:00:00 01/01/1970 the test fails. This indicates no NTP messages have been received. Check that the server is actually sending packet, using the correct port (123), correct IPv6 multicast address, and at a sufficiently frequent rate that the target has a chance to receive a message within the 2 minute interval. If all this is correct, assume the target is broken.

The second test is that the current system time is compared with the build time as reported by the CPP macro __DATE__. If the build date is in the future relative to the system time, the test fails. If the build date is more than 90 days in the past relative to the system time the test also fails. If such failures are seen, use wallclock time to verify the time printed during the test. If this seems correct check the build date for the test. This is printed at startup. If all else fails check that the computer used to build the test has the correct time.

If SNTP unicast mode is enabled, the above tests are run twice. The first time, the SNTP client is configured with NTP server addresses from DHCP. The second time, unicast mode is disabled and only multicasts are listened for. Note that the unicast test is partially bogus in the sense that any multicast packet received will also make the unicast test pass. To reduce the chance of this happening the test will wait for a shorter time for replies. This is not ideal, but it is the best that can be done with an automated test.

Part LVII. WLAN

Table of Contents

Chapter 193. WLAN overview

Important

This eCosPro-WiFi Middleware package is STRICTLY LICENSED FOR NON-COMMERCIAL PURPOSES ONLY. It may not be used for Commercial purposes in full or in part in any format, including source code, binary code and object code format.

A Commercial eCosPro License version 3 (or above) which explicity includes this Middleware Package is required for Commercial use.

Introduction

The CYGPKG_NET_WLAN package defines the common eCos Wireless LAN API. This allows eCos applications to operate with a variety of different WiFi driver implementations.

The WLAN package relies on the presence of the CYGPKG_NET_LWIP and the CYGPKG_IO_ETH_DRIVERS packages.

Chapter 194. Configuration

This chapter shows how to include the WLAN support into an eCos configuration, and to configure it once installed.

Configuration Overview

The common eCos WLAN layer is contained in the package `CYGPKG_NET_WLAN`. However, it depends on the services of a collection of other packages for complete functionality. Currently the WLAN implementation is tightly bound with the lwIP TCP/IP networking stack provided by the `CYGPKG_NET_LWIP` package.

Incorporating the WLAN support into your application is straightforward. The essential starting point is to incorporate the WLAN eCos package (`CYGPKG_NET_WLAN`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Configuration Options

Once added to the eCos configuration, the WLAN package has a number of configuration options.

The CDL configuration provides default settings for the use by wireless network interfaces. The application documented in the section called “wlan_switch” provides an example implementation of using the run-time interface configuration, where appropriate, to associate with different access-points.

`CYGDAT_NET_WLAN_COUNTRY`

> This option is used to define the regulatory domain for the radio.

`CYGPKG_NET_WLAN_STA`*`x`*

> If infrastructure (station) interfaces are provided by the underlying wireless device driver package then a number of these STA*x* options become available.
>
> `CYGPKG_NET_WLAN_STAx_SSID`
>
> > This option specifies the SSID (network name) that the interface should associate with.
>
> `CYGPKG_NET_WLAN_STAx_SEC`
>
> > This option is used to select the security encoding required to associate with the named SSID access-point.
>
> `CYGPKG_NET_WLAN_STAx_PASS`
>
> > For pre-shared key security encodings this option supplies the passphrase associated with the SSID access-point.

`CYGPKG_NET_WLAN_AP`*`x`*

> If master (access-point) or adhoc (p2p) capable interfaces are provided by the underlying wireless device driver package then a number of these AP*x* options become available.
>
> `CYGPKG_NET_WLAN_APx_SSID`
>
> > For access-point or P2P interfaces this option supplies the network name used for the connection.

`CYGPKG_NET_WLAN_APx_SEC`

This option specifies the security encoding exposed by the interface.

`CYGPKG_NET_WLAN_APx_PASS`

For pre-shared key security encoding this option defines the passphrase to be used.

`CYGPKG_NET_WLAN_APx_TYPE`

This option allows selection between the “Infrastructure”(master, access-point) and “Adhoc” (P2P) interface modes.

`CYGPKG_NET_WLAN_APx_CHANNEL`

The radio channel to be used for the interface.

Chapter 195. WLAN API

The WLAN API is primarily via the device driver get/set config (`ioctl()`-alike) interface, implemented via the driver supplied interface function:

`int` **`cyg_lwip_eth_ioctl`** `(`*`netif`*`,` *`key`*`,` *`data`*`,` *`data_length`*`);`

See Chapter 16, *User API* for an overview of the general I/O config interface.

SET operations are used to change the active wireless configuration.

`WLAN_DRV_SET_COMMIT`

> This option is used to activate any pending wireless configuration setting changes. This can result in disassociating from the active network configuration, and establishing a new session with the cached (pending) configuration. This information can include the MODE, ESSID, PASSPHRASE and SECTYPE settings.

`WLAN_DRV_SET_MODE`

> This option is used to configure the pending interface wireless mode. It is not used for the active configuration until a `WLAN_DRV_SET_COMMIT` operation is performed.
>
> ### Note
>
> Not all available WLAN mode definitions will necessarily be supported by the underlying wireless hardware driver. For example the `CYGPKG_NET_WIFI_BROADCOM_WWD` package only supports the modes `WLAN_MODE_INFRA`, `WLAN_MODE_MASTER` and `WLAN_MODE_ADHOC`.
>
> The supplied (`wlan_drv_mode_t`) parameter value can be one of:
>
> `WLAN_MODE_INFRA`
>
> > Infrastructure (multi-cell, roaming) network station. The interface will connect to an access-point, which will act as a bridge to other network segments.
>
> `WLAN_MODE_MASTER`
>
> > Access-point (synchronisation master).
>
> `WLAN_MODE_ADHOC`
>
> > Adhoc (P2P) single-cell group network. Such a network has no structure, and no access-point is involved.
>
> `WLAN_MODE_REPEAT`
>
> > Wireless repeater. Packet forwarder.
>
> `WLAN_MODE_SECOND`
>
> > Secondary master/repeater.
>
> `WLAN_MODE_MONITOR`
>
> > Passive monitor. This is used to listen on a network interface to capture packets, without transmitting to the network.
>
> `WLAN_MODE_MESH`
>
> > IEEE 802.11s mesh network.

`WLAN_MODE_AUTO`

This is a special option that is used to allow the driver to select which mode should be used. Normally this would not be appropriate, but some implementations may be limited to specific hardware implementions.

`WLAN_DRV_SET_ESSID`

This option is used to configure the pending network name (SSID). It is not used for the active configuration until a `WLAN_DRV_SET_COMMIT` operation is performed.

The passed (`wlan_drv_essid_t`) structure provides the SSID vector (upto `WLAN_ESSID_MAX_SIZE` bytes in length).

`WLAN_DRV_SET_SECTYPE`

This option is used to configure the pending network security encoding. It is not used for the active configuration until a `WLAN_DRV_SET_COMMIT` operation is performed.

The (`wlan_drv_sectype_t`) parameter is a bitfield encoding of the desired security features. The `WLAN_SECTYPE_TYPE_MASK` can be used to mask out the main security type encoding:

`WLAN_SECURITY_TYPE_WPA2`

Wi-Fi Protected Access 2.

`WLAN_SECURITY_TYPE_WPA`

Wi-Fi Protected Access.

`WLAN_SECURITY_TYPE_WEP`

Wired Equivalent Privacy.

Note

Deprecated. Due to security weaknesses it is not recommended to use WEP.

`WLAN_SECURITY_TYPE_NONE`

Open network, with no security required.

Along with the basic security type encoding the passed parameter can contain a set of authentication and cipher flags.

The authentication type flags:

`WLAN_SECURITY_AUTH_PSK`

Pre-Shared-Key (passphrase). The PSK mode is sometimes referred to as “Personal”.

`WLAN_SECURITY_AUTH_1X`

IEEE 802.1x (enterprise).

The support cipher flags:

`WLAN_CIPHER_TYPE_WEP`

Wired Equivalent Privacy.

`WLAN_CIPHER_TYPE_TKIP`

Temporal Key Integrity Protocol.

`WLAN_CIPHER_TYPE_CCMP`

Counter Mode with CBC-MAC (CCM) mode Protocol. Sometimes referred to as AES (Advanced Encryption Standard) mode.

`WLAN_DRV_SET_PASSPHRASE`

This option is used to configure the pending network security pre-shared key value. It is not used for the active configuration until a `WLAN_DRV_SET_COMMIT` operation is performed.

The passed (`wlan_drv_passphrase_t`) structure provides the key vector (upto `WLAN_SECURITY_PASSPHRASE_LEN` bytes in length).

Note

For security reasons there is no equivalent `GET` operation to read the active passphrase value.

`WLAN_DRV_SET_ENCODE`

This option is used to configure the pending network security WEP key set. It is not used for the active configuration until a `WLAN_DRV_SET_COMMIT` operation is performed.

The passed (`wlan_drv_wepkeys_t`) structure contains the keys to be used for WEP authentication. The passed *`keys[]`* vector contains the binary keys when the supplied *`length`* field is either `WLAN_SECURITY_WEP104_LEN` or `WLAN_SECURITY_WEP40_LEN`. If hexadecimal ASCII representations are being supplied in the *`keys[]`* vector then the *`length`* is twice the binary key length.

`WLAN_DRV_SET_CHANNEL`

The passed (`wlan_drv_channel_t`) value is used to configure the radio channel to be used for the interface. This is used for `WLAN_MODE_ADHOC` and `WLAN_MODE_MASTER` configurations.

Note

For `WLAN_MODE_INFRA` configurations the WiFi device will scan for the required Access Point on all the allowed channels, and so the channel set via this operation may not actually be used.

`WLAN_DRV_SET_FREQ`

This option is an alternative method for setting the WiFi channel as a frequency (specified in MHz).

`WLAN_DRV_SET_SCAN_START`

This key is used to initiate a wireless network scan. The underlying wireless device driver defines for how long a scan is actually active.

The passed (`wlan_drv_scan_t`) structure is used to define the callback context for the application supplied handler executed for each network found during the scanning process. A handler function pointer, with the prototype as defined in `wlan.h`:

```
typedef void (*wlan_drv_scan_callback_fn)(void *private,wlan_drv_scan_info_t *info);
```

is required, along with a private context pointer.

For each network found the handler is called with a suitable (`wlan_drv_scan_info_t`) *`info`* pointer. If the scan is terminated then a NULL *`info`* parameter is passed to the handler, and the wireless device driver scan support will no longer reference the registered callback.

The eCos scan support is designed to allow the WLAN driver to have a minimal memory footprint, and so the application is responsible for storing/caching any network information seen.

Note

To support this common eCos WLAN layer (allowing eCos applications to use WLAN functionality without having to have special handling for different chipset/driver combinations) when scanning there is a slight overhead in converting the driver specific scan results into the common eCos structure.

The application documented in the section called “wlan_scan” provides an example implementation using the eCos wireless network scan interface.

`WLAN_DRV_SET_SCAN_ABORT`

This key can be used to abort (terminate) an active scan.

`WLAN_DRV_SET_TXPOWER`

The passed (`wlan_drv_dbm_t`) dBm value is used to configure the interface transmit power.

`WLAN_DRV_SET_RTS`

The passsed (`wlan_drv_rts_t`) threshold value specifies the number of bytes in a network packet as the point where the RTS/CTS mechanism is initiated.

GET operations are used to acquire the current, active, wireless configuration.

`WLAN_DRV_GET_INIT`

A non-error return for this operation indicates a WLAN capable driver.

Note

The `CYGPKG_NET_WLAN` package requires that all eCos WLAN capable drivers provide support for a successful result from the `WLAN_DRV_GET_INIT` config key since it is used as an indicator that a specific Ethernet driver instance is a wireless interface. If `WLAN_DRV_GET_INIT` returns an error then the interface does *NOT* support the eCos wireless features.

`WLAN_DRV_GET_CHANNEL`

Returns the active (`wlan_drv_channel_t`) channel number.

`WLAN_DRV_GET_MODE`

Returns the interface (`wlan_drv_mode_t`) mode.

`WLAN_DRV_GET_ESSID`

This key returns the current SSID configuration in the referenced (`wlan_drv_essid_t`) structure.

`WLAN_DRV_GET_SECTYPE`

This key obtains the active (`wlan_drv_sectype_t`) security encoding setting.

`WLAN_DRV_GET_RATE`

Obtains the current (`cyg_drv_rate_t`) bps communication rate value.

`WLAN_DRV_GET_TXPOWER`

Obtains the current (`wlan_drv_dbm_t`) dBm transmission power setting.

`WLAN_DRV_VENDOR`

The interpretation of this key is *NOT* defined. It is provided as an extension hook for any driver (hardware) specific control operations that may be needed.

API

Name

wlan_diag_dump_ascii — Output human-readable string

Synopsis

#include <wlan.h>

`cyg_uint32` **`wlan_diag_dump_ascii`** `(`*`tag`*`, `*`addr`*`, `*`amount`*`);`

Description

Since ESSID and passphrase values may contain non-printable characters this helper function is just a wrapper to `diag_printf()` to display an arbitrary buffer in a human-readable form. It is purely provided for test and diagnostic use.

The *`tag`* parameter is optional and can be NULL. If non-NULL then the simple NUL-terminated string is output before decoding the supplied *`amount`* bytes of data from the *`addr`* memory reference.

Return value

The number of characters output.

Chapter 196. Testing

The default configuration provides a set of basic tests that can be built.

wlan_scan

The wlan_scan application provides an example of using the `WLAN_DRV_SET_SCAN_START` and `WLAN_DRV_SET_SCAN_ABORT` keys. It starts multiple scans (if required) over a configured time period reporting on wireless networks seen.

wlan_switch

The wlan_switch application provides an example of run-time access-point configuration and switching between access points. It shows the use of the `cyg_lwip_eth_ioctl()` interface to set various wireless configuration options and `WLAN_DRV_SET_COMMIT` to update the active setting.

Part LVIII. Cypress WWD WLAN

Table of Contents

Chapter 197. Cypress WWD overview

Introduction

The `CYGPKG_NET_WIFI_BROADCOM_WWD` package implements the eCos specific support for the Cypress (previously Broadcom) WICED Wireless Driver (WWD) sources present in (3rd-party) Cypress WICED-SDK releases. The WWD package is for use with the generic eCos WLAN (wireless networking) support layer to present the common eCos wireless API. The WICED-SDK is now owned and developer by Cypress., but was originally developed by Broadcom, hence the historic use of `BROADCOM` in names provided by this package.

The WWD package relies on the presence of the `CYGPKG_NET_WLAN`, `CYGPKG_NET_LWIP` and the `CYGPKG_IO_ETH_DRIVERS` networking packages. It also requires the eCos Kernel C API (`CYGFUN_KERNEL_API_C`) to provide the required thread support.

Note

The BSD network stacks `CYGPKG_NET_FREEBSD_STACK` and `CYGPKG_NET_OPENBSD_STACK` are not supported by this Cypress WWD support package.

Warning

Due to licensing restrictions the WICED-SDK package *cannot* be distributed as part of an eCos release. The developer is responsible for obtaining a supported WICED-SDK version via the normal Cypress channels. e.g. the WICED Studio developer website.

Currently only WICED-SDK-3.5.2 and WICED-Studio-6.4.0.61 are officially supported. Adding CDL support for future WICED-SDK releases is an easy process assuming no fundamental restructuring of the SDK is undertaken by Cypress.

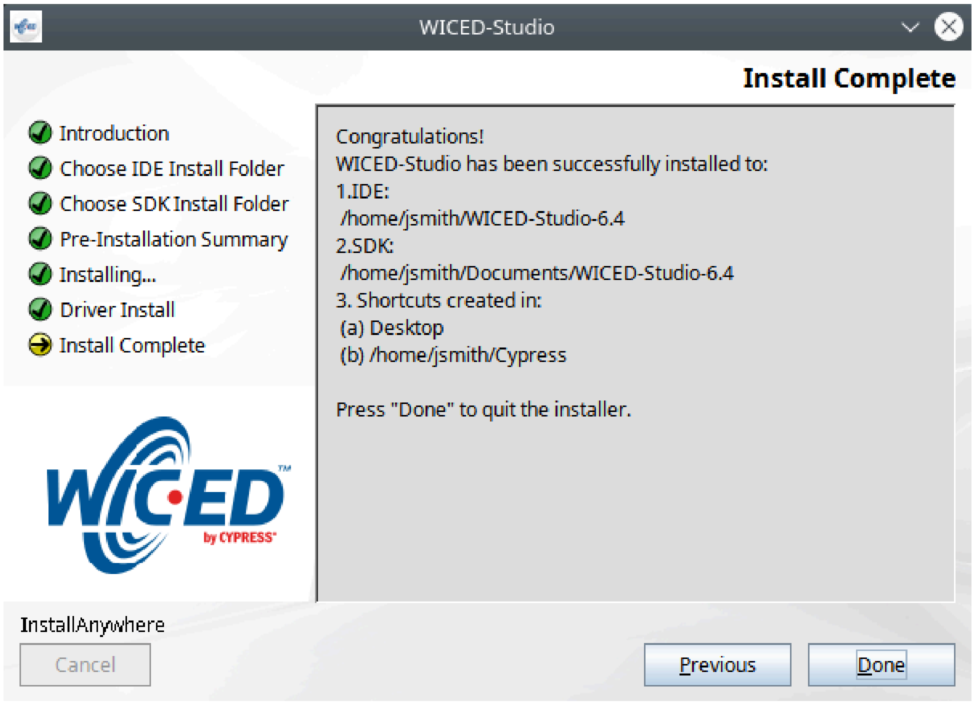
See the section called “WICED-SDK Installation” for a description of how to install the WICED-SDK.

NOTE: The WICED-SDK source tree must be installed into the correct eCosPro tree location prior to any target configuration via ecosconfig or configtool.

WICED-SDK Installation

After acquiring a supported Cypress WICED-Studio release package the SDK needs to be extracted into the correct location within your eCosPro release source tree. The WiFi SDK is written to your filesystem as part of the executable WICED Studio installer run. On completion of the installation process you should be presented with a window similar to Figure 197.1, “Example WICED-Studio installation complete” where the filesystem path location of the SDK should be noted. A copy of the installed SDK tree needs to be copied into the eCosPro tree.

Figure 197.1. Example WICED-Studio installation complete



Congratulations!
WICED-Studio has been successfully installed to:
1.IDE:
/home/jsmith/WICED-Studio-6.4
2.SDK:
/home/jsmith/Documents/WICED-Studio-6.4
3. Shortcuts created in:
(a) Desktop
(b) /home/jsmith/Cypress

Press "Done" to quit the installer.

The source path for the eCosPro tree depends on your specific installation, as does the specific eCosPro release `vsn` number. Similarly, the installer executable created WiFi SDK sub-directory is copied and renamed to conform to the package version naming scheme to allow identification of specific SDKs when multiple WICED SDK trees are installed into an eCosPro tree.

For Linux hosted development this can be achieved as follows:

```
$ cd /home/jsmith/Documents/WICED-Studio-6.4
$ tar cf - 43xxx_Wi-Fi | \
(cd path_to_ecospro_release/packages/net/wireless/wifi_bcmwwd/current/src/; tar xf -)
```

```
$ cd  path_to_ecospro_release/packages/net/wireless/wifi_bcmwwd/current/src
$ mv 43xxx_Wi-Fi WICED-SDK-6.4.0.61
```

For Windows hosted development the `43xxx_Wi-Fi` directory can be copied from its installed SDK location into the eCosPro source tree and renamed accordingly:

<- Renamed

Note

The WICED Studio installed WiFi SDK directory `43xxx_Wi-Fi` is renamed above to reflect the version number of the WICED Studio installer executable used.

With the SDK tree copied and renamed as above it is now available for eCos configuration.

Previously the WICED-SDK archives were distributed by Broadcom as `.7z` packages (e.g. version 3.5.2).

The WICED-SDK sources need to be installed into the `src` sub-directory of the `CYGPKG_NET_WIFI_BROADCOM_WWD` package within the eCosPro release tree.

Using the `WICED-SDK-3.5.2.7z` package as an example, the following is a command-line example of extracting into the eCosPro tree. The source path for the eCosPro tree depends on your specific installation, as does the specific eCosPro release *`vsn`* number:

```
$ cd /path_to_ecospro_release/packages/net/wireless/wifi_bcmwwd/current/src
$ 7z x ~/Downloads/WICED-SDK-3.5.2.7z

7-Zip [64] 9.20  Copyright (c) 1999-2010 Igor Pavlov  2010-11-18
p7zip Version 9.20 (locale=en_GB.UTF-8,Utf16=on,HugeFiles=on,8 CPUs)

Processing archive: /home/user/Downloads/WICED-SDK-3.5.2.7z

Chapter 198. Configuration

This chapter shows how to include the WWD support into an eCos configuration, and to configure it once installed.

Configuration Overview

The WWD driver is contained in the package `CYGPKG_NET_WIFI_BROADCOM_WWD`. However, it depends on the services of a collection of other packages for complete functionality. Currently the WWD implementation is tightly bound with the lwIP TCP/IP networking stack provided by the `CYGPKG_NET_LWIP` package.

Incorporating the WWD support into your application is straightforward. The essential starting point is to incorporate the WWD eCos package (`CYGPKG_NET_WIFI_BROADCOM_WWD`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Note

Prior to the first configuration attempt the 3rd-party WICED-SDK sources need to be installed into the eCosPro source tree as per the section called “WICED-SDK Installation”.

The package also relies on specific WWD functionality being provided by the platform (or variant) HAL for supported targets. See Chapter 199, *Platform/Variant HAL* for an overview of the HAL support required.

Chipset Firmware

The Cypress/Broadcom WICED WiFi chipsets require a binary firmware image to be downloaded to the WiFi chip for correct operation. For some platforms the required binary firmware image is available as part of the installed WICED SDK. However, the WICED SDK does not have support all platforms and the configuration world allows for the firmware binary images to be located outside the user installed WICED SDK tree.

For example the Raspberry Pi platforms use binary images included as part of the `CYGPKG_NET_WIFI_BROADCOM_WWD` package. For reference these images are located in individual sub-directories in the eCosPro `packages/net/wireless/wifi_bcmwwd/`*`version`*`/src/platforms` directory.

pi43430 This directory holds the 3rd party binary firmware image for the Raspberry Pi 3B and and Raspberry Pi 0W platforms.

pi43455 This directory holds the 3rd party binary firmware image for the Raspberry Pi 3B+ platform.

A `README.txt` is present in each sub-directory describing from where the 3rd-party binary blobs were acquired.

When porting the WWD driver to a new platform it may be necessary to acquire a suitable binary-blob to match the Cypress chipset being used and the hardware I/O configuration of the platform.

Configuration Options

Once added to the eCos configuration, the WWD package has a number of configuration options. As well as the core CDL options for the common WWD support, a WICED-SDK version specific set of CDL options are also available.

`CYGFUN_NET_WIFI_BROADCOM_WWD_RESOURCES_INDIRECT`

Most Cypress/Broadcom WICED WiFi chipsets require a binary firmware image to be downloaded to the WiFi chip.

Where the platform provides the necessary support, this option can be enabled to configure the application to access non-memory-mapped resource images. If disabled then the resource binaries are built into the application binary. For example, with platforms where limited amounts of (on-chip) direct memory are available the size of the required firmware binary blob could severely limit the usable application code size.

Please read the relevant platform specific documentation for details of any requirements, or processes, involved in initialising the non-memory-mapped firmware storage.

`CYGPKG_NET_WIFI_BROADCOM_WWD_MODULE`

This option allows the selection of the base WICED module to be targetted. Normally the configured eCos target (platform HAL) configuration will force a suitable value, and the developer should not need to manually configure this setting.

Similarly, depending on the configured module, the `CYGPKG_NET_WIFI_BROADCOM_WWD_CHIPSET` option defines the Cypress/Broadcom WiFi chipset to be configured.

`CYGIMP_NET_WIFI_BROADCOM_WWD_ACCESS`

This option selects the transport bus used between the WICED module host CPU and the WiFi controller Normally the configured eCos target (platform HAL) configuration will force a suitable value, and the developer should not need to manually configure this setting.

`CYGPKG_NET_WIFI_BROADCOM_WWD_WICED_SDK`

This is the main option for selecting the supported WICED-SDK version to be used. As mentioned in the section called “WICED-SDK Installation” the relevant WICED-SDK source should be present in the package `src` sub-directory.

As appropriate, WICED-SDK version specific CDL options are then made available to the system. These are not normally user-editable since they are primarily hooks for the config and build systems.

`CYGDBG_WIFI_BROADCOM_WWD_DEBUG`

This option, and its associated sub-options, are primarily for development of the driver internals. It is not normally expected that the application developer making use of the WWD package will ever need to enable the debug features.

If enabled this option provides access to a set of individually controllable diagnostic options. These can be used to provide low-level `diag_printf()` diagnostic output. It should be noted that some diagnostics if enabled will adversely affect the performance of the system such that incorrect behaviour can result.

As well as the WWD package specific options, the lwIP configuration will affect how the WWD driver is configured. For example the calculated `CYGNUM_NET_WIFI_BROADCOM_WWD_MTU` value for the MTU of the WWD layer is limited to what will fit within a single lwIP buffer, and so the setting is based on the relevant lwIP package configuration. The developer may need to tune the lwIP memory footprint to reflect both the expected usage of the system and the available memory at run-time.

Chapter 199. Platform/Variant HAL

To correctly operate the WWD driver needs to have some platform specific support that identifies the WICED-SDK features needed to support a specific Cypress/Broadcom chipset configuration. This chapter is primarily aimed at developers that need to provide WWD support on platforms without existing WWD support.

Some manifests control the features that are provided by the platform, and may be required depending on the specific WICED module being supported.

Table 199.1. WICED options

Manifest	Description
`WICED_CPU_CLOCK_HZ`	Provides the eCos run-time clock frequency to the WICED system.
`WICED_WIFI_USE_GPIO_FOR_BOOTSTRAP_0`	Specifies that a GPIO pin is provided for the `BOOTSTRAP_0` startup configuration of the WiFi chip.
`WICED_WIFI_USE_GPIO_FOR_BOOTSTRAP_1`	Specifies that a GPIO pin is provided for the `BOOTSTRAP_1` startup configuration of the WiFi chip.
`WICED_WIFI_OOB_IRQ_GPIO_PIN`	Out-Of-Band (asynchronous) interrupt pin provided.
`WICED_USE_WIFI_POWER_PIN`	WiFi chip power control pin provided.
`WICED_USE_WIFI_POWER_PIN_ACTIVE_HIGH`	Selects active-HIGH polarity for the power control pin, otherwise is active-LOW.
`WICED_USE_WIFI_RESET_PIN`	WiFi chip reset control pin provided.
`WICED_USE_WIFI_32K_CLOCK_MCO`	32kHz clock provided.

As well as the WICED feature configuration, the platform needs to define the set of hardware features as present on the targetted platform. Only the necessary subset of these will be defined, as dictated by how the WiFi chipset signals are wired on the target platform.

Table 199.2. Hardware manifests

Manifest	Description
`CYGHWR_HAL_STM32_WWD_MCO1`	Pin descriptor for clock source.
`CYGHWR_HAL_PLF_CLOCK_MCO_32K`	Platform specific function used to configure the 32kHz clock source.
`CYGHWR_HAL_PLF_WWD_PIN_POWER`	GPIO pin descriptor for power control.
`CYGHWR_HAL_PLF_WWD_PIN_RESET`	GPIO pin descriptor for reset control.
`CYGHWR_HAL_PLF_WWD_PIN_32K_CLK`	Pin descriptor for 32kHz clock source.
`CYGHWR_HAL_PLF_WWD_PIN_32K_GPIO`	GPIO pin descriptor for 32kHz clock source.
`CYGHWR_HAL_PLF_WWD_PIN_BOOTSTRAP_0`	GPIO pin descriptor for bootstrap 0.
`CYGHWR_HAL_PLF_WWD_PIN_BOOTSTRAP_1`	GPIO pin descriptor for bootstrap 1.
`CYGHWR_HAL_PLF_WWD_PIN_SPI_IRQ`	GPIO pin descriptor for SPI transport bus interrupt.
`CYGHWR_HAL_PLF_WWD_PIN_SPI_CS`	GPIO pin descriptor for SPI transport bus chip-select.
`CYGHWR_HAL_PLF_WWD_PIN_SDIO_OOB_IRQ`	GPIO pin descriptor for SDIO transport bus interrupt.
`CYGHWR_HAL_PLF_WWD_SDIO_ALIGN4`	Manifest to control word-aligned transport bus transfers. This manifest may be needed for some platforms if the underlying

Manifest	Description
	platform transport bus implementation requires word-aligned memory buffers (e.g. due to DMA limitations).
`CYGHWR_HAL_PLF_WWD_SDIO_SPEED`	Manifest defining the platform SDIO clock rate.

If the platform can support “out of application” storage of the WiFi firmware then the CDL option `CYGFUN_NET_WIFI_BROADCOM_WWD_RESOURCES_INDIRECT` will be configured, and the platform is then expected to provide manifests that map to the low-level firmware storage support. Normally such a large binary firmware image will be held in off-chip memory; but for certain architectures it may just be held in a specific region of some on-chip flash memory.

Table 199.3. Indirect firmware access

Manifest	Description
`HAL_PLF_WIFI_BROADCOM_WWD_INDIRECT_FW_READ`	The platform specific function used to read an amount of raw firmware data from a logical byte offset.
`HAL_PLF_WIFI_BROADCOM_WWD_LL_INIT`	If required the function to be called to perform low-level memory system initialisation prior to the WWD layer performing indirect firmware reads.

Part LIX. Common Clock Services

Table of Contents

Chapter 200. Overview

Introduction

The Common Clock package (`CYGPKG_CLOCK_COMMON`) provides a centralized management interface for system time, also known as calendar time, which corresponds to the real time of day. System time is distinct from other clock-related concepts such as the kernel "real time clock" which drives the kernel scheduler, or hardware timers.

The purpose of this package is primarily to keep system time management and related functionality focused in a central location to ensure a consistent and coherent approach to time management across all eCos packages, and to avoid duplication. It is used by the C library and by the POSIX compatibility layer for underlying time support, and also provides interfaces to manipulate time which may be used by services such as NTP, as well as to the user. It encapsulates the underlying eCos wallclock driver layer.

At the present time, it only operates when using the eCos kernel package, as it uses a dedicated thread to perform time management functions.

It has been verified safe for use past year 2038 - the so-called Year 2038 problem refers to the overflow of signed 32-bit representations of time in seconds since 1970-01-01 00:00:00 UTC.

Functionality

The package provides an API which presents functions to the user or higher layers to:

- Get the system time;
- Set the system time;
- Adjust the system time by a small amount, manage such adjustments, and potentially manage other aspects of clock discipline;
- Receive notifications of changes to system time;
- Instruct the package to update a wallclock (RTC) device configured into eCos with the current system time;
- Provide a kernel C API clock handle linked to the clock which is driving system time (which may or may not be the same as the real time clock driving the kernel scheduler). This can in turn be used to set alarms associated with ticks of that clock;
- Convert between system time clock ticks and calendar time, both in the form of relative time offsets, or absolute timestamps.

Concepts and structure

The main focus of the architecture of this package is the clock management thread. This thread acts as a central processing point in the system to: asynchronously initialize the clocks at system startup time; update the wallclock time either if directed by the user, or if required to by configuration settings (at regular periods, or whenever time is updated); and notify registered modules when the system time has been set or updated.

This thread should be a high priority thread as it is inherently time-sensitive, and the behaviour may not be as expected if pre-empted. For example, after the time has been changed, registered modules will be notified, but a higher priority thread could pre-empt and run before the notification has taken place, with the potential for different parts of the system to have different understandings of what the current time is. Although be aware there is a chance this can happen anyway as a potential consequence of the notification process, as obviously only one module can be notified at a time, meaning there can be a lag between the time change and notification.

The API functions of this package represent time using the POSIX standard defined structure struct timespec. This offers the most flexible and high resolution representation. The type is defined in the header file `<time.h>` and the standard mandates its definition as follows:

```
struct timespec {
    time_t tv_sec;    /* Seconds */
    long   tv_nsec;   /* Nanoseconds */
}
```

All uses of absolute time values are expressed using time as a struct timespec with an "epoch" (reference start date) of 1970-01-01 00:00:00 UTC. All time is based in the UTC time frame - no support for timezones is provided, which is instead left to higher layers.

Overall, the system time is maintained by reading a high resolution HAL clock, and maintaining a fixed relationship between that clock value and the set time. Global variables are used within the common clock package to allow for this, and are protected from simultaneous access, thus making the package thread safe. However no functions in this package can be considered safe to call from either an ISR or a DSR. At the beginning of system operation, interlocks are used to ensure that it is not possible to retrieve the system time until the common clock package has been initialized.

Time can be adjusted by a small amount - the maximum allowable range being a parameter set in the package configuration. When this happens, the clock is not set to the new time immediately ("stepped") but instead it gradually converges towards the new time base. It will still increase monotonically. Making changes to time in this way can be much less disruptive to applications, however it is not appropriate for large changes, as it would take either take too long to converge, or spend a significant duration with the time being significantly inaccurate. Time can be adjusted both forwards and backwards.

Conversion functions are available to convert between real time and tick counts for the kernel clock object associated with the clock which is driving system time. These use the clock converter functions provided in the eCos kernel.

Chapter 201. Dependencies

HAL

This package relies on the HAL clock API. It is strongly recommended that the HAL clocks are implemented using the full newer version of the HAL clock API, and not the older backward compatibility API (`HAL_CLOCK_INITIALIZE()`, `HAL_CLOCK_READ()`, `HAL_CLOCK_RESET()`). The package will still operate with the older form of API implementation, but it is likely to be less accurate, and possibly slightly slower.

The HAL clock API provides a high-resolution interface to an appropriate hardware clock, allowing fine-grained access with subtick access. Naturally, the resolution and accuracy that this package is able to provide is subject to what the hardware and HAL clock implementation provides. It is desirable, if possible, for the HAL clock to be configured with auto-reloading on interrupt. This reduces clock drift.

Kernel

At the present time, the common clock package relies on kernel facilities. It is hoped in future that this dependency will be removed.

However at the present time, a clock management thread is used to provide an asynchronous route for managing clock operations. This can be important if the package is required to update the wallclock, since with some wallclock drivers, it can take over one second to update the wallclock time in hardware, and it would be inappropriate for applications to stall and wait for such operations to complete.

It also allows modules to be notified that time has changed, either by a step change or by gradual fine adjustment. It can either use a user-supplied callback function, or broadcast a nominated kernel condition variable as the mechanism for notification. When it does so, it passes both the newly set time, and the cumulative time offset since the last received notification.

If a callback function has been provided, it should return as soon as possible, as no further notifications or other processing by the clock management thread can proceed until control is returned to it.

At present, the only underlying HAL clock supported must be the same clock as that used by the kernel, however the API and implementation have been designed to accommodate alternative clocks, and very little is required to complete such an implementation, once an appropriate platform which requires it has been selected, so that it can be verified. Users of this package should certainly not assume that the clock being used to control system time will continue to be the same as the kernel's clock.

The package also makes use of the kernel clock conversion facilities in order to translate clock ticks to or from real time in a scalable way when calling this package's tick conversion functions. The HAL clock API also provides a mechanism to convert ticks to and from real time, but this is not designed to scale beyond nanosecond times, nor tick values greater than 32-bits in width.

It is strongly recommended that users use the time conversion functions provided by this package, not only to avoid duplication, but also because in the case of conversion of absolute time values, the values returned can be affected by any fine adjustment in progress at that time.

Wallclock (RTC)

This package can optionally be configured to use a wallclock (RTC) device driver if configured in the system (the `CYGPKG_CLOCK_COMMON_USE_WALLCLOCK` CDL configuration option). If enabled, time will be retrieved from the wallclock device when the system starts, which is then used to initialize system time.

If no wallclock device is present in the configuration, then time will be initialized to a default date of 2012-01-01 00:00:00 UTC, although obviously it can then be subsequently set to the correct time by the user, or by services such as a network time client.

The user is free to trigger an update of the wallclock from the system time with the API function `cyg_clock_sync_wallclock()`. This will cause the clock management thread to wake up and set the wallclock time. An argument to the function indicates whether to do so synchronously (i.e. to wait for completion) or asynchronously (complete in the background).

Alternatively, CDL configuration options are provided to force the wallclock to be updated whenever time is set. However this can be expensive if time is updated frequently, which can sometimes happen, for example, with Network Time Protocol (NTP) clients.

A second alternative is also provided to periodically wake the clock management thread up regularly after a configured number of kernel ticks.

C library and POSIX layers

The C library time functions, and POSIX layer clock and timer functions will always use this package if present in the configuration. Obviously there can only be one notional system time, so when this package is present, no other means of providing a system time is used.

It also avoids significant duplication. In particular, similarly implemented clock conversion functions had existed in multiple locations prior to this package being used.

Chapter 202. Configuration

The following properties may be configured in this package using the configuration tool:

Management thread priority (CYGNUM_CLOCK_COMMON_THREAD_PRIO)

> This specifies the thread priority of the clock management thread. It is strongly recommended that this be a high priority (smaller number) as this thread is intrinsically sensitive to time delays.

Management thread stack size (CYGNUM_CLOCK_COMMON_THREAD_STACK_SIZE)

> This sets the stack size for the clock management thread. It must be large enough to accommodate calls into a wallclock driver (potentially in turn using bus drivers such as I²C), as well as any potential registered user callback functions. Note the value of this option is text, not a number.

Fine clock adjustment (CYGFUN_CLOCK_COMMON_ADJTIME)

> This component is used to allow fine adjustment of clock times, using the `cyg_clock_adjust_systime()` API function. This allows system time to be gradually adjusted to a new time, rather than there being a step change by just setting the time. Some extra overhead is incurred when getting and setting time if this is enabled, so it is disabled by default.

Maximum adjustment range (CYGNUM_CLOCK_COMMON_ADJTIME_MAX_RANGE)

> If fine clock adjustment is enabled, this option specifies the limit to how far the clock is allowed to be fine adjusted, measured in milliseconds. Requests to adjust beyond this range are rejected. Setting the range too large results in the clock remaining quite inaccurate over a longer time, and setting the time directly would be more relevant. The default is +/- 128ms which corresponds to the norm for NTPv3 (RFC1305) compliance.

Adjustment period as shift (CYGNUM_CLOCK_COMMON_ADJTIME_PERIOD_SHIFT)

> This option is used to set the period of time over which the time should be adjusted. After this time has elapsed, the clock adjustment will be complete. The value of this option is used as a shift value to give a power of two in nanoseconds. A value of 1 corresponds to 2ns, a value of 2 corresponds to 4ns, a value of 3 corresponds to 8ns, and so on. As a convenience, a calculated CDL variable CYGNUM_CLOCK_COMMON_ADJTIME_PERIOD_SECS is provided alongside to see the effect of different settings of this variable. Having to use a power of two may seem restrictive, but it avoids some particularly expensive calculations which would be detrimental to efficiency and accuracy.

Adjustment period as secs (CYGNUM_CLOCK_COMMON_ADJTIME_PERIOD_SECS)

> This configuration point is not actually used by the package, and exists purely as a convenience to the user. It uses the setting of CYGNUM_CLOCK_COMMON_ADJTIME_PERIOD_SHIFT to report an approximation of the corresponding period of time in seconds over which the time should be adjusted, to allow inspection of the effects of different shift values. The value displayed here is rounded down to the nearest second, although the actual value would not be.

Use wallclock (CYGPKG_CLOCK_COMMON_USE_WALLCLOCK)

> Leave this option enabled if a wallclock (RTC) device driver is to be used to maintain time persistently. Time will be initialized using the wallclock driver. If this option is disabled, then a default date of 2012-01-01 00:00:00 is used when starting up, but the time can be set by the application (for example based on user input, or via an external process such as a network time client), and can then be maintained, even though the time will be lost on power off.

Wallclock updates (CYGPKG_CLOCK_COMMON_WALLCLOCK_UPDATES)

> When this component is enabled, the wallclock can be updated by this package based on the system time held in this package. The user can request an update using the `cyg_clock_sync_wallclock()` API function, along with other automatic methods which can be enabled in the following options.

Always update when set (`CYGSEM_CLOCK_COMMON_ALWAYS_UPDATE_WALLCLOCK`)

> This option defaults to disabled, but if it is enabled, whenever the system time is set it always results in the wallclock also being updated immediately afterwards. This could result in unnecessary load if the time is updated often, or delays if parts of the system need to wait for the update to complete.

Regular update interval (`CYGNUM_CLOCK_COMMON_WALLCLOCK_UPDATE_PERIOD`)

> When this option is enabled, the wallclock will be updated periodically. The value of this option gives the period between updates, measured in kernel ticks. The default value of 720000 would correspond to 2 hours if the kernel is using a 100Hz clock.

Tick conversions (`CYGFUN_CLOCK_COMMON_TICK_CONVERTERS`)

> Various subsystems, and users, may need to convert between system clock ticks and real time. This option enables the provision of functionality to do so. These functions also take account of any fine time adjustments made (if `CYGFUN_CLOCK_COMMON_ADJTIME` is enabled). However this functionality is not enabled by default as there is overhead in having and initialising the converters even if unused. Note that the system clock driving system time may not be the same clock as the kernel clock.

Chapter 203. API reference

Name

cyg_clock_get_systime() — Retrieve the current system time

Synopsis

#include <cyg/clock/api.h>

```
Cyg_ErrNo cyg_clock_get_systime(ts);
```

Description

Retrieves the current system time as a struct timespec and stores it in *ts*. This time is represented as a UTC offset from the Epoch, defined as 1970-01-01 00:00:00 UTC for consistency with POSIX.

Return value

This function returns a standard error code, as defined in `<errno.h>`, or ENOERR on success.

Name

cyg_clock_get_systime_res — Obtain the resolution of the system clock

Synopsis

#include <cyg/clock/api.h>

```
Cyg_ErrNo cyg_clock_get_systime_res(ts);
```

Description

This function can be called to obtain the resolution of the system clock. The resolution is expressed as the time difference (quantum) corresponding to the smallest increment the clock may make, in nanoseconds, and returned in the struct timespec pointed to by *ts*.

Due to rounding errors in calculations, and the possibly of a fine adjustment being in progress (if `CYGFUN_CLOCK_COMMON_ADJTIME` is enabled), it is not guaranteed that the difference between two sequential reads of system time will never be smaller than the resolution returned here.

Return value

This function returns a standard error code, as defined in `<errno.h>`, or ENOERR on success.

Name

cyg_clock_set_systime() — Sets the system clock to the supplied time

Synopsis

```
#include <cyg/clock/api.h>
```

```
Cyg_ErrNo cyg_clock_set_systime(ts);
```

Description

Sets the system time to the time represented in the struct timespec at *ts*. The time is treated as a UTC offset from the Epoch, defined as 1970-01-01 00:00:00 UTC for consistency with POSIX.

Upon setting, the clock management thread will wake up and notify any modules which registered for notifications of time changes. If `CYGSEM_CLOCK_COMMON_ALWAYS_UPDATE_WALLCLOCK` is enabled, it will also update the wallclock device.

Note

If another thread attempts to set the time before the previous time setting has been processed by the clock management thread (including notifications and updating wallclock), it will be forced to block and wait for the previous set operation to complete. This may also occur if the clock management thread is busy updating the wallclock in response to a periodic request as configured by `CYGNUM_CLOCK_COMMON_WALLCLOCK_UPDATE_PERIOD`.

Return value

This function returns a standard error code, as defined in `<errno.h>`, or ENOERR on success.

Name

cyg_clock_sync_wallclock() — Force the wallclock to be updated from system time

Synopsis

#include <cyg/clock/api.h>

```
Cyg_ErrNo cyg_clock_sync_wallclock(wait_for_completion);
```

Description

Calling this function instructs the clock management thread to update the time stored in the wallclock (RTC) device from the current system time.

Depending on the underlying wallclock hardware and driver implementation, this may block for an extended period, possibly over one second. If *wait_for_completion* is true, the function will not return until the wallclock has been updated. If *wait_for_completion* is false, it should not block, unless the eCos kernel is not in use. If there was a failure while updating the wallclock, this may only be reported if *wait_for_completion* is set.

Return value

This function returns a standard error code, as defined in `<errno.h>`, or ENOERR on success.

Name

cyg_clock_adjust_systime() — Adjust the system time

Synopsis

#include <cyg/clock/api.h>

`Cyg_ErrNo` **`cyg_clock_adjust_systime`**`(`*`adj`*`);`

Description

We supply a function to allow fine adjustment of the time. Unlike `cyg_clock_set_systime()`, these adjustments will not cause an abrupt step change but allow gradual adjustment, while still preserving the principle of the clock monotonically increasing.

The cyg_clock_time_adj_t type is defined by including `<cyg/clock/api.h>`, and its contents are as follows:

```
typedef struct cyg_clock_time_adj_s {
    struct {
        unsigned int set_offset : 1;
        unsigned int get_adjremaining : 1;
    } flags;
    struct timespec  offset;       // Time offset
    struct timespec  adjremaining; // Remaining adjustment (can be negative)
} cyg_clock_time_adj_t;
```

Note

Do not rely on the ordering of members of this structure remaining the same in future. Similarly, additional structure members are likely to be added in future.

To adjust to a fixed offset from the current time, the adjustment is set with the *`offset`* member of the struct. The *`set_offset`* flag is also set, to indicate the vality of the *`offset`* member. Time will be gradually adjusted until this offset is reached. The time over which the offset is reached is derived from the value of `CYGNUM_CLOCK_COMMON_ADJTIME_PERIOD_SHIFT`. The offset may be positive or negative (represented by a positive or negative *`tv_sec`* field for the struct timespec).

Setting the offset will immediately cause any modules registered for time change notifications to be notified of the new adjustment, with an indication that an adjustment, rather than a step change occurred.

Setting the *`get_adjremaining`* flag will cause this function to fill in the *`adjremaining`* field with the total adjustment remaining to be enacted on the system clock. In other words, an adjustment was requested, but not fully complete because the adjustment period has not been reached, and the field is set with the adjustment remaining.

If no adjustment remains, the contents of *`adjremaining`* will be set to 0.

If both *`get_adjremaining`* and *`set_offset`* flags are set, then the *`adjremaining`* field is filled in with the adjustment remaining after the adjustment specified by the *`offset`* field has been applied, which will always simply be identical to the requested offset.

To allow for forward compatibility, a cyg_clock_time_adj_t must be initialized with the macro `CYG_CLOCK_INIT_ADJ_T(`*`adjt_p`*`)` where *`adjt_p`* is of type cyg_clock_time_adj_t *.

Example

```
{
  Cyg_ErrNo             err;
  cyg_clock_time_adj_t  adj;
```

```
struct timespec       timediff;

get_time_difference(&timediff);

CYG_CLOCK_INIT_ADJ_T( &adj );
adj.flags.set_offset = 1;
adj.offset = timediff;

err = cyg_clock_adjust_systime( &timediff );
if ( ENOERR != err )
{
  etc. …
```

Return value

This function returns a standard error code, as defined in `<errno.h>`, or ENOERR on success. Notably, ERANGE will be returned if the offset exceeds the limit configured with `CYGNUM_CLOCK_COMMON_ADJTIME_MAX_RANGE`.

Name

Time change notification — Registering and deregistering for notification of changes to system time

Synopsis

#include <cyg/clock/api.h>

`Cyg_ErrNo` **`cyg_clock_timechange_register`**`(`*`info`*`);`

`Cyg_ErrNo` **`cyg_clock_timechange_deregister`**`(`*`info`*`);`

Description

These functions are used to allow users of this package to register and deregister for notifications of changes to system time. This may help allow the user to know when to update any timers or alarms.

Parameters which affect the method of delivering notifications are passed in within the *`info`* function argument. Other fields in that same structure are then used to pass information about time updates back to the user when a time change event occurs, which happens as a consequence of calls to either `cyg_clock_set_systime()` or to `cyg_clock_adjust_systime()`.

There are two primary mechanisms for notification: the user may supply a callback function; or the user can supply a condition variable, which they may then wait on to be signalled.

The cyg_clock_timechange_info structure is defined by including `<cyg/clock/api.h>` and has the following contents relevant to the user:

```
/* Forward definition to avoid circular dependency */
struct cyg_clock_timechange_info_s;

typedef struct cyg_clock_timechange_info_s cyg_clock_timechange_info;

typedef void (cyg_clock_timechange_cb_fn_t)( cyg_clock_timechange_info *changeinfo );

struct cyg_clock_timechange_info_s {
    CYG_ADDRWORD                  userdata;
    cyg_drv_mutex_t               *mutex;
    cyg_drv_cond_t                *cv;
    cyg_clock_timechange_cb_fn_t  *cb;

    /* VALUES ABOVE ARE SET BY USER BEFORE REGISTRATION
     * VALUES BELOW ARE SET BY THE CLOCK PACKAGE ON TIME CHANGE EVENTS
     */

    cyg_bool                      adjtime;
    struct timespec               newtime;
    struct timespec               offset;
};
```

Other members of this structure exist, but are private to the common clock package's implementation and do not form part of the API. They must not be modified by the user.

The cyg_clock_timechange_info structure passed in must be persistent while the registration is in effect, as it will be used by the common clock package to maintain the registration. The address of the same structure object must be passed in on deregistration.

cyg_clock_timechange_info details

Here is a description of the purpose of each of the cyg_clock_timechange_info structure members:

`userdata`

This is user-supplied data, which the user is free to set to any value if it may help uniquely identify the registration.

This value must be set prior to registration.

`mutex`

If non-NULL, a mutex protecting this structure's contents. Once registered with the clock package, it must be locked before reading/writing the cyg_clock_timechange_info structure to avoid any chance of simultaneous access. It is not mandatory in case users can guarantee non-simultaneous access by some other means.

This value must be set prior to registration.

`cv`

If non-NULL, a condition variable which should be signalled when time is updated. It must be associated with the above mutex. It should not be used if setting a callback function.

This value must be set prior to registration.

`cb`

If non-NULL, a user-supplied callback function to be called on time changes. It should not be used if the *`cv`* condition variable has been set to be signalled.

This value must be set prior to registration.

`adjtime`

The value of this boolean field is set by the common clock package on time change events. It will be `true` if is this is a fine adjustment (from `cyg_clock_adjust_systime()`), or false if the time has been set with `cyg_clock_set_systime()`.

If reading this field, but before unlocking the mutex (if applicable) it must be reset to `true`. This is because the clock package will only ever set it from `true` to `false`, never from `false` to `true`. This is so that if multiple time change events occur before the user has processed any of the events, an indication that the time was "set" will override any indication of fine adjustment.

If the time update was due to a fine adjustment (*`adjtime`* is true) then the time change will not necessarily have yet been reflected in what can be read from the system clock - the effect on the system clock happens over a period of time as described earlier.

This field does not need to be initialized prior to registration.

`newtime`

The new time at the point the time update happened. Note that the relevance of this depends on the real-time properties of the program - if the system has been busy performing other operations, including consequences of notifying other users, it may be quite a long time in the past by the time the user can process the event.

`offset`

The offset (difference) from the previous time. If it is positive, the time moved forwards, if negative, the time moved backwards.

It is a mandatory part of the API contract that after reading this value, but before unlocking the mutex (if applicable) it must be reset to 0. This is required so that if multiple time changes occur before any of the events are processed by the API user, the effect on *`offset`* can be cumulative - the clock package can simply modify the existing offset, thus guaranteeing that when the user reads the offset, it will be the offset since it was last read by the user.

Using a callback function

Some special care is required if using the callback function method for notifications.

If a callback function is used, it must be brief, as further users of this package who have registered a callback will not be notified until the callback returns. For this reason, and to improve determinism, and to avoid delaying clock package operations, the condition variable approach should be preferred.

The callback function method is still available however as it is realized that sometimes there may be no alternative.

Users should not call back into any time-keeping functions (in this package or others) from a callback function, in order to avoid re-entrancy issues. An exception is for the time conversion functions.

Even with a callback function, it is recommended to still use a mutex lock to prevent the timechange info structure being updated while it is in the process of being read; and if such a mutex is provided with the 'mutex' member, it will be locked before the callback is called, and unlocked after.

Return value

These functions return a standard error code, as defined in `<errno.h>`, or ENOERR on success.

Name

cyg_clock_sysclock_handle() — Return a handle to the system clock

Synopsis

#include <cyg/kernel/kapi.h> #include <cyg/clock/api.h>

```
cyg_handle_t cyg_clock_sysclock_handle();
```

Description

This function returns a handle to the clock object associated with the hardware clock driving the system time. This clock handle is usable with the kernel C API functions such as `cyg_clock_to_counter()`, and thereby with other kernel functions which use kernel counters such as kernel alarms.

However to be clear, this clock may or may not be the same clock as used for the kernel real-time clock. Users must avoid operations which could interfere with system operation, such as setting the clock resolution or deleting the clock.

Note that this function may be implemented as a macro, and therefore taking the address of this function is not supported.

This function is only supplied when the tick conversion functionality is enabled.

Return value

This function returns a cyg_handle_t which can be used as a handle for kernel C API clock functions. No errors are reported.

Name

Time conversions — Converting between clock ticks and calendar time

Synopsis

#include <cyg/clock/api.h>

Cyg_ErrNo **cyg_clock_ticks_to_time**(*ticks*, *ts*);

Cyg_ErrNo **cyg_clock_time_to_ticks**(*ts*, *ticks*, *roundup*);

void **cyg_clock_ticks_to_reltime**(*ticks*, *ts*);

Cyg_ErrNo **cyg_clock_reltime_to_ticks**(*ts*, *ticks*, *roundup*);

Description

These functions allow conversions between the 'ticks' of the clock which is driving system time, and calendar time values. These are intended to be used in conjunction with the clock identified by the clock handle returned by `cyg_clock_sysclock_handle()`.

`cyg_clock_ticks_to_time()` returns what the calendar time (which is defined as relative to the Epoch 1970-01-01 00:00:00) will be when the system time clock reaches the supplied tick count. If a fine adjustment is in progress, it will be taken into account.

`cyg_clock_time_to_ticks()` returns what the system time clock's tick value will be when the supplied system time (which is defined as relative to the epoch 1970-01-01 00:00:00) is reached. If *roundup* is `true`, *ticks* will be rounded up to the next tick; if *roundup* is `false`, it will be rounded to the nearest tick. If a fine adjustment is in progress, it will be taken into account.

`cyg_clock_ticks_to_reltime()` returns the relative time interval (as a struct timespec) corresponding to the supplied number of ticks. Note this does not take into account any effect of fine clock adjustment.

`cyg_clock_reltime_to_ticks()` returns the number of ticks corresponding to the relative time interval specified in the struct timespec *ts*. If *roundup* is `true`, *ticks* will be rounded up to the next tick; if *roundup* is `false`, it will be rounded to the nearest tick. Note this does not take into account any effect of fine clock adjustment.

These functions are only provided if the configuration option `CYGFUN_CLOCK_COMMON_TICK_CONVERTERS` is enabled.

Return value

These functions return a standard error code, as defined in `<errno.h>`, or `ENOERR` on success. Notably `cyg_clock_reltime_to_ticks()` may return ERANGE for values which cannot be converted.

Part LX. Object Loader

Name

CYGPKG_OBJLOADER — eCos Support for Dynamic Module Loading

Synopsis

#include <cyg/objloader/objload.h>

void ***cyg_ldr_open***(*open_stream*, *data*);

void **cyg_ldr_close**(*handle*);

char ***cyg_ldr_error***();

void ***cyg_ldr_find_symbol***(*handle*, *symbol*);

Description

Note

The Object Loader package does not support all processor architectures at present.

The Object Loader package provides support for dynamically loading executable modules into an eCos system. Modules may be loaded into memory from a variety of sources, linked in to the running system and entry points invoked to execute the code of the module. When the module is no longer required, it may be unloaded and the memory reused for other purposes or other modules.

This system is modelled most closely on the Linux kernel module mechanism, rather than Windows DLLs or Unix shared objects. As a result, it has a number of restrictions:

- Only modules written in C are supported. The Object Loader does not currently provide support for invoking static constructors and destructors, C++ exceptions, RTTI and other parts of the C++ runtime system.
- Automatic symbol resolution only works for references from a module into the main executable. References between modules are not supported, and resolution of unresolved symbols in the main executable to module symbols is not supported.
- Loaded modules need to be built using the same, or similar, configuration to the main system.
- Loaded modules should be built with the same or compatible compiler flags as the main system. There is one important exception. Some architectures including MIPS and Nios II implement a global pointer register. Small global variables are placed in an area of memory up to 64K. The gp register points at this area of memory, allowing the variables to be accessed directly using a single instruction instead of the two or more instructions that would otherwise be required. This technique cannot be used for a dynamically loaded module. Hence the use of gp-relative addressing must be suppressed with a compiler flag, typically -G0.

Creating Loadable Modules

Modules can be just object files as generated by the compiler. In a Makefile including the $(INSTALL_DIR)/include/pkgconf/ecos.mak definitions file, the entry to build module.o might be:

```
module.o: module.c
        $(ECOS_COMMAND_PREFIX)gcc -c -I$(INSTALL_DIR)/include $(ECOS_GLOBAL_CFLAGS) -o $@ $<
        $(ECOS_COMMAND_PREFIX)strip -g $@
```

The compile line generates a .o file. The -I option allows includes to be fetched from the eCos installation. The command prefix and global flags are stored in the ecos.mak file by the eCos build process. If the compile flags include -g or some other debug option then to save memory and maybe load time it is useful to pass the finished module through **strip** to limit the file contents to just the loadable ELF sections.

It is possible to create a module out of several object files by using the linker's ability to perform a partial link:

```
module.o : file1.o file2.o file3.o
        $(ECOS_COMMAND_PREFIX)gcc $(subst --gc-sections,-r,$(ECOS_GLOBAL_LDFLAGS)) -L$(PREFIX)/lib \
            -Tmodule.ld -o $@ $^
        $(ECOS_COMMAND_PREFIX)strip -g $@
```

The `module.ld` linker script is defined by the Object Loader package and is copied out to the install lib directory. It should be used when combining multiple files, or when advanced features such as HAL tables are used in a single object file.

If the module makes use of float, double, long long and some long arithmetic operations, then it should be partially linked against `libgcc` before loading. This can be done with the following makefile fragments:

```
# Single source file module…
module.o: module.c
        $(ECOS_COMMAND_PREFIX)gcc -c -I$(INSTALL_DIR)/include $(ECOS_GLOBAL_CFLAGS) -o $@.tmp $<
        $(ECOS_COMMAND_PREFIX)gcc $(subst --gc-sections,-r,$(ECOS_GLOBAL_LDFLAGS)) \
            -L`dirname \`$(ECOS_COMMAND_PREFIX)gcc $(ECOS_GLOBAL_CFLAGS) \
            -print-libgcc-file-name\`` -L$(PREFIX)/lib -Tmodule.ld -o $@ $@.tmp -lgcc
        $(ECOS_COMMAND_PREFIX)strip -g $@

# Combine multiple object files…
module.o : file1.o file2.o file3.o
        $(ECOS_COMMAND_PREFIX)gcc $(subst --gc-sections,-r,$(ECOS_GLOBAL_LDFLAGS)) \
            -L`dirname \`$(ECOS_COMMAND_PREFIX)gcc $(ECOS_GLOBAL_CFLAGS) \
            -print-libgcc-file-name\`` -L$(PREFIX)/lib -Tmodule.ld -o $@ $^ -lgcc
        $(ECOS_COMMAND_PREFIX)strip -g $@
```

Target Specific Considerations

There are a number of special considerations for particuar target architectures:

- Modules compiled for Thumb may be loaded into targets compiled for either ARM32 or Thumb. Thumb builds of eCos that use the object loader should have the "-mlong-calls" compiler option set. ARM32 builds should have thumb interworking enabled if thumb modules are to be loaded (the object loader module does this automatically). Thumb modules should be compiled with "-mthumb -mthumb-interwork -mlong-calls" compiler options. However, some later ARM variants do not need the "-mthumb-interwork" option since this is implicit in the architecture. For such targets this option need not be given.

- Modules compiled for ARM, Thumb or Thumb 2 may require the "-mlong-calls" compiler option if the module to be loaded will occupy a different region of the address space to the rest of the program. The most frequent scenario causing this to arise is if the main program runs from FLASH memory, but with the module loaded into RAM. If in doubt, use the option as it is always safe, and the only downside is a small code size and runtime execution penalty on function calls.

- Modules compiled for the MIPS16 instruction set may be loaded into a MIPS target, so long as the processor supports the instruction set. To compile and link such a module, the "-mips16" compiler option must be substituted for "-mips32", along with "-fwritable-strings".

- Modules compiled for NIOS II processors must be compiled with the "-G0" compiler option. This ensures that loaded modules do not make assumptions about the accessibility of small initialised data (".sdata") or small zero-initialised data (".sbss") relative to the address it was loaded at.

Loading Modules

The function `cyg_ldr_open()` is used to load a module into memory. It takes two arguments. The first argument defines a module loader, while the second argument is a generic `data` item whose value depends on the loader. If the load is successful, then a non-NULL handle will be returned. A NULL pointer will be returned on failure.

If there is an error in the loading process, then the function `cyg_ldr_error()` will return a string describing the last error that occurred. Note that this is not thread-safe since there is only a single last error recorded for all load operations.

At present the following loaders are implemented:

CYG_LDR_FILESYSTEM

This loader uses FILEIO operations to read an ELF file from a named file in a filesystem. For example, to read a module from the file "/lib/modules/module.o":

```
mod_handle = cyg_ldr_open( CYG_LDR_FILESYSTEM,
                           (CYG_ADDRWORD)"/lib/modules/module.o");
```

This loader is included by default if the `CYGPKG_IO_FILEIO` package is included, although it can be omitted by disabling `CYGPKG_OBJLOADER_LOADER_FS`.

CYG_LDR_MEMORY

This loader uses memory access primitives to read an ELF file from any addressable memory such as ROM, FLASH or RAM. For example to read a module from the location `module_base`:

```
mod_handle = cyg_ldr_open( CYG_LDR_MEMORY,
                           (CYG_ADDRWORD)&module_base );
```

This loader is included by default, although it can be omitted by disabling `CYGPKG_OBJLOADER_LOADER_MEM`.

Loaders `CYG_LDR_FTP`, `CYG_LDR_TFTP`, `CYG_LDR_HTTP` and `CYG_LDR_FLASH` are defined, but not currently implemented.

Unloading Modules

A module may be unloaded by calling `cyg_ldr_close()`, passing it the handle returned from `cyg_ldr_open()`. This will cause the memory occupied by the loader to be released. Any pointers into the code or data of the module will be rendered invalid and should not be used.

Referencing Module Symbols

When a module is loaded, a symbol table listing all the external symbols that it defines is loaded with it. The function `cyg_ldr_find_symbol()` searches this table and returns a pointer to the location defined by a symbol. For example, to create a thread running from a function in a module:

```
cyg_thread_entry_t *thread_entry;

thread_entry = cyg_ldr_find_symbol( handle, "thread_entry");

cyg_thread_create(THREAD_PRIORITY,
                  thread_entry,
                  0,
                  "Module Thread",
                  (void *)thread_stack,
                  THREAD_STACK_SIZE,
                  &thread_handle,
                  &thread_object);
```

Both functions and variables may be accessed in this way.

There is no mechanism for resolving dangling references in the main eCos application, or other modules, to symbols in a newly loaded module. The main eCos application must have all references resolved at link time. However, it is possible to simulate the effect of dynamic resolution by using function pointers. For example define a global function pointer to an initial dummy function:

```
typedef int module_fn_t(int a, int b);

module_fn_t dummy_fn;

module_fn_t *module_fn = dummy_fn;
```

```
int dummy_fn( int a, int b )
{
    return -1;
}
```

When the module is loaded the function pointer can be pointed at the function within the module, and pointed back to the dummy function when it is unloaded:

```
void *mod_handle;

void load_module(void)
{
    mod_handle = cyg_ldr_open( CYG_LDR_FILESYSTEM, (CYG_ADDRWORD)"/lib/modules/module.o");

    module_fn = cyg_ldr_find_symbol( mod_handle, "module_fn");
}

void unload_module(void)
{
    cyg_ldr_close( mod_handle );

    module_fn = dummy_fn;
}
```

One could even implement a form of demand loading by combining `dummy_fn` and `load_module`:

```
int dummy_fn( int a, int b )
{
    mod_handle = cyg_ldr_open( CYG_LDR_FILESYSTEM, (CYG_ADDRWORD)"/lib/modules/module.o");

    module_fn = cyg_ldr_find_symbol( mod_handle, "module_fn");

    return module_fn( a, b );
}
```

Module Open and Close Functions

When a module is loaded the Object Loader will look for a symbol with the name "module_open" and if found will call it with the following prototype:

```
void module_open( void );
```

Similarly, when `cyg_ldr_close()` is called, the Object Loader will look for a symbol named "module_close" and call it, with the same prototype.

External References

When a module is loaded, the Object Loader package performs any relocations it requires and resolves any unresolved symbol references it contains. The load only succeeds if all of these can be completed. For these symbols to be resolved it is necessary for the main eCos executable to contain a symbol table defining the symbols to be resolved. Normal eCos executables do not contain such a symbol table since it would occupy an unreasonably large amount of memory. There is also no mechanism to persuade the linker to include a loadable symbol table into the executable. Hence it is necessary for the application to explicitly define a symbol table that maps symbol names to addresses.

The loader provides an empty table; the user can then define additional entries required by any loadable modules. In order to keep the size of the table to a minimum, the user can selectively include only those functions that are expected to be used by the loader to resolve all references. There are several macros defined in `objload.h` for defining table entries:

`CYG_LDR_TABLE_FUN( name )`

This macro defines a table entry for a function with the given `name`.

`CYG_LDR_TABLE_VAR( name )`

This macro defines a table entry for a data variable with the given `name`.

`CYG_LDR_TABLE_ENTRY( entry_name, symbol_name, address )`

This is a low level macro that allow all aspects of a symbol table entry to be controlled. The *`entry_name`* argument defines the table entry object name (a C language requirement since anonymous objects are not permitted). The *`symbol_name`* argument is a string giving the symbol that will be matched by the loader. The *`address`* argument gives the memory location to which this symbol will resolve.

The `objload.h` file contains a number of macros that collect together groups of functions as a convenient way to include blocks of Kernel, C Library and FILEIO functionality. These include the following:

```
CYG_LDR_TABLE_KAPI_ALARM()
CYG_LDR_TABLE_KAPI_CLOCK()
CYG_LDR_TABLE_KAPI_COND()
CYG_LDR_TABLE_KAPI_COUNTER()
CYG_LDR_TABLE_KAPI_EXCEPTIONS()
CYG_LDR_TABLE_KAPI_FLAG()
CYG_LDR_TABLE_KAPI_INTERRUPTS()
CYG_LDR_TABLE_KAPI_MBOX()
CYG_LDR_TABLE_KAPI_MEMPOOL_FIX()
CYG_LDR_TABLE_KAPI_MEMPOOL_VAR()
CYG_LDR_TABLE_KAPI_MUTEX()
CYG_LDR_TABLE_KAPI_SCHEDULER()
CYG_LDR_TABLE_KAPI_SEMAPHORE()
CYG_LDR_TABLE_KAPI_THREAD()
CYG_LDR_TABLE_STRING()
CYG_LDR_TABLE_STDIO()
CYG_LDR_TABLE_INFRA_DIAG()
CYG_LDR_TABLE_FILEIO()
CYG_LDR_TABLE_NET()
```

Name

CYGPKG_OBJLOADER — Extending the Object Loader

Description

The Object Loader package has a number of features that allow it to be extended. To support a new CPU architecture a new relocator needs to be written. If ELF files are to be read from a source that differs from those currently supported, then a new loader needs to be written. Finally, the mechanism by which the loader allocates the memory used to store loaded sections can be redirected by the application.

Adding New Relocators

When the loader loads a new module some locations in it must be adjusted to account for the address at which is it loaded. References to external symbols must also be installed. The location and nature of these modifications are described by one or more sections in the ELF file which contain a sequence of relocation records. The exact meaning of the relocations that these records define is architecture specific and is usually described as part of the ABI for that CPU type.

To define a new relocator for a CPU, it is necessary to add an extra definition to the `objloader.cdl` file, and add a header and source file to the package. To support the XYZ CPU the following must be added to the `CYGPKG_OBJLOADER_ARCHITECTURE` component:

```
cdl_option CYGBLD_OBJLOADER_ARCHITECTURE_XYZ {
  display       "Support loading on XYZ processors"
  calculated    CYGPKG_HAL_XYZ
  implements    CYGINT_OBJLOADER_RELOCATOR
  define_proc {
     puts $::cdl_header "#include <cyg/objloader/relocate_xyz.h>"
  }
  compile relocate_xyz.c
}
```

The `relocate_xyz.h` file needs to define some macros to customize the loader:

`ELF_ARCH_MACHINE_TYPE`

This defines the value that the *e_machine* machine type field of the ELF header. If this does not match, the module load will fail.

`ELF_ARCH_ENDIANNESS`

This defines the value that the `EI_DATA` byte of the *e_ident* field of the ELF header. It should be either `ELFDATA2LSB` or `ELFDATA2MSB`. If this does not match, the module load will fail. Architectures that are bi-endian need to test either a compiler or a HAL definition to select the correct endianness for the current build.

`CYG_LDR_MAKE_LOCAL_ADDRESS( addr, sym )`

This macro is used to combine the section address of a symbol with information from its symbol table entry. The *addr* argument is the base address of the section in which the symbol is defined. The *sym* is the symbol table entry; this is not a pointer, so fields should be accessed using the "." operator, not the "->" operator. The return value should be of type void *. This is an optional macro, if it is not defined here then a default definition will be used which simply adds the *st_value* field of the symbol table entry to the address.

In addition to these, it may also contain definitions that are useful to the relocator. Typically the relocation record types and any support macros may be defined here.

The `relocate_xyz.c` file contains two functions:

`void cyg_ldr_flush_cache(void)`

This function is called to perform any cache flushing needed. The loader modifies code in memory that will subsequently be executed. It does this using data accesses, so it is essential that these updates are flushed from the data cache, and that stale entries are flushed from the instruction cache. This function must call appropriate HAL cache operations to ensure that this is done.

`cyg_int32 cyg_ldr_relocate(cyg_int32 rel_type, cyg_uint32 flags, cyg_uint32 mem, cyg_int32 sym_value)`

The loader will call this function for each relocation record in each relocation section found in the module.

The *rel_type* argument defines the relocation record type and will be one of the relocation types defined for the architecture. Most architecture ABIs define a large number of relocations, not all of which will be relevant to the use that eCos makes of the object file format. In general only a small subset of relocation types need to be handled which can usually be determined by inspecting the object files generated by compiling eCos.

The *flags* argument contains flags that provide additional information about the relocation record. At present only one flag is defined: `CYG_LDR_FLAG_RELA` which is set when the relocation is from a RELA record, otherwise it comes from a REL record.

The *mem* argument contains the address of the location in memory to be relocated. It is constructed from the base address of the segment targeted by the relocation section, plus the *r_offset* field from the relocation record.

The *sym_value* argument contains the address of any symbol associated with the relocation record. If it was a RELA record, then the contents of the *r_addend* field will have been added.

Adding new Loaders

The Object Loader package needs to fetch a module from some source to load it into memory. This is the job of a loader. A loader consists of an open function plus read, seek and close functions.

The loader open function is supplied as the first parameter to `cyg_ldr_open()`. It is called with the second argument as a parameter. On success it returns a pointer to a CYG_LDR_ELF_OBJECT object. On failure it returns NULL.

The open function has a number of duties, best described by an annotated example for the ABC loader:

```
__externC CYG_LDR_ELF_OBJECT *cyg_ldr_open_abc(CYG_ADDRWORD arg)
{
    // Allocate a CYG_LDR_ELF_OBJECT
    CYG_LDR_ELF_OBJECT * obj = (CYG_LDR_ELF_OBJECT *)cyg_ldr_malloc(sizeof(CYG_LDR_ELF_OBJECT));

    // Allocate a private data descriptor. Depending on the nature of
    // the loader this may not be necessary.
    struct abc_desc *desc = cyg_ldr_malloc(sizeof(struct abc_desc));

    // Check that the memory allocations worked
    if( obj == NULL || desc == NULL )
    {
        if( obj != NULL ) free(obj);
        if( desc != NULL ) free(desc);
        cyg_ldr_last_error = "ERROR IN MALLOC";
        return NULL;
    }

    // Perform any operations to enable access to the ELF file and
    // fill in the descriptor. If this fails then free both descriptor
    // and ELF object, set cyg_ldr_last_error and return NULL.

    // Clear the CYG_LDR_ELF_OBJECT
    memset( obj, 0, sizeof(CYG_LDR_ELF_OBJECT));

    // Install private data pointer
    obj->ptr    = (CYG_ADDRWORD)desc;

    // Install pointers to read, seek and close functions
    obj->read   = cyg_ldr_abc_read;
    obj->seek   = cyg_ldr_abc_seek;
    obj->close  = cyg_ldr_abc_close;

    // Return completed object
    return obj;
}
```

The read function will be called via the pointer in the ELF object whenever the Object Loader needs to read data from the file. It has the following definition:

```
static size_t cyg_ldr_abc_read(struct CYG_LDR_ELF_OBJECT* obj, size_t size, void* buf)
```

The *obj* argument is the ELF object returned from the open function. The *size* argument gives the number of bytes to be read and *buf* points to a location to store them. The function returns the number of bytes read.

The seek function will be called via the pointer in the ELF object whenever the Object Loader needs to reposition the point in the file at which the next read will occur. It has the following definition:

```
static cyg_int32 cyg_ldr_abc_seek(struct CYG_LDR_ELF_OBJECT* obj, cyg_uint32 offset)
```

The *obj* argument is the ELF object returned from the open function. The *offset* argument gives the number of bytes from the start of the file to which the read point should be moved. The function returns the new read offset. Some sources may not be able to reposition the read pointer backwards, and may only be capable of advancing it. If the reposition fails then this function should return -1.

The close function will be called via the pointer in the ELF object when the Object Loader has finished with the file. It has the following definition:

```
static cyg_int32 cyg_ldr_abc_close(struct CYG_LDR_ELF_OBJECT* obj)
```

The *obj* argument is the ELF object returned from the open function. This function should close down access to the file, free the private data descriptor if necessary and set the `obj->ptr` field to zero. It should not free the ELF object itself, the Object Loader will do this itself later. If the close succeeds then this function should return zero, and -1 if it fails.

Redirecting Memory Allocation

All memory allocation in the Object Loader is made via the `cyg_ldr_malloc()` function and it is freed via the `cyg_ldr_free()` function. These have the following prototypes:

```
__externC void *cyg_ldr_malloc(size_t) CYGBLD_ATTRIB_WEAK;

__externC void cyg_ldr_free(void *) CYGBLD_ATTRIB_WEAK;
```

These functions by default simply call the standard `malloc()` and `free()` heap functions. However, they are defined with the `weak` linker attribute. This means that the application can redefine these functions to provide an alternative allocation and free mechanism if, for example, the standard heap support has been omitted.

Part LXI. CPU load measurements

The cpuload package provides a way to estimate the cpuload. It gives an estimated percentage load for the last 100 milliseconds, 1 second and 10 seconds.

Table of Contents

Chapter 204. CPU Load Measurements

CPU Load API

The package allows the CPU load to be estimated. The measurement code must first be calibrated to the target it is running on. Once this has been performed the measurement process can be started. This is a continuous process, so always providing the most up to data measurements. The process can be stopped at any time if required. Once the process is active, the results can be retrieved.

Note that if the target/processor performs any power saving actions, such as reducing the clock speed, or halting until the next interrupt etc, these will interfere with the CPU load measurement. Under these conditions the measurement results are undefined. The synthetic target is one such system. See the implementation details at the foot of this page for further information.

SMP systems are supported and are described later.

The API for load measuring functions can be found in the file `cyg/cpuload/cpuload.h`.

cyg_cpuload_calibrate

This function is used to calibrate the cpu load measurement code. It makes a measurement to determine the CPU properties while idle.

```
void cyg_cpuload_calibrate(cyg_uint32  *calibration);
```

The function returns the calibration value at the location pointed to by *`calibration`*.

This function is quite unusual. For it to work correctly a few conditions must be met. The function makes use of the two highest thread priorities. No other threads must be using these priorities while the function is being used. The kernel scheduler must be started and not disabled. The function takes 100ms to complete during which time no other threads will be run.

cyg_cpuload_create

This function starts the CPU load measurments.

```
void cyg_cpuload_create(cyg_cpuload_t *cpuload,
                        cyg_uint32 calibrate,
                        cyg_handle_t *handle);
```

The measurement process is started and a handle to it is returned in *`*handle`*. This handle is used to access the results and the stop the measurement process.

cyg_cpuload_delete

This function stops the measurement process.

```
void cyg_cpuload_delete(cyg_handle_t handle);
```

`handle` should be the value returned by the create function.

cyg_cpuload_get

This function returns the latest measurements.

```
void cyg_cpuload_get(cyg_handle_t handle,
         cyg_uint32 *average_point1s,
         cyg_uint32 *average_1s,
         cyg_uint32 *average_10s);
```

`handle` should be the value returned by the create function. The load measurements for the last 100ms, 1s and 10s are returned in *`*average_point1s`*,*`*average_1s`* and *`*average_10s`* respectively.

Implementation details

This section gives a few details of how the measurements are made. This should help to understand what the results mean.

When there are no other threads runnable, eCos will execute the idle thread. This thread is always runnable and uses the lowest thread priority. The idle thread does little. It is an endless loop which increments the variable, `idle_thread_loops` and executes the macro `HAL_IDLE_THREAD_ACTION`. The cpu load measurement code makes use of the variable. It periodically examines the value of the variable and sees how much it has changed. The idler the system, the more it will have incremented. From this it is simple to determine the load of the system.

The function `cyg_cpuload_calibrate` executes the idle thread for 100ms to determine how much `idle_thread_loops` is incremented on a system idle for 100ms. `cyg_cpuload_create` starts an alarm which every 100ms calls an alarm function. This function looks at the difference in `idle_thread_loops` since the last invocation of the alarm function and so calculated how idle or busy the system has been. The structure `cyg_cpuload` is updated during the alarm functions with the new results. The 100ms result is simply the result from the last measurement period. A simple filter is used to average the load over a period of time, namely 1s and 10s. Due to rounding errors, the 1s and 10s value will probably never reach 100% on a fully loaded system, but 99% is often seen.

As stated above, clever power management code will interfere with these measurements. The basic assumption is that the idle thread will be executed un-hindered and under the same conditions as when the calibration function was executed. If the CPU clock rate is reduced, the idle thread counter will be incremented less and so the CPU load measurements will give values too high. If the CPU is halted entirely, 100% cpu load will be measured.

SMP Support

This section described how CPU load is measured on SMP systems. SMP support has been introduced without changing or extending the existing API. To achieve this, both `cyg_cpuload_calibrate()` and `cyg_cpuload_create()` query the CPU that they are running on and bind the cyg_cpuload_t object to that CPU. The remaining API calls, `cyg_cpuload_delete()` and `cyg_cpuload_get()`, can be called from any CPU.

To gather load information for each CPU in the system, a separate cyg_cpuload_t object must be allocated, calibrated and created for each CPU. The following example shows how this might be done during application initialization:

```

static cyg_uint32 calibration[HAL_SMP_CPU_COUNT];
static cyg_cpuload_t cpuload[HAL_SMP_CPU_COUNT];
static cyg_handle_t handle[HAL_SMP_CPU_COUNT];

static void create_cpuload( void )
{
    HAL_SMP_CPU_TYPE cpu;
    HAL_SMP_CPU_MASK old_affinity;

    // Get current thread affinity.
    cyg_thread_get_affinity( cyg_thread_self(), &old_affinity );

    for( cpu = 0; cpu < HAL_SMP_CPU_COUNT; cpu++ )
    {
        // Set this thread's affinity to single CPU.
        cyg_thread_set_affinity( cyg_thread_self(), 1<<cpu );

        // Calibrate and create cpuload object.
        cyg_cpuload_calibrate(&calibration[cpu]);
        cyg_cpuload_create(&cpuload[cpu],calibration[cpu],&handle[cpu]);
    }

    // Restore thread's original affinity.
    cyg_thread_set_affinity( cyg_thread_self(), old_affinity );
}
```

Following this, the following call, from any CPU, will return the load for the given CPU:

```
cyg_cpuload_get(handle[cpu],&average_point1s,&average_1s,&average_10s);
```

Part LXII. gprof Profiling Support

Name

`CYGPKG_PROFILE_GPROF` — eCos Support for the gprof profiling tool

Description

The GNU gprof tool provides profiling support. After a test run it can be used to find where the application spent most of its time, and that information can then be used to guide optimization effort. Typical gprof output will look something like this:

```
Each sample counts as 0.003003 seconds.
  %   cumulative   self              self     total
 time   seconds   seconds    calls  us/call  us/call  name
 14.15       1.45     1.45   120000    12.05    12.05  Proc_7
 11.55       2.63     1.18   120000     9.84     9.84  Func_1
  8.04       3.45     0.82                             main
  7.60       4.22     0.78    40000    19.41    86.75  Proc_1
  6.89       4.93     0.70    40000    17.60    28.99  Proc_6
  6.77       5.62     0.69    40000    17.31    27.14  Func_2
  6.62       6.30     0.68    40000    16.92    16.92  Proc_8
  5.94       6.90     0.61                             strcmp
  5.58       7.47     0.57    40000    14.26    26.31  Proc_3
  5.01       7.99     0.51    40000    12.79    12.79  Proc_4
  4.46       8.44     0.46    40000    11.39    11.39  Func_3
  3.68       8.82     0.38    40000     9.40     9.40  Proc_5
  3.32       9.16     0.34    40000     8.48     8.48  Proc_2
…
```

This output is known as the flat profile. The data is obtained by having a hardware timer generate regular interrupts. The interrupt handler stores the program counter of the interrupted code. gprof performs a statistical analysis of the resulting data and works out where the time was spent.

gprof can also provide information about the call graph, for example:

```
index % time    self  children    called     name
…
                0.78    2.69   40000/40000       main [1]
[2]     34.0    0.78    2.69   40000         Proc_1 [2]
                0.70    0.46   40000/40000       Proc_6 [5]
                0.57    0.48   40000/40000       Proc_3 [7]
                0.48    0.00   40000/120000      Proc_7 [3]
```

This shows that function `Proc_1` was called only from `main`, and `Proc_1` in turn called three other functions. Callgraph information is obtained only if the application code is compiled with the `-pg` option. This causes the compiler to insert extra code into each compiled function, specifically a call to `mcount`, and the implementation of `mcount` stores away the data for subsequent processing by gprof.

Caution

There are a number of reasons why the output will not be 100% accurate. Collecting the flat profile typically involves timer interrupts so any code that runs with interrupts disabled will not appear. The current host-side gprof implementation maps program counter values onto symbols using a bin mechanism. When a bin spans the end of one function and the start of the next gprof may report the wrong function. This is especially likely on architectures with single-byte instructions such as an x86. When examining gprof output it may prove useful to look at a linker map or program disassembly.

The eCos profiling package requires some additional support from the HAL packages, and this may not be available on all platforms:

1. There must be an implementation of the profiling timer. Typically this is provided by the variant or platform HAL using one of the hardware timers. If there is no implementation then the configuration tools will report an unresolved conflict related to `CYGINT_PROFILE_HAL_TIMER` and profiling is not possible. Some implementations overload the system clock, which means that profiling is only possible in configurations containing the eCos kernel and `CYGVAR_KERNEL_COUNTERS_CLOCK`.

2. There should be a hardware-specific implementation of `mcount`, which in turn will call the generic functionality provided by this package. It is still possible to do some profiling without `mcount` but the resulting data will be less useful. To check whether or not `mcount` is available, look at the current value of the CDL interface `CYGINT_PROFILE_HAL_MCOUNT` in the graphical configuration tool or in an `ecos.ecc` save file.

3. The current profiling support is only suitable for single-core systems, it is not SMP-aware. Since profiling is driven by interrupts from a timer, samples can only be collected from the CPU to which that interrupt is bound. There is no mechanism for sampling the state of the other CPUs. The array of sample counters is not updated atomically, so updates to the same, or close, entries may result in readings being lost. For these reasons, targets that might support profiling in a single-core configuration will disable it in a multi-core configuration.

This document only describes the eCos profiling support. Full details of gprof functionality and output formats can be found in the gprof documentation. However it should be noted that that documentation describes some functionality which cannot be implemented using current versions of the gcc compiler: the section on annotated source listings describes basic block counting which is not relevant. For basic block counting, the GNU gcov tool should be used instead.

Building Applications for Profiling

To perform application profiling the gprof package `CYGPKG_PROFILE_GPROF` must first be added to the eCos configuration. On the command line this can be achieved using:

```
$ ecosconfig add profile_gprof
$ ecosconfig tree
$ make
```

Alternatively the same steps can be performed using the graphical configuration tool by adding the package "Application profile support" with the `Build->Packages` menu item.

If the HAL packages implement `mcount` for the target platform then usually application code should be compiled with `-pg`. Optionally eCos itself can also be compiled with this option by modifying the configuration option `CYGBLD_GLOBAL_CFLAGS`. Compiling with `-pg` is optional but gives more complete profiling data.

Note

The profiling package itself must not be compiled with `-pg` because that could lead to infinite recursion when doing `mcount` processing. This is handled automatically by the package's CDL.

Profiling does not happen automatically. Instead it must be started explicitly by the application, using a call to `profile_on`. A typical example would be:

```
#include <pkgconf/system.h>
#ifdef CYGPKG_PROFILE_GPROF
# include <cyg/profile/profile.h>
#endif
…
int
main(int argc, char** argv)
{
    …
#ifdef CYGPKG_PROFILE_GPROF
    {
        extern char _stext[], _etext[];
        profile_on(_stext, _etext, 16, 3500);
    }
#endif
    …
}
```

The `profile_on` takes four arguments:

`start address`
`end address`

These specify the range of addresses that will be profiled. Usually profiling should cover the entire application. On most targets the linker script will export symbols `_stext` and `_etext` corresponding to the beginning and end of code, so these can be used as the addresses. It is possible to perform profiling on a subset of the code if that code is located contiguously in memory.

`bucket size`

`profile_on` divides the range of addresses into a number of buckets of this size. It then allocates a single array of 16-bit counters with one entry for each bucket. When the profiling timer interrupts the interrupt handler will examine the program counter of the interrupted code and, assuming it is within the range of valid addresses, find the containing bucket and increment the appropriate counter.

The size of the array counters is determined by the range of addresses being profiled and by the bucket size. For a bucket size of 16, one counter is needed for every 16 bytes of code. For an application with say 512K of code that means dynamically allocating a 64K array. If the target hardware is low on memory then this may be unacceptable, and the requirements can be reduced by increasing the bucket size. However this will affect the accuracy of the results and gprof is more likely to report the wrong function. It also increases the risk of a counter overflow.

For the sake of run-time efficiency the bucket size must be a power of 2, and it will be adjusted if necessary.

`time interval`

The final argument specifies the interval between profile timer interrupts, in units of microseconds. Increasing the interrupt frequency gives more accurate profiling results, but at the cost of higher run-time overheads and a greater risk of a counter overflow. The HAL package may modify this interval because of hardware restrictions, and the generated profile data will contain the actual interval that was used. Usually it is a good idea to use an interval that is not a simple fraction of the system clock, typically 10000 microseconds. Otherwise there is a risk that the profiling timer will disproportionally sample code that runs only in response to the system clock.

`profile_on` can be invoked multiple times, and on subsequent invocations, it will delete profiling data and allocate a fresh profiling range.

Profiling can be turned off using the function `profile_off`:

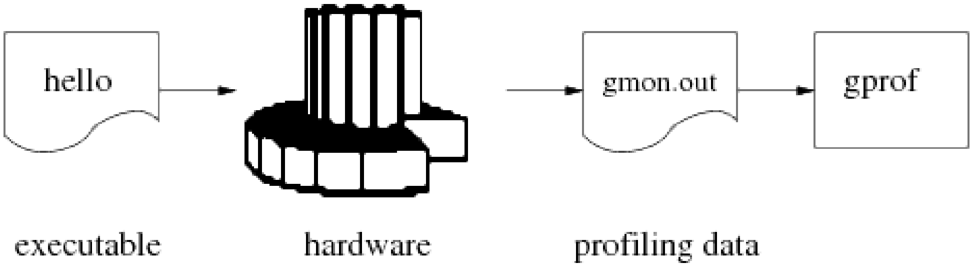
```
void profile_off(void);
```

This will also reset any existing profile data.

If the eCos configuration includes a TCP/IP stack and if a tftp daemon will be used to extract the data from the target then the call to `profile_on` should happen after the network is up. `profile_on` will attempt to start a tftp daemon thread, and this will fail if networking has not yet been enabled.

```
int
main(int argc, char** argv)
{
    …
    init_all_network_interfaces();
    …
#ifdef CYGPKG_PROFILE_GPROF
    {
        extern char _stext[], _etext[];
        profile_on(_stext, _etext, 16, 3000);
    }
#endif
    …
}
```

The application can then be linked and run as usual.



When gprof is used for native development rather than for embedded targets the profiling data will automatically be written out to a file `gmon.out` when the program exits. This is not possible on an embedded target because the code has no direct access to the host's file system. Instead the `gmon.out` file has to be extracted from the target as described below. gprof can then be invoked normally:

```
$ gprof dhrystone
Flat profile:

Each sample counts as 0.003003 seconds.
  %   cumulative   self              self     total
 time   seconds   seconds    calls  us/call  us/call  name
 14.15      1.45     1.45   120000    12.05    12.05  Proc_7
 11.55      2.63     1.18   120000     9.84     9.84  Func_1
  8.04      3.45     0.82                             main
…
```

If `gmon.out` does not contain call graph data, either because `mcount` is not supported or because this functionality was explicitly disabled, then the `-no-graph` must be used.

```
$ gprof --no-graph dhrystone
Flat profile:

Each sample counts as 0.003003 seconds.
  %   cumulative   self              self     total
 time   seconds   seconds    calls  us/call  us/call  name
 14.15      1.45     1.45                             Proc_7
 11.55      2.63     1.18                             Func_1
  8.04      3.45     0.82                             main
…
```

Extracting the Data

By default gprof expects to find the profiling data in a file `gmon.out` in the current directory. This package provides two ways of extracting data: a gdb macro or tftp transfers. Using tftp is faster but requires a TCP/IP stack on the target. It also consumes some additional target-side resources, including an extra tftp daemon thread and its stack. The gdb macro can be used even when the eCos configuration does not include a TCP/IP stack. However it is much slower, typically taking tens of seconds to retrieve all the data for a non-trivial application.

The gdb macro is called **gprof_dump**, and can be found in the file `gprof.gdb` in the `host` subdirectory of this package, and in the `ECOS_INSTALL_DIR/etc` subdirectory. A typical way of using this macro is:

```
(gdb) source <ECOS_INSTALL_DIR>;/etc/gprof.gdb
(gdb) gprof_dump
```

This macro can be used any time after the call to `profile_on`. It will store the profiling data accumulated so far to the file `gmon.out` in the current directory, and then reset all counts. gprof uses only a 16 bit counter for every bucket of code. These counters can easily saturate if the profiling run goes on for a long time, or if the application code spends nearly all its time in just a few tight inner loops. The counters will not actually wrap around back to zero, instead they will stick at 0xFFFF, but this will still affect the accuracy of the gprof output. Hence it is desirable to reset the counters once the profiling data has been extracted.

The file `gprof.gdb` contains two other macros which may prove useful. **gprof_fetch** extracts the profiling data and generates the file `gmon.out`, but does not reset the counters. **gprof_reset** only resets the counters, without extracting the data or overwriting `gmon.out`.

If the configuration includes a TCP/IP stack then the profiling data can be extracted using tftp instead. There are two relevant configuration options. `CYGPKG_PROFILE_TFTP` controls whether or not tftp is supported. It is enabled by default if the configuration includes a TCP/IP stack, but can be disabled to save target-side resources. `CYGNUM_PROFILE_TFTP_PORT` controls the UDP port which will be used. This port cannot be shared with other tftp daemons. If neither application code nor any other package (for example the gcov test coverage package) provides a tftp service then the default port can be used. Otherwise it will be necessary to assign unique ports to each daemon.

If enabled the tftp daemon will be started automatically by `profile_on`. This should only happen once the network is up and running, typically after the call to `init_all_network_interfaces`.

The data can then be retrieved using a standard tftp client. There are a number of such clients available with very different interfaces, but a typical session might look something like this:

```
$ tftp
tftp> connect 10.1.1.134
tftp> binary
tftp> get gmon.out
Received 64712 bytes in 0.9 seconds
tftp> quit
```

The address `10.1.1.134` should be replaced with the target's IP address. Extracting the profiling data by tftp will automatically reset the counters.

Configuration Options

This package contains a number of configuration options. Two of these, `CYGPKG_PROFILE_TFTP` and `CYGNUM_PROFILE_TFTP_PORT`, related to support for tftp transfers and have already been described.

Support for collecting the call graph data via `mcount` is optional and can be controlled via `CYGPKG_PROFILE_CALLGRAPH`. This option will only be active if the HAL provides the underlying `mcount` support and implements `CYGINT_PROFILE_HAL_MCOUNT`. The call graph data allows gprof to produce more useful output, but at the cost of extra run-time and memory overheads. If this option is disabled then the `-pg` compiler flag should not be used.

If `CYGPKG_PROFILE_CALLGRAPH` is enabled then there are two further options which can be used to control memory requirements. Collecting the data requires two blocks of memory, a simple hash table and an array of arc records. The `mcount` code uses the program counter address to index into the hash table, giving the first element of a singly linked list. The array of arc records contains the various linked lists for each hash slot. The required number of arc records depends on the number of function calls in the application. For example if a function `Proc_7` is called from three different places in the application then three arc records will be needed.

`CYGNUM_PROFILE_CALLGRAPH_HASH_SHIFT` controls the size of the hash table. The default value of 8 means that the program counter is shifted right by eight places to give a hash table index. Hence each hash table slot corresponds to 256 bytes of code, and for an application with say 512K of code `profile_on` will dynamically allocate an 8K hash table. Increasing the shift size reduces the memory requirement, but means that each hash table slot will correspond to more code and hence `mcount` will need to traverse a longer linked list of arc records.

`CYGNUM_PROFILE_CALLGRAPH_ARC_PERCENTAGE` controls how much memory `profile_on` will allocate for the arc records. This uses a simple heuristic, a percentage of the overall code size. By default the amount of arc record space allocated will be 5% of the code size, so for a 512K executable that requires approximately 26K. This default should suffice for most applications. In exceptional cases it may be insufficient and a diagnostic will be generated when the profiling data is extracted.

Implementing the HAL Support

The profiling package requires HAL support: A function `hal_enable_profile_timer` and an implementation of `mcount`. The profile timer is required. Typically it will be implemented by the variant or platform HAL using a spare hardware timer, and that HAL package will also implement the CDL interface `CYGINT_PROFILE_HAL_TIMER`. Support for `mcount` is optional but very desirable. Typically it will be implemented by the architectural HAL, which will also implement the CDL interface `CYGINT_PROFILE_HAL_MCOUNT`.

```
#include <pkgconf/system.h>
#ifdef CYGPKG_PROFILE_GPROF
# include <cyg/profile/profile.h>
#endif

int
hal_enable_profile_timer(int resolution)
{
    …
    return actual_resolution;
}
```

This function takes a single argument, a time interval in microseconds. It should arrange for a timer interrupt to go off after every interval. The timer VSR or ISR should then determine the program counter of the interrupted code and register this with the profiling package:

```
    …
    __profile_hit(interrupted_pc);
    …
```

The exact details of how this is achieved, especially obtaining the interrupted PC, are left to the HAL implementor. The HAL is allowed to modify the requested time interval because of hardware constraints, and should return the interval that is actually used.

`mcount` can be more difficult. The calls to `mcount` are generated internally by the compiler and the details depend on the target architecture. In fact `mcount` may not use the standard calling conventions at all. Typically implementing `mcount` requires looking at the code that is actually generated, and possibly at the sources of the appropriate compiler back end.

The HAL `mcount` function should call into the profiling package using standard calling conventions:

```
    …
    __profile_mcount((CYG_ADDRWORD) caller_pc, (CYG_ADDRWORD) callee_pc);
    …
```

If `mcount` was invoked because `main` called `Proc_1` then the caller pc should be an address inside `main`, typically corresponding to the return location, and the callee pc should be an address inside `Proc_1`, usually near the start of the function.

For some targets the compiler does additional work, for example automatically allocating a per-function word of memory to eliminate the need for the hash table. This is too target-specific and hence cannot easily be used by the generic profiling package.

Part LXIII. gcov Test Coverage Support

Name

CYGPKG_GCOV — eCos Support for the gcov test coverage tool

Description

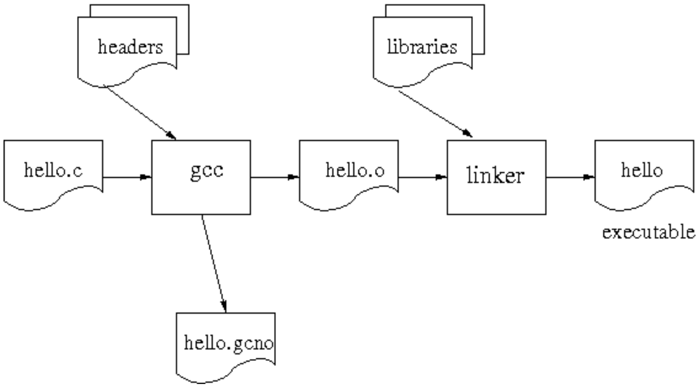
The GNU gcov tool provides test coverage support. After a test run it can be used to find code that was never actually executed. The testing conditions can then be adjusted for another test run to ensure that all the code really has been tested. The tool can also be used to find out how often each line of code was executed. That information can help application developers to determine where cpu time is being spent, and optimization effort can be focussed on critical parts of the code.

A typical fragment of gcov output looks something like this:

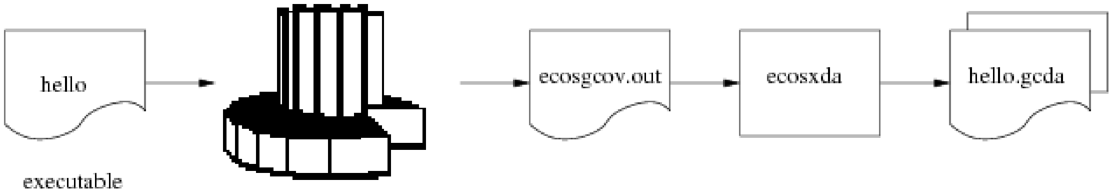
```
       80002:   60:  for (Run_Index = 1; Run_Index <= Number_Of_Runs; ++Run_Index)
       -: 61:  {
       -: 62:
       80000:   63:    Proc_5();
       80000:   64:    while (Int_1_Loc < Int_2_Loc)  /* loop body executed once */
       -: 65:    {
       80000:   66:      Int_3_Loc = 5 * Int_1_Loc - Int_2_Loc;
       80000:   67:      Proc_7 (Int_1_Loc, Int_2_Loc, &Int_3_Loc);
       80000:   68:      Int_1_Loc += 1;
       -: 69:    } /* while */
      240000:   70:    for (Ch_Index = 'A'; Ch_Index <= Ch_2_Glob; ++Ch_Index)
       -:   71:                          /* loop body executed twice */
       -: 72:    {
      160000:   73:      if (Enum_Loc == Func_1 (Ch_Index, 'C'))
       -: 74:       /* then, not executed */
       -: 75:        {
      ######:   76:        Proc_6 (Ident_1, &Enum_Loc);
      ######:   77:        strcpy (Str_2_Loc, "DHRYSTONE PROGRAM, 3'RD STRING");
      ######:   78:        Int_2_Loc = Run_Index;
      ######:   79:        Int_Glob = Run_Index;
       -: 80:        }
       -: 81:    }
           -:   82:    …
           -:   83:  }
```

Each line show the execution count and line number. An execution count of `-:` means that there is no executable code at that line. In this example the main loop is executed 80000 times. The body of the inner `for` loop is executed more often, but the `if` condition never triggers so four lines of code have not been tested.

The gcov tool works in conjunction with the gcc compiler. Application code should be built with two additional compiler flags `-fprofile-arcs` and `-ftest-coverage`. The first option causes the compiler to generate additional code which counts the number of times each basic block is executed. The second option results in additional files with `.gcno` suffixes which allow gcov to map these basic blocks onto lines of source code. Older versions of the compiler used to generate files with `.bb` and `.bbg` suffixes instead.



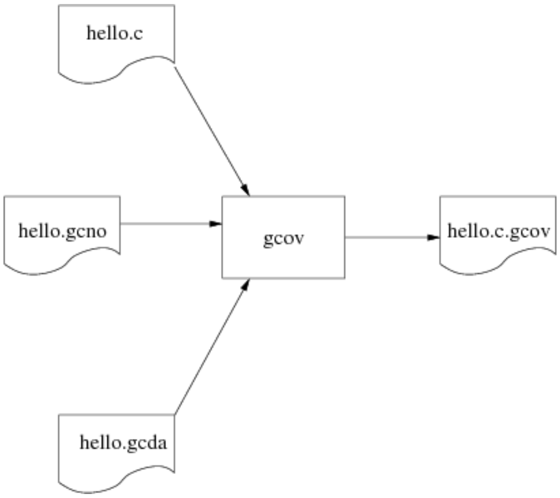
The resulting executable can be run on the target hardware as usual. The basic block counting will initialize automatically and the counts will accumulate. If gcov is used for native development rather than for embedded targets then these counts will be written out to `.gcda` data files automatically when the program exits (older versions of the compiler used to generate files with `.da` suffixes). A typical embedded target will not have access to the host file system so a different approach must be used. The counts can be extracted from the target using either a gdb macro or by a tftp transfer, giving a single `ecosgcov.out` file with counts for the entire application. This file should then be processed with the ecosxda script to give count files for each application source file.



It is now possible to run gcov on each source file. The exact format of the various files varies with the compiler version so it is important to use the version of gcov that comes with the compiler.

```
$ m68k-elf-gcov dhrystone.c
 89.25% of 214 source lines executed in file dhrystone.c
Creating dhrystone.c.gcov.
#
```

gcov will read in the basic block counts from the generated `.gcda` file. These basic blocks are mapped onto the source code using the information in the `.gcno` files.



gcov provides various options, for example it can output summaries for each function. Full details of the available functionality can be found in the gcov section of the gcc documentation.

Building Applications for Test Coverage

To perform application test coverage the gcov package `CYGPKG_GCOV` must first be added to the eCos configuration. On the command line this can be achieved using:

```
$ ecosconfig add gcov
$ ecosconfig tree
$ make
```

Alternatively the same steps can be performed using the graphical configuration tool. The package only has two configuration options related to tftp transfers, described below.

In addition application code should be compiled with two additional options, `-fprofile-arcs` and `-ftest-coverage`. The first option causes the compiler to insert additional code for basic block counting, plus an initialization call to `__gcov_init_func()` which is provided by the eCos gcov package. The second option results in additional `.gcno` output files which gcov will need later. The target-side memory needed to store the basic block counts is allocated statically.

When code is compiled with optimization the compiler may rearrange some of the code, if that leads to better performance. Sometimes this causes the gcov output to be rather confusing. Compiling with `-O0`, thus disabling optimization, can help.

Extracting the Data

The basic block counts must be extracted from the target and saved to a file `ecosgcov.out` on the host. This package provides two ways of doing this: a gdb macro or tftp transfers. Using tftp is faster but requires a TCP/IP stack on the target. It also consumes some additional target-side resources, including an extra tftp daemon thread and its stack. The gdb macro can be used even when the eCos configuration does not include a TCP/IP stack. However it is much slower, typically taking several minutes to retrieve all the counts for a non-trivial application.

The gdb macro is called `gcov_dump`, and can be found in the file `gcov.gdb` in the `host` subdirectory of this package, and in the `ECOS_INSTALL_DIR/etc` subdirectory. A typical way of using this macro is:

```
(gdb) source <ECOS_INSTALL_DIR>/etc/gcov.gdb
(gdb) gcov_dump
```

This macro can be used any time after the application has initialized, and will store the counts accumulated so far to the file `ecosgcov.out` in the current directory. The counts are not reset.

If the configuration includes a TCP/IP stack then the data can be extracted using tftp instead. There are two relevant configuration options. `CYGPKG_GCOV_TFTPD` controls whether or not tftp is supported. It is enabled by default if the configuration includes a TCP/IP stack, but can be disabled to save target-side resources. `CYGNUM_GCOV_TFTPD_PORT` controls the UDP port which will be used. This port cannot be shared with other tftp daemons. If neither application code nor any other package (for example the gprof profiling package) provides a tftp service then the default port can be used. Otherwise it will be necessary to assign unique ports to each daemon.

Using tftp requires some additional code in the application. Specifically the daemon cannot be started until the network is up and running, and that usually happens at the behest of application code rather than automatically. The following code fragment illustrates what is required:

```
#include <pkgconf/system.h>
#include <network.h>
#ifdef CYGPKG_GCOV
# include <pkgconf/gcov.h>
# include <cyg/profile/gcov.h>
#endif
…
int
main(int argc, char** argv)
{
    …
    init_all_network_interfaces();
#ifdef CYGPKG_GCOV_TFTPD
    gcov_start_tftpd();
#endif
    …
}
```

The data can then be retrieved using a standard tftp client. There are a number of such clients available with very different interfaces, but a typical session might look something like this:

```
$ tftp
tftp> connect 10.1.1.134
tftp> binary
tftp> get ecosgcov.out
Received 138740 bytes in 1.7 seconds
tftp> quit
```

The address `10.1.1.134` should be replaced with the target's IP address.

ecosxda

gcov expects separate `.gcda` files for each application source file compiled with `-fprofile-arcs`. However it would be inconvenient to extract each `.gcda` file via tftp or a gdb macro. Instead the data is first written to a single file `ecosgcov.out`. The ecosxda utility script should then be used to process `ecosgcov.out` and generate the `.gcda` files.

The ecosxda script can be found in the `host` subdirectory of this package. Since it is a simple Tcl script it does not need to be built or installed. If desired it can be copied to a suitable location on the user's `PATH`. Alternatively the subdirectory contains suitable `configure` and `Makefile.in` files, allowing the script to be installed automatically as part of the generic eCos host-side build system. The toplevel file `README.host` contains more information about this.

Typically ecosxda will be invoked with no arguments.

```
$ ecosxda
```

It will read in an `ecosgcov.out` file from the current directory and output or update the `.gcda` files appropriate for the application. If a given `.gcda` file already exists then by default ecosxda will read it in and merge the old and new counts, rather than write a new set. This allows data from several test runs to accumulate, giving more comprehensive test coverage. Merging the counts is only possible if the source file has not been recompiled, otherwise the old counts will be discarded to avoid contaminated results.

ecosxda takes a number of command line options.

-h
--help
Provide brief usage information.

-V
--version
Display the version of the ecosxda script being used.

-v
--verbose
Provide additional diagnostic output. Repeated uses increase the level of verbosity.

-n
--no-output
Do not actually create or modify any `.gcda` files. Typically this is used to find out whether any files would be replaced rather than merged, and it can also be used to validate the `ecosgcov.out` file.

-r
--replace
This forces ecosxda to ignore any existing counts in the `.gcda` files, rather than try to merge the existing and new counts. Typically it is used to discard the results from previous test runs.

In addition it is possible to specify the file containing the new counts, instead of the default `ecosgcov.out`. This may prove useful if several sets of results are extracted to different files during a single test run, to determine what code gets run at various stages. For example:

```
$ ecosxda -r stage2.out
```

Directories and eCos Test Coverage

In a simple build environment the source code, the `.gcno` files generated by the compiler, and the `.gcda` files output by ecosxda, will all reside in the same directory. That makes it easy for gcov to find the various files it needs. gcov will also generate its `.gcov` files in the same directory.

In more complicated build environments the source code may be kept completely separate from the build tree. eCos itself provides an example of this: the source code is held in a clean component repository, and builds happen in separate build trees. To use gcov in such an environment it is necessary to understand what files will be created where:

1. The compiler will output the `.gcno` file in the same directory as the object file. For an eCos build tree this will be below the version directory of each package. For example, if the kernel source file `sync/mutex.cxx` is built with `-ftest-coverage` then the `kernel/current/src/sync` subdirectory in the build tree will contain the `mutex.gcno` files.

2. The `.gcda` files will end up in the same directory as the `.gcno` files. The compiler puts the full path name in each object file, and this path is copied into the `ecosgcov.out` file and used by ecosxda. It is assumed that `ecosgcov.out` will be processed on the same machine that was used to compile the code.

3. When gcov is invoked it can be given a full pathname for the source file. By default it assumes that the other files will be in the current directory, but a `-o` command line option can be used to override this.

4. gcov will output its `.gcov` files in the current directory.

To perform test coverage of eCos itself, in addition to or instead of the application, it is necessary to rebuild eCos with the appropriate flags. This involves changing the configuration option `CYGBLD_GLOBAL_CFLAGS` to include `-ftest-coverage` and `-fprofile-arcs`, then performing a clean and a full make. The basic block counts can be extracted and processed with ecosxda as before, and the `.gcno` and `.gcda` files will all end up in the build tree. This test coverage data can then be processed in the build tree using, for example:

```
$ cd <build>
$ cd kernel/<version>
$ m68k-elf-gcov -o . <repo>/kernel/<version>/sync/mutex.cxx
…
 58.50% of 147 source lines executed in file <repo>/kernel/current/src/sync/mutex.cxx
Creating mutex.cxx.gcov.
```

Where <build> is the location of the build tree and <repo> is the location of the eCos component repository.

Additional Target-side Functions

The eCos gcov package provides a small number of additional target-side functions. Prototypes for these are provided in the header file `<cyg/profile/gcov.h>`.

```
…
int
main(int argc, char** argv)
{
    …
    init_all_network_interfaces();
#ifdef CYGPKG_GCOV_TFTPD
    gcov_start_tftpd();
#endif
    …
}
```

If the eCos configuration includes a TCP/IP stack and if a target-side tftp daemon will be used to extract the data from the target to the host then application code should call `gcov_start_tftpd` once the network is up. This cannot be done automatically by the gcov package itself since that package has no simple way of detecting when the network is ready.

```
extern void gcov_reset(void);
```

This function can be used to reset all basic block counts. If the application operates in a number of distinct stages then it may be useful to get coverage data for each stage, rather than a single set of results for the whole test run. It can also be used to get test coverage for a specific sequence of external inputs.

64-bit arithmetic is used for the basic block counts. Hence it should not be necessary to perform occasional resets to avoid counters overflowing.

To operate properly `gcov_reset` needs to disable interrupts for a while, so it should not be used in situations which require hard real-time performance.

```
extern void gcov_dump(void);
```

This is a utility routine which outputs some of the basic block information via `diag_printf` calls. It is intended primarily to help with debugging the gcov code itself.

In addition the `<cyg/profile/gcov.h>` header exports the data type gcov_module and a variable `gcov_head` which acts as the head of a linked list of gcov_module structures. This allows application code to access and manipulate the basic block data directly, if desired.

Part LXIV. CRC Algorithms

The CRC package provides implementation of CRC algorithms. This includes the POSIX CRC calculation which produces the same result as the cksum command on Linux, another 32 bit CRC by Gary S. Brown and a 16bit CRC. The CRC used for Ethernet FCS is also implemented.

Table of Contents

Chapter 205. CRC Functions

CRC API

The package implements a number of CRC functions as described below. The API to these functions is in the include file `cyg/crc/crc.h`.

cyg_posix_crc32

This function implements a 32 bit CRC which is compliant to the POSIX 1008.2 Standard. This is the same as the Linux cksum program.

```
cyg_uint32 cyg_posix_crc32(unsigned char * s, int len);
```

The CRC calculation is run over the data pointed to by *s*, of length *len*. The CRC is returned as an unsigned long.

cyg_crc32

These functions implement a 32 bit CRC by Gary S. Brown. They use the polynomial X^32+X^26+X^23+X^22+X^16+X^12+X^11+X^10+X^8+X^7+X^5+X^4+X^2+X^1+X^0.

```
cyg_uint32 cyg_crc32(unsigned char * s, int len);
cyg_uint32 cyg_crc32_accumulate(cyg_uint32 crc, unsigned char * s, int len);
```

The CRC calculation is run over the data pointed to by *s*, of length *len*. The CRC is returned as an unsigned long.

The CRC can be calculated over data separated into multiple buffers by using the function `cyg_crc32_accumulate()`. The parameter *crc* should be the result from the previous CRC calculation.

cyg_ether_crc32

These functions implement the 32 bit CRC used by the Ethernet FCS word.

```
cyg_uint32 cyg_ether_crc32(unsigned char * s, int len);
cyg_uint32 cyg_ether_crc32_accumulate(cyg_uint32 crc, unsigned char * s, int len);
```

The CRC calculation is run over the data pointed to by *s*, of length *len*. The CRC is returned as an unsigned long.

The CRC can be calculated over data separated into multiple buffers by using the function `cyg_ether_crc32_accumulate()`. The parameter *crc* should be the result from the previous CRC calculation.

cyg_crc16

This function implements a 16 bit CRC. It uses the polynomial x^16+x^12+x^5+1.

```
cyg_uint16 cyg_crc16(unsigned char * s, int len);
```

The CRC calculation is run over the data pointed to by *s*, of length *len*. The CRC is returned as an unsigned short.

Part LXV. CryptoAuthLib

Table of Contents

Chapter 206. CryptoAuthLib overview

Introduction

The `CYGPKG_CRYPTOAUTHLIB` package provides a standard CryptoAuthLib library implementation to eCos applications.

This package is covered by an “AS IS” license as distributed in the original CryptoAuthLib package:

Example 206.1. “AS IS” License

```
(c) 2015-2021 Microchip Technology Inc. and its subsidiaries.

Subject to your compliance with these terms, you may use the Microchip Software
and any derivatives exclusively with Microchip products. It is your
responsibility to comply with third party license terms applicable to your
use of third party software (including open source software) that may

SPECIAL, PUNITIVE, INCIDENTAL OR CONSEQUENTIAL LOSS, DAMAGE, COST OR EXPENSE
OF ANY KIND WHATSOEVER RELATED TO THE SOFTWARE, HOWEVER CAUSED, EVEN IF
MICROCHIP HAS BEEN ADVISED OF THE POSSIBILITY OR THE DAMAGES ARE FORESEEABLE.
TO THE FULLEST EXTENT ALLOWED BY LAW, MICROCHIP'S TOTAL LIABILITY ON ALL
CLAIMS IN ANY WAY RELATED TO THIS SOFTWARE WILL NOT EXCEED THE AMOUNT OF
FEES, IF ANY, THAT YOU HAVE PAID DIRECTLY TO MICROCHIP FOR THIS SOFTWARE.
```

For definitive CryptoAuthLib documentation please refer to the main Microchip Trust Platform website. We do not duplicate that documentation here.

Chapter 207. Configuration

This chapter shows how to incorporate the CryptoAuthLib support into an eCos configuration, and how to configure it once included.

Configuration Overview

The CryptoAuthLib support is contained in a single eCos package `CYGPKG_CRYPTOAUTHLIB`. However, some functionality is dependant on other eCos features. e.g. the eCos I²C support.

Quick Start

Incorporating the CryptoAuthLib support into your application is straightforward. The essential starting point is to incorporate the CryptoAuthLib eCos package (`CYGPKG_CRYPTOAUTHLIB`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Depending on the CryptoAuthLib package configuration other packages may be required (e.g. I²C support). The package requires that the `CYGPKG_INFRA` and `CYGPKG_MEMALLOC` packages are included in the eCos application configuration.

Chapter 208. eCos port

Overview

The goal for the CYGPKG_CRYPTOAUTHLIB package is to avoid where possible having to have any core CryptoAuthLib source file changes made specifically for eCos. This is to ensure that re-imports of newer versions of the library sources involve minimal effort. The files are as provided in the official CryptoAuthLib release package as imported, with the following exceptions:

1. Files have been moved, unmodified, to create a standard eCos package tree structure to integrate with the eCosPro build environment

   Only **relevant** files from the original project have been included in the eCos package.

2. The file include/hal/atca_hal.h has a different hal_delay_us() prototype to match the underlying eCos run-time function actually referenced due to the naming clash.

The current CryptoAuthLib version provided by the eCos package is the github tagged release 20220614, which is a v3.3.3 release (8th October 2021) with bug fixes applied up to 14th June 2022.

The original project homepage can be found on github: cryptoauthlib

The release package was downloaded from the github project page: cryptoauthlib/releases/tag/20220614

The following table highlights the files taken from the CryptoAuthLib package and their new location within the eCos CYGPKG_CRYPTOAUTHLIB package:

Chapter 209. Test Programs

Test Programs

Some CryptoAuthLib specific tests are built and can be used to verify correct operation of the library.

1. `basiccheck`

   This test executes some basic device sanity checks to exercise the I2C transport layer, and to verify target device operation. It does not use the CryptoAuthLib test environment, put purely calls the CryptoAuthLib library functionality.

2. `basicinfo`

   This test executes some basic device sanity checks to exercise the I2C transport layer, and to verify target device operation. It uses the CryptoAuthLib test environment and provides similar diagnostic output as the direct `basiccheck` test.

3. `cryptoauth_test`

   This test is only built when `CYGBLD_CRYPTOAUTHLIB_TESTS_MANUAL` is enabled since it relies on the `/dev/haldiag` diagnostic terminal connection for interactive command input.

   The test is a build of the “command-line” test application allowing interaction with devices. On startup the application will display an inital prompt and wait for user input:

   ```
   INFO:<code from 0x20209008 -> 0x202420c4, CRC a43d^gt;
   INFO:<Using haldiag for interactive test>
   INFO:<Enter "help\n" to display help menu>
   $
   ```

   Depending on the eCos configuration, and the specific options for this CryptoAuthLib package, the features of the test may vary. The following is purely an example. The `help` command should list all of the supported commands. Normally a device needs to be selected prior to use. e.g.:

   ```
   $ help
   Usage:
   help - Display Menu
   ecc608 - Set Target Device to ATECC608
   info - Get the Chip Revision
   sernum - Get the Chip Serial Number
   rand - Generate Some Random Numbers
   readcfg - Read the Config Zone
   lockstat - Zone Lock Status
   tng - Run unit tests on TNG type part.
   basic - Run Basic Test on Selected Device
   util - Run Helper Function Tests
   clkdivm0 - Set ATECC608 to ClockDivider M0(0x00)
   clkdivm1 - Set ATECC608 to ClockDivider M1(0x05)
   clkdivm2 - Set ATECC608 to ClockDivider M2(0x0D)
   cd - Run Unit Tests on Cert Data
   cio - Run Unit Test on Cert I/O
   crypto - Run Unit Tests for Software Crypto Functions
   pbkdf2 - Run pbkdf2 tests

   $ ecc608
   Device Selected.

   $ info
   revision:
   00 00 60 01
   ```

```
$ sernum
serial number:
01 23 C4 71 E0 E7 45 37 EE

$
```

Note

For some devices, e.g. ATECC608 family, some operations will not operate, or will return errors, if the device is not locked or configured suitably. Knowledge of the device, and its features, being used should taken into account when running commands and interpreting the results.

Part LXVI. LibTomCrypt Cryptography Library

Important

The LibTomCrypt Cryptography Library package for eCos is distributed as an optional eCos add-on package that may not be included in your release of eCosPro. If this package is not listed in either the graphical or command line eCos Configuration tool, please contact eCosCentric for availability and pricing.

Name

`CYGPKG_CRYPT_LIBTOMCRYPT` — Cryptography

Description

`CYGPKG_CRYPT_LIBTOMCRYPT` is a port to eCos of the Tom St Denis LibTomCrypt cryptography library. Full documentation on this library can be found in the file `crypt.pdf` in the package's `doc` subdirectory.

The port to eCos has involved only very minor changes to the generic LibTomCrypt sources. Appropriate CDL has been added to turn the library into an eCos package. The package's `src` subdirectory has essentially the same contents as a LibTomCrypt tarball. The exported headers have been moved from the `src/headers` subdirectory to the package's `include` subdirectory in accordance with eCos conventions. Some of these headers have had minor modifications to allow the package to be built and used within an eCos configuration. The prebuilt documentation file `crypt.pdf` has been moved to the `doc` subdirectory.

The package has no architectural dependencies so can be added to any eCos configuration. However it does depend on dynamic memory allocation support from `CYGPKG_MEMALLOC`, on standard C library support from `CYGPKG_LIBC_STDLIB`, `CYGPKG_LIBC_I18N`, `CYGPKG_LIBC_STRING`, `CYGPKG_LIBC_TIME`, and on the multi-precision arithmetic support provided by `CYGPKG_LIBTOMMATH`.

The package provides three CDL configuration options. `CYGIMP_CRYPT_LIBTOMCRYPT_SMALL_CODE` corresponds to the libtomcrypt `LTC_SMALL_CODE` option and selects for smaller but slower code. Similarly `CYGIMP_CRYPT_LIBTOMCRYPT_NO_TABLES` corresponds to `LTC_NO_TABLES` and also selects for smaller but slower code. `CYGDBG_CRYPT_LIBTOMCRYPT_ARGCHK` determines what argument checking gets performed. By default in a debug build (`CYGPKG_INFRA_DEBUG` enabled) invalid arguments result in an assertion failure, and in a normal build argument checking is disabled.

Caution

In some jurisdictions use of this library may be subject to patent and trademark restrictions. More information on this can be found in section 1.4 of the `crypt.pdf` document. It is the application developer's responsibility to consider the legal issues before using this library.

Part LXVII. LibTomMath Multi-Precision Math Package

Important

The LibTomMath Multi-Precision Math package for eCos is distributed as an optional eCos add-on package that may not be included in your release of eCosPro. If this package is not listed in either the graphical or command line eCos Configuration tool, please contact eCosCentric for availability and pricing.

Name

CYGPKG_MATH_LIBTOMMATH — Multi-Precision Maths

Description

CYGPKG_MATH_LIBTOMMATH is a port to eCos of the Tom St Denis LibTomMath Multi-Precision Math package. Full documentation on this package can be found in the files bn.pdf, tommath.pdf, and poster.pdf in the package's doc subdirectory.

The port to eCos has involved only very minor changes to the generic LibTomMath sources, to allow the code to adapt to eCos configurations lacking standard I/O functionality. The package's src subdirectory has essentially the same contents as a LibTomMath tarball. The exported headers tommath.h, tommath_class.h and tommath_superclass.h have been moved to the package's include subdirectory, The prebuilt documentation files have been moved to the package's doc subdirectory. Appropriate CDL has been added so that the package can be built as part of an eCos configuration.

The package has no architectural dependencies so can be added to any eCos configuration. However it does depend on dynamic memory allocation support from CYGPKG_MEMALLOC and on standard C library support from CYGPKG_LIBC_STDLIB, CYGPKG_LIBC_I18N, and CYGPKG_LIBC_STRING.

Part LXVIII. BootUp ROM loader

Table of Contents

Chapter 210. BootUp overview

Introduction

eCosPro-BootUp is eCosCentric's commercial name for the CYGPKG_BOOTUP package. The package is not included as standard in eCosPro Developer's Kit releases. Review the board specific documentation to determine if support has been included for your target platform.

The CYGPKG_BOOTUP package implements a lightweight bootROM that is intended to be easily portable and customizable to support the requirements of a given platform. It is purposely designed to provide an uncomplicated and straightforward boot mechanism, but does however provide a framework that the target platform code can use to easily extend its basic functionality. This can be used to incorporate more advanced features such as secure boot capabilities and application or system updates.

The BootUp code does NOT support any debug ROM monitor features. It is targeted at deployment of SoC-based designs that have limited memory resources and where hardware debugging (JTAG, SWD, BDM, etc.) will be used. It does not incorporate a debug agent such as GDB stubs, a CLI or any other debug monitor features. If you require these kinds of features then the RedBoot bootloader and debug firmware will be a more appropriate vehicle.

The BootUp package provides the generic, logical, framework for optional updating and execution of application images. Most of the heavy-lifting implementation for this is provided by architecture, variant or platform specific code that is incorporated when CYGPKG_BOOTUP is built. This is primarily because the location and format of the relevant application images is platform specific. This provides the greatest flexibility to developers with regards to how applications are stored and what extra information may be embedded to support updating and any other custom bootROM features.

Note

Normally it is envisaged that the BootUp ROM image will be loaded onto devices once, and then very rarely (if ever) updated. The BootUp world is designed to be very simple to minimise the chances of errors in the implementation that would stop the system from booting, or from allowing a different main application to be loaded into the device. The simpler implementations make no use of specific run-time configuration, and all implementations do not impose any footprint on the target after it has started the main application.

BootUp has been utilised by various example target platform implementations to support different mechanisms for safe application updates. These examples can be used as the basis of an update mechanism for your target platform. For example:

- *A simple implementation with no update support.* The on-chip BootUp loader is simply used to validate, load and execute an off-chip NVM based, RAM loaded, application.

  The Atmel SAMA5D3x platform provides an example BootUp implementation for starting RAM based applications. This platform also, optionally, supports secure booting an encrypted applications.

- *A basic update mechanism that is intended to support booting and update of on-chip flash resident applications.* In this case, each time the target is reset BootUp checks if a different, valid, application is present in a separate non volatile memory (NVM) area. If an update is found it will be installed into the on-chip flash, prior to the on-chip flash application being executed. The term “different” is used when distinguishing main application images since BootUp does not interpret the binary signature, which need not be a version number. This allows the update system to be used to revert to an earlier version of the application. It will simply update the on-chip application if an application with a different signature is found in the NVM.

  The application itself is responsible for identifying, acquiring, verifying and storing any update into the NVM. BootUp is responsible solely for installation and execution of the application held in on-chip flash.

  The design of this mechanism avoids halving the available on-chip memory space in order to store images of both the existing and updated application. It also avoids possible target complications resulting from executing out of the same memory space that will need to be erased and written to. However, if the on-chip flash is large enough, and the final application small enough, it is possible for the main and alternative application images to be held on the same on-chip flash.

The robustness (safe update) of an application via this BootUp mechanism relies on the code only attempting to perform an update when a different valid application image is available. If the system loses power, or suffers a reset, during an update the original alternative image will still be available. When the system recovers from the reset state it will just re-start the update (regardless of whether the on-chip application image is still valid, since even if it is, it will still be different from the alternative image that started the original update).

Specific examples of this style of BootUp implementation can be found in the ST STM324x9I-EVAL and ST STM32F7xx-EVAL platforms' `ROMAPP` startup type.

- *A more sophisticated update solution that supports a “bundle” of application specific files.* In this case BootUp is responsible for identifying, loading and executing the main application from within a bundle held in NVM. The application is loaded into and executed in external RAM memory.

  The application itself is generally responsible for identifying, acquiring, verifying and installing any available bundle updates into NVM. BootUp is responsible solely for loading and executing an updated “main” application from within the bundle. Optionally, as a fall-back, if no valid bundle can be located in NVM, then BootUp can locate, verify and install a complete bundle from external media such as an SD card.

  The design of this update mechanism enables, in addition to pure application updates, the update of other target resident code and data. These files might include FPGA bitfiles, DSP firmware, application data and so forth. The bundle update system includes support for decompression and checksumming of the bundle contents. See the Bundle image support chapter for further details.

  Examples of this BootUp approach are available in the ST STM324x9I-EVAL and ST STM32F7xx-EVAL platforms' bundle support.

Architectures, variants or platforms that support the BootUp loader will implement `CYGINT_BOOTUP_APPSTART`. This feature allows BootUp to start the main application and is an essential requirement for the BootUp world to be used.

If BootUp starts when there is no valid on-chip application, and no valid alternative application is available, then if the platform provides the macro `CYG_HAL_BOOTUP_BADAPP` then that is used to call platform specific code. This provides a hook to allow target specific feedback indicating the lack of an application.

Configuration

If `CYGINT_BOOTUP_UPDATE` is not defined then the BootUp loader will simply just execute the “main” application if it is present and valid. If the platform defines `CYG_HAL_BOOTUP_COPYAPP` then platform supplied code to copy an application to its executation location is called (e.g. for RAM loaded applications). In reality if neither `CYGINT_BOOT_UPDATE` and `CYG_HAL_BOOTUP_COPYAPP` are provided by the target then there is no real need for the BootUp to be used, and a normal simple `ROM` application configuration would suffice.

When `CYGINT_BOOTUP_UPDATE` is defined by a platform it indicates that the platform provides the mechanism for identifying if a different alternative application image is available, and that the alternative image should replace the current main (normally on-chip) application when different. It is the responsibility of the platform supplied routines to implement how such image validation is performed.

The following configuration options control the main features of the BootUp bootROM world:

`CYGBLD_BUILD_BOOTUP` controls whether the BootUp image is created, and will normally be defined for all BootUp configurations.

`CYGIMP_BOOTUP_UPDATE` controls whether the BootUp bootROM supports replacing the main application image with a different image from the alternative storage location. If not defined then BootUp will simply start the main application.

`CYG_HAL_BOOTUP_COPYAPP` controls whether the platform provides code to copy an application from NVM to RAM for execution.

Platform Support

A platform supporting the BootUp application update and start features provides the necessary support via specifically named functions. When defined by the platform the BootUp code will call the named macro to perform the necessary action. In the list below the function prototypes are shown using example names. Normally the platform will just map the macro name to a specific named function provided by the platform HAL.

- `CYG_HAL_BOOTUP_VALID_MAIN`

  `cyg_bool` *`plf_bootup_valid_main`*`(void);`

  The function referenced by this macro returns boolean `true` if the main application image is valid (this is the application image that BootUp starts). It will return boolean `false` if no valid main application is found.

- `CYG_HAL_BOOTUP_VALID_ALT`

  `cyg_bool` *`plf_bootup_valid_alt`*`(void);`

  The function referenced by this macro returns boolean `true` if the alternative (pending update) application image is valid *and* different from the current main application. This is the application image that BootUp will *automatically* replace the main application with when it is *different* from the current main application. It will return boolean `false` if no valid alternative application is available, or the alternative image is the same as the current main application.

- `CYG_HAL_BOOTUP_VALID_UPDATE`

  `cyg_bool` *`plf_bootup_validate_update`*`(void);`

  The function referenced by this macro is only called if `CYG_HAL_BOOTUP_VALID_MAIN` has returned `false` to indicate that the main application image is missing or invalid. This macro returns boolean `true` if the alternative (pending update) application image is valid and the main application has been updated successfully. This macro will return boolean `false` if no valid alternative image is available or the update process has failed.

  ## Note

  The `CYG_HAL_BOOTUP_VALID_ALT` and `CYG_HAL_BOOTUP_VALID_UPDATE` macros are mutually exclusive, since they implement slightly different “update” logic based on the presence of a valid main application. A platform should only define one of these macros depending on the style of automatic application update required.

- `CYG_HAL_BOOTUP_UPDATE`

  `cyg_bool` *`plf_bootup_update`*`(void);`

  The function referenced by this macro will replace the main application image with the alternative image. It is only called after the respective images have been validated and only when the alternative image is different as ascertained by a `CYG_HAL_BOOTUP_VALID_ALT` call. It will return boolean `true` if it successfully updates the main application, otherwise boolean `false` is returned to indicate failure.

- `CYG_HAL_BOOTUP_COPYAPP`

  `cyg_bool` *`plf_bootup_copyapp`*`(void);`

  The function referenced by this macro returns boolean `true` if the main application image has been successfully copied to its execution location. It will return boolean `false` if no valid main application is available.

- `CYG_HAL_BOOTUP_BADAPP`

  `void plf_bootup_badapp(void);`

  The function referenced by this macro is called when no valid main application exists. This can be used to provide platform specific feedback to the user that the system cannot boot.

If the `CYGSEM_BOOTUP_PLF_STARTUP` configuration option is enabled then the following C function is called:

`void` **`cyg_plf_bootup_startup`**`();`

This function can be used to provide platform specific optional initialisation prior to the normal BootUp operation being started. This may be performing specific hardware initialisation, or some level of Power On Self Test support.

Application Identity

The identification of valid application images is the responsibility of the platform specific code. Depending on the BootUp model implemented by the target platform, it may be the case that a simple binary value will be enough to distinguish different applications, e.g. a monotonically increasing version number, or the `UTC` timestamp when the binary was produced.

If an application signature needs to be embedded inside the actual application binary then platforms that support the use of BootUp will normally provide a mechanism to provide space within the produced eCos executable. For example the Cortex-M architecture provides the `CYGNUM_HAL_CORTEXM_VSR_TABLE_PAD` configuration option that allows space for an application specific header to be provided at a fixed offset from the binary start. Similarly the ARM architecture allows for the `PLATFORM_PREAMBLE` macro to be define to allow for a header to be installed to hold, for example, the BootUp signature, CRC, or whatever information is needed.

The header/block being used to hold such a “signature” need not just contain information for supporting BootUp. For example, it may also need to hold information for the mechanism used to install the pending update application image into the alternative location.

Building BootUp

Platforms that support a BootUp configuration will normally provide a suitable `.ecm` configuration file to allow a minimal BootUp application to be constructed. The specific platform documentation will provide information regarding BootUp configuration and use, and any specific build sequences. Such documentation should be read in conjunction with this generic BootUp information.

This package provides an example import file in the `$ECOS_REPOSITORY/bootup/<version>/misc/bootup_ROM.ecm.example` file. When porting BootUp support to a new platform this example file can be used as the basis for the target specific `.ecm` fragment.

Should it prove necessary to rebuild a BootUp binary it is done most conveniently at the command line. The steps needed to rebuild a ROM version would be similar to:

```
$ ecosconfig new <target> minimal
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/hal/TARGETPATH/VERSION/misc/bootup_ROM.ecm
[ … ecosconfig output elided … ]
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory will contain the file `bootup.bin`. This may be programmed into the target platform as specified for the system being targeted.

Applications using `VALID_ALT`

The following section is only relevant for target platforms that define `CYG_HAL_BOOTUP_UPDATE` and `CYG_HAL_BOOTUP_VALID_ALT` where the BootUp world is designed to allow for robust in-field updates of the firmware on a device.

For such systems the application started by BootUp must implement some of the support needed with regard to providing the “pending update” application image. When a new firmware update has been downloaded by the main application it will normally force a system restart, which will cause BootUp to perform the necessary update prior to starting the new main application.

The main application, when loading a pending update application into the alternative memory/device (e.g. off-chip SPI), should ensure that it does not set (write) the "valid signature" until it has validated the correct storage of the rest of the image. This requirement ensures that if a system reset occurs before the signature has been written that the image will NOT be interpreted by BootUp as being valid. This allows the BootUp loader to be simpler since it can treat a valid, complete, signature as an indication that the application was written correctly.

At a minimum (and critically) the main application needs to ensure that it invalidates the alternative image signature prior to starting the process of storing a new application image into the alternative area. This ensures a partial image is not incorrectly identified as a valid, pending, update. If CRC checking is also being used by the platform HAL then this likelihood is minimised.

Note

This requirement that the alternative storage area must have a complete valid image, whenever there is a complete signature present, ensures that in the case where the implementation does not use a CRC (or similar check) for the BootUp code to perform validation of a complete image, that any previous previous valid signature is not incorrectly accessed and treated as “valid”. For example, if the writing of a subsequent pending update is interrupted (CPU reset, etc.) before it “overwrites” the signature of the previously stored image. If a pending update is downloaded to the holding area, validated and marked as such *BUT* the system is not rebooted (so the pending update is not applied). Subsequently another pending update starts to download a different image to the holding area but the process is interrupted before the previous image “valid” signature is over-written. The BootUp code could then incorrectly interpret the invalid (partially overwritten) image as being valid if no other validity checks are performed. This is why the *rule* exists that the code performing the pending update storage should first invalidate the signature.

It is the responsibility of the main application storing the pending update to ensure that the complete image is valid *PRIOR* to finalising the platform specific signature. To reiterate, the BootUp package, in combination with the platform HAL support, only requires a simple “signature validity check” for robustness *WHEN* the code storing the pending update ensures that if there is a valid signature in the alternative area then the rest of the bytes are also valid (i.e. a complete valid image is in place).

Since the BootUp will only perform an update when the valid alternative image is different, there is no strict need to erase the signature/image until the main application needs to provide a new update. However, doing so during its normal startup will avoid BootUp having to spend CPU cycles validating and checking the alternative image prior to checking the signature and deciding not to update.

Notes

1. To reiterate, the main application (not BootUp) is responsible for invalidating (erasing/removing) the alternative image, or at least the signature. This allows BootUp to be simpler since it only needs to be able to read from the alternative image location.

2. The signature can either be embedded in the application (assuming the caveat of it being the last data written), or it can be a totally separate distinct section maintained in conjunction with the update application image. Such design decisions are left to the specific platform HAL support. The use of other validation mechanisms, e.g. a CRC, will

only be required if the medium that is used to store the alternative (pending) image can suffer from data corruption, or transient read errors. Such a situation will be extremely unlikely for the vast majority of implementations.

Supported Platform HALs and targets

BootUp is supported by the following platform HALs:

- NXP i.MX RT10XX Variant HAL
- SAMA5D3x-MB Platform HAL
- SAMA5D3 Xplained Platform HAL
- ST STM324x9I-EVAL
- ST STM32F7xx-EVAL
- STM32F746G-DISCO Platform HAL
- STM32H735-DISCO Platform HAL
- STM32L4R9-DISCO Platform HAL
- STM32L476-DISCO Platform HAL
- **Note**

  This is not a complete list. Refer to your platform documentation to determine if it supports `CYGPKG_BOOTUP`.

Part LXIX. Bundle image support

Table of Contents

Chapter 211. Bundle overview

Introduction

The CYGPKG_BUNDLE package implements support for a simple, compact, multi-element, binary distribution format, referred to as a "bundle". The bundle format is primarily designed to be used for in-field system updates in conjunction with the BootUp lightweight BootROM package.

The format can be easily parsed and processed by deeply embedded systems, and is used to encapsulate multiple discrete binary data blobs and optional metadata. Bundles can therefore incorporate all the elements that may be required for a system update, including application executables, FPGA bitfiles, DSP firmware, application data and so forth.

The bundle package implements an API to parse and extract data from a bundle and an associated host tool used to create and manage bundle images.

The STM324X9i-Eval platform includes an example implementation of the BootUp bootROM package that uses the bundle package format as the distribution format underpinning its system update mechanism.

A bundle is normally expected to be used as a matched collection of binaries, and is treated as a whole with regards to production and in-field updates. It is *NOT* expected that in-field operations will ever split and re-combine elements of a deployment package in the field. As such the format is read-only for eCos applications.

Although the bundle format is designed to be flexible and allow modification and extensions, it is vital that for a given target platform that the host-based creation tool and runtime code share a common format and set of expected features. For example the use of MD5 as a "hash" and `zlib` as a compressor.

Configuration

This section shows how to include the bundle support into an eCos configuration, and how to configure it once installed.

The bundle support is contained in a single eCos package `CYGPKG_BUNDLE`. However, it depends on the services of a collection of other packages for complete functionality.

Incorporating the bundle support into your application is straightforward. The essential starting point is to incorporate the bundle eCos package (`CYGPKG_BUNDLE`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

`CYGFUN_BUNDLE_COMPRESS`

> If the eCos `zlib` package `CYGPKG_COMPRESS_ZLIB` is configured then, when enabled, this option provides support for decompressing items. If the `CYGPKG_COMPRESS_ZLIB` package is not available, or this option is disabled, then only uncompressed items within a bundle can be read.

`CYGIMP_BUNDLE_HASH_MD5`

> This option can be enabled to include support for the `RFC 1321` MD5 Message-Digest Algorithm as a valid hash used to verify data integrity.

`CYGIMP_BUNDLE_HASH_SHA256`

> This option can be enabled to include support for the FIPS PUB 180-2 SHA-256 hash as a valid hash used to verify data integrity.

`CYGIMP_BUNDLE_HASH_CRC32`

This option when enabled implements support for the standard IEEE 802.3 (Ethernet) CRC-32 as a valid hash used to verify data integrity.

`CYGNUM_BUNDLE_BUFSIZE`

This option defines the size of the internal buffer used for decompressing data. Currently it makes use of a dynamic memory allocation and so may need to be tuned appropriately for target systems with a small dynamic heap.

`CYGBLD_BUNDLE_BUNDLE`

This option allows the host-side `bundle` tool to be automatically built on suitably capable systems.

Note

This option is disabled by default, since normally only a Linux system with a standard `zlib` library installation would automatically succeed. The package supplied `host/Makefile` provides an example of cross-building (under Linux) the host tool for Windows.

`CYGDBG_BUNDLE_DEBUG`

If this option is enabled then it provides access to individually controlled CDL debug options for various sub-systems or package features. This allows the detail and amount of debug information to be controlled. Normally such diagnostic output would only need to be enabled for developers working on the internals of the bundle processing.

`CYGTST_BUNDLE_BUILD_TESTS`

This option enables the building of any bundle run-time verification tests included in the package.

Chapter 212. Bundle format

Introduction

A “bundle” file has a custom format, designed to minimise the code overhead of supporting the bundle on the target platform.

Note

An advantage of a custom binary format over, for example, the use of a tar-file, is that the binary image held on an SD card for update delivery would be *IDENTICAL* to the version installed in the target's SPI flash.

With the tar-file format there is an overhead associated with individual entries (e.g. 512-byte header, per-item padding) that would mean for (the limited space) target SPI flash storage the processing code would need to extract the individual items for efficient storage in the SPI flash. This process can be avoided by a simple binary structure that is copied unchanged.

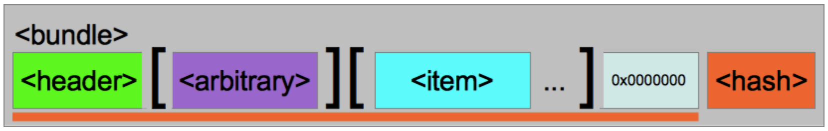
A host-based command-line tool is provided to create a correctly formatted bundle binary image. The binary image can then be used in manufacturing and in-field update processes to distribute the main target application and all associated target data.

Internal Structure

A bundle is a contiguous binary image containing a set of uniquely tagged items. Individual items may be compressed (using the standard `zlib` compression library). The bundle, and each item within a bundle, can optionally have “arbitrary” metadata attached. An overall hash object is used as a verification of the data integrity of the complete bundle image, but individual items also have the option of hashes covering their specific item data, and in the case of compressed items, a hash that can be used to validate the decompressed data.

The following figure highlights the underlying bundle format. The <header> block provides the basic bundle identification and description information. As previously discussed the bundle <arbitrary> block is optional and may not be present in all bundle images. It is perfectly valid for a bundle to contain no items, though a valid bundle always contains the <item> terminator `0x00000000` marker. The bundle is completed with a <hash> object providing the verification code for the complete bundle up to (but not including) the <hash> block.

Figure 212.1. <bundle> image

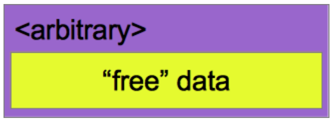


The *optional* <arbitrary> data that may be attached to the complete <bundle>, or to individual <item>s, is just a contiguous, uncompressed (as far as the bundle processing code is concerned), block of metadata. This metadata is not interpreted by the host-tool or bundle API code, but may be used by the target application as required. For example it could be used to hold a set of “key[=value];” pairs to provide “Identification” data for human-readable or programmatic access as required. e.g. it could encode tags like:

```
Version=1.02_B02;Required-HW-Version=rev1b;Development;
```

This arbitrary metadata could also be used as a mechanism for “Manifest” style information, which may be needed to support an organization's release process requirements.

Figure 212.2. <arbitrary> chunk



A <hash> object is used to hold a validation hash which can be used to ensure data integrity. Support is provided for avoiding the overhead of data verification by the special `CYG_BUNDLE_HASH_NONE` signature. However, in most situations (especially when the bundle format is being used as an in-field update delivery mechanism for example) some level of hash verification should be considered.

Figure 212.3. <hash> chunk

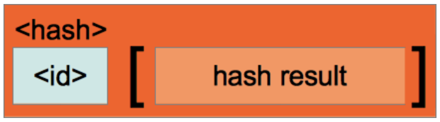


Table 212.1. HASH signatures

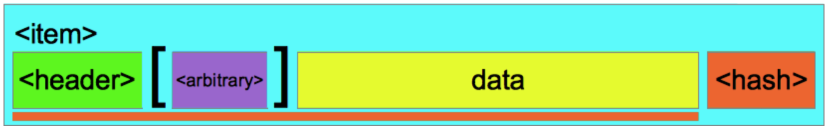
HASH Signature	Description
`CYG_BUNDLE_HASH_NONE`	This is used when no data validation hash support is required. The <hash> object does not contain a “hash result”.
`CYG_BUNDLE_HASH_CRC32`	A standard 4-byte IEEE 802.3 (Ethernet) CRC-32 value.
`CYG_BUNDLE_HASH_MD5`	A 16-byte `RFC 1321` MD5 Message-Digest Algorithm value is held. Though the use of MD5 is deprecated for cryptographic security purposes, its use as a <hash> for “data validity” checks is perfectly acceptable.
`CYG_BUNDLE_HASH_SHA256`	A 32-byte FIPS PUB 180-2 SHA-256 hash value is held.

A <bundle> comprises a set of items, each of which has a simple fixed “enum”-style tag rather than using fixed “ASCII filenames” to identify its specific purpose or use. This tag “namespace” is managed by the platform/customer and is not interpreted by the tools or bundle package API. For example, the customer may have the following mappings: `0x0001`==HostMCU, `0x0401`==MotorDSP, `0x0812`==LineDSP, `0x8003`==MotorTable, etc. The tag is used as both the name and filetype as required by the target application. This approach saves some binary space in the bundle format, plus the run-time overhead of string parsing when dealing with bundle items.

Data items are held either uncompressed or compressed, and may contain an optional <arbitrary> metadata block.

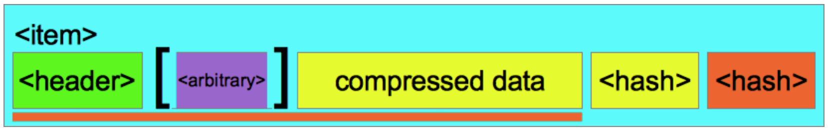
For uncompressed items a single <hash> object is appended covering the validation of the complete <item> chunk.

Figure 212.4. Uncompressed <item>



For compressed items a seperate <hash> object is maintained provided the hash value for the original, uncompressed, source data.

Figure 212.5. Compressed <item>



All <bundle> and <item> descriptor fields are held in the binary image in the target native endianess, and it is the responsibility of the host tool used to create the bundle to ensure the correct target endianness is selected. This ensures that the deeply embedded target does not need to swap bytes, as might be the case if a single fixed endianness was chosen for the bundle format. The bundle header 32-bit signature is designed to allow the endianness of the bundle to be detected at run-time, providing a simple validity check on the target that the bundle is valid.

Note

The host tool creating the bundle may need to be explicitly told the target endianness, which may be different from the build host native order. The provided example host `bundle` application provides the `--little-endian` and `--big-endian` options which can be used to override the host default selection if needed.

As discussed, a bundle is identified by a fixed header 32-bit signature. This signature is used to identify the binary as containing a bundle. At its simplest this signature is used to identify the platform/hardware that will accept the bundle (since the platform based applications will only recognise a valid matching signature value). The system support allows for a MASK/VALUE pair to be defined to allow (if required) a subset of the 32-bit signature to be used for “bundle is valid for this run-time” acceptance.

Notes

1. The “customer specific” field (currently 8-bits) can be used to provide a mechanism to restrict <bundle> images to specific platforms (or revisions of a platform) as required.

2. The `bundle` host executable provided within your eCosPro installation is required to construct, and examine, “bundle” binaries. This executable must be on your path, and will normally be copied into eCosPro host tools bin directory. Under Windows this is typically `C:\eCosPro\ecoshosttools\bin` and on Linux hosts `/opt/ecospro/ecoshosttools/bin`. The above bin directory will be on your path if you use the eCos GUI configuration tool or the eCos CLI Shell environment.

3. The bundle <header> and item <header> descriptors contain a `flags` field that can be extended as required to have any extension settings as needed to add extra information blocks into a bundle or item respectively. This allows for future extensions to the format to be added without affecting software (e.g. the BootUp firmware or the BootUp loaded main application) already in the field, since they will not interpret or be affected by any extra data that may be provided.

Chapter 213. Bundle API

The bundle API provides routines to extract data from a binary bundle image.

For eCos applications the approach used is that a suitable “access” strategy is chosen depending on where the bundle image is held. The access initialisation returns an opaque bundle descriptor reference that is used by an application to find a specific item. Similarly the opaque item descriptor reference is subsequently used to read the required data. The descriptor references need to be released when no longer required to ensure any held resources are returned to the system.

API

Name

cyg_bundle_access_direct — Initialise “direct” bundle context

Synopsis

#include <cyg/bundle/bundle_api.h>

```
cyg_bundle_context_t *cyg_bundle_access_direct(bundle_mem, blen);
```

Description

Initialises context for accessing contiguous directly-accessable (memory-mapped) based bundle image. This access strategy would be used for RAM or memory-mapped flash/ROM based bundles.

Return value

Pointer to object or NULL if unable to create context.

Name

cyg_bundle_access_file — Initialise “file” bundle context

Synopsis

#include <cyg/bundle/bundle_api.h>

```
cyg_bundle_context_t *cyg_bundle_access_file(fd);
```

Description

Initialises context for accessing a file based bundle image. This function requires the caller to have initialised and accessed the relevant file system, and to pass a valid “readable” file descriptor of an opened bundle image file. This functionality is only available if `CYGPKG_IO_FILEIO` is configured.

Return value

Pointer to object or NULL if unable to create context.

Name

cyg_bundle_access_flash — Initialise “flash” bundle context

Synopsis

#include <cyg/bundle/bundle_api.h>

```
cyg_bundle_context_t *cyg_bundle_access_flash(bundle_addr, limit_addr);
```

Description

Initialises context for accessing non-memory-mapped flash based bundle images via the standard eCos flash API. This “flash” access mechanism is primarily for indirectly-accessed flash memory (e.g. SPI devices), though nothing prohibits the use of the flash API from accessing memory-mapped flash images. This functionality is only available if `CYGPKG_IO_FLASH` is configured.

Note

If the target flash memory *is* accessible as a readable memory-mapped area then it is highly recommended to use the “direct” access mechanism for performance and dynamic memory footprint reasons.

Return value

Pointer to object or NULL if unable to create context.

Name

cyg_bundle_access_init — Common bundle context initialisation

Synopsis

#include <cyg/bundle/bundle_api.h>

```
cyg_bundle_context_t *cyg_bundle_access_init(am, aminitctx);
```

Description

The application developer should only need to use this function if providing an alternative access method. This may be needed if none of the default access strategies provide the necessary support. e.g. image is held on a memory using a non-standard bus connection.

Return value

Pointer to object or NULL if unable to create context.

Name

cyg_bundle_access_release — Release bundle context

Synopsis

#include <cyg/bundle/bundle_api.h>

```
void cyg_bundle_access_release(bc);
```

Description

Releases a previously allocated bundle context. To avoid resource leaks the application should always release a previously initialized access bundle context when it is no longer required.

Name

cyg_bundle_verify — Verify bundle and initialise context references

Synopsis

#include <cyg/bundle/bundle_api.h>

`int` **`cyg_bundle_verify`**`(`*`bc`*`, `*`valid_signature_mask`*`, `*`valid_signature`*`);`

Description

The *`bc`* parameter should be a bundle descriptor reference as returned by a suitable `cyg_bundle_access_`…`()` call.

After obtaining a context for the chosen “access” strategy this function **must** be called to verify that the bundle is valid prior to any subsequent data access API calls, since this function also initialises context data-structures required by the item access API functions.

Currently the *`valid_signature_mask`* and *`valid_signature`* parameters are **not** used. The code may be extended in the future to allow bundle validity to be selected based on the 8-bits of platform/application ID specific signature.

The following pseudo code is an example of expected, normal, use case of this function after selecting an access method:

```
#include <pkgconf/system.h>
#include <pkgconf/bundle.h>

#include <cyg/bundle/bundle.h>
#include <cyg/bundle/bundle_api.h>

void do_some_work(int fd)
{
    cyg_bundle_context_t *bc;

    bc = cyg_bundle_access_file(fd);
    if (bc) {
        if (CYG_BUNDLE_VALID == cyg_bundle_verify(bc,CYG_BUNDLE_SIG_MASK,CYG_BUNDLE_SIG_BASE)) {

            … perform item, or bundle arbitrary data, operations …

        } else {
            …report bundle validity error…
        }

        cyg_bundle_access_release(bc);
    } else {
        …report file access error…
    }

    return;
}
```

Return value

If the bundle is valid then the value `CYG_BUNDLE_VALID` is returned, and the *`bc`* context will be valid for subsequent item API calls. If the bundle data is invalid, or cannot be read, then `CYG_BUNDLE_INVALID` is returned.

Name

cyg_bundle_item_find — Provide handle onto bundle item

Synopsis

#include <cyg/bundle/bundle_api.h>

`cyg_bundle_object_t *`**`cyg_bundle_item_find`**`(`*`bc`*`, `*`entag`*`);`

Description

This function is used to generate an item access descriptor that can be subsequently used to extract data from a bundle.

The *`bc`* parameter should be a bundle descriptor reference as returned by a suitable `cyg_bundle_access_...()` call.

The *`entag`* parameter identifies the information to be accessed. The simplest form consists of passing a simple 16-bit (non-zero) `tag` identifier, used when the application requires access to the item data.

The `CYG_BUNDLE_ARBITRARY` flag can be OR-ed with the `tag` value to request access to any “arbitrary” data that may be associated with the requested `tag` item. When using `CYG_BUNDLE_ARBITRARY` then a `0x0000` tag value is acceptable, and is used to reference the parent bundle “arbitrary” data.

Return value

Pointer to the required object descriptor, or NULL if unable to find the data described by the *`entag`* or if an invalid *`entag`* value was used.

Name

cyg_bundle_item_release — Release reference to specific bundle item

Synopsis

#include <cyg/bundle/bundle_api.h>

```
void cyg_bundle_item_release(ic);
```

Description

Release handle onto bundle item. This releases any state held regarding the referenced item. The application should always release the item descriptor when it is no longer required to avoid resource leaks.

Name

cyg_bundle_enumerate — Enumerate bundle contents

Synopsis

#include <cyg/bundle/bundle_api.h>

```
int cyg_bundle_enumerate(bc, cb, private);
```

Description

This function is passed a callback function *cb* that is called once for each item present in the referenced *bc* bundle. The *private* parameter is an application specific context passed to the callback routine, and may reference any data required.

The callback function is passed the specific item identifying *tag*, along with the *length* of the item data. The *arblength* parameter provides the length of any arbitrary data associated with the item, or `0x00000000` if the item has no arbitrary data attached.

The callback function is passed the special *tag* value of `0x0000` to indicate “no more items”.

Return value

If at least 1 item exists in the bundle then `CYG_BUNDLE_VALID` is returned. If the passed *bc* parameter is invalid, or the bundle contains no items then the function will return `CYG_BUNDLE_INVALID`.

Name

cyg_bundle_info — Length of raw item

Synopsis

#include <cyg/bundle/bundle_api.h>

```
uint32_t cyg_bundle_info(ic);
```

Description

This function returns the length of the referenced object data. For uncompressed items (or “arbitrary” attachments) this is the length of the data as held in the bundle image. For compressed items this is the length of the original, raw, data.

Return value

Length of item or 0 if cannot be ascertained.

Name

cyg_bundle_read — Extract data from a bundle item

Synopsis

#include <cyg/bundle/bundle_api.h>

```
uint32_t cyg_bundle_read(ic, dst, offset, amount);
```

Description

This function copies a chunk of data from the reference bundle object to the supplied *dst* address. The *offset* parameter is the byte-offset within the data object where reading should start, with the *amount* specifying the number of bytes to be read. If the data is held in a compressed format then it will be automatically decompressed before being written to the supplied *dst* address. In this case the *offset* parameter always refers to the offset within the decompressed data.

Return value

Number of bytes read, or 0 on error. The returned number of bytes read may be less than the specified *amount* if an attempt is made to read more data than is available for the referenced object.

Chapter 214. Host tool

Introduction

The host-based command-line `bundle` tool is used to create bundle format images, as well as add and delete items, list and verify the contents, extract data, and other relevant commands.

```
Usage: bundle [option(s)] <bundlefilename> [cmds]
```

For a full list of the `bundle` tool's options and commands use the `--help` option:

```
$ bundle --help
```

The <bundlefilename> should always be supplied. The default behaviour if no operations are specified is to `verify` the <bundlefilename> and `list` its contents.

Explicit parameter options are case-insensitive. e.g. When providing a *`hash`* value either `MD5` or `md5` are acceptable and identical in their result.

The command-line bundle parameters are processed left to right, with parameters for operations following the command. The following examples are identical in the result produced:

```
$ bundle testbundle_minimum_md5.bin create hash md5
```

```
$ bundle testbundle_minimum_md5.bin hash md5 create
```

Both examples would create a bundle file `testbundle_minimum_md5.bin` that incorporates an md5 hash.

The following example creates a bundle called `egbundle.bin`. The bundle has a signature of `0x1` and includes bundle metadata from the `manifest.txt`. The entire bundle's contents will be covered by an sha256-based hash. The bundle would contain a single compressed item identified by a tag of `0x2`. The item's data comes from `short.bin` and its metadata from `itemarb.txt`. The item's contents including the tag, metadata, and compressed data will be covered by an md5 hash. Note that as the item includes compressed data an additional md5 hash for the uncompressed data would also be incorporated.

```
$ bundle egbundle.bin create hash sha256 signature 0x01 arbitrary manifest.txt add \
        0x0002:short.bin:compress:md5:itemarb.txt
```

The `bundle` tool's *`add`* command is quite flexible in its usage. It has a single parameter describing the item to be added, with multiple fields separated by ':' characters. Only the *`tag`* and *`srcfile`* are required, with other optional fields specifying whether the source file should be compressed, whether or not a hash should be added and finally what metadata, if any, is to be included with the item.

```
add tag:srcfile[:[compress][:hash[:arbitrarymetadata]]]
```

The *`tag`* value of `0x0000` is reserved for the system, with all other tag values being available for application use. This gives a maximum possible bundle item count of `65635` items, which is unlikely to be a limitation for embedded targets. Most bundles will contain a small (<`10`) number of items, e.g. the main target application, FPGA initialisation data, device initialisation tables, etc.

`add` command examples:

Uncompressed, no hash

```
add 0x0001:datafile
```

Compressed, no hash

```
add 0x2:dfile:compress
```

Compressed, MD5 hash

```
add 11:dfile:c:md5
```

Uncompressed, CRC-32 hash with arbitrary data

```
add 0xF:dfile::crc32:textfile
```

Compressed, no hash with arbitrary data

```
add 2:dfile:C::textfile
```

The `--commands` option allows for a fixed set of bundle operations to be held in a file, rather than being passed individually as command line options to the tool. Individual operations (e.g. command name and its required arguments) should *NOT* be split across lines, but multiple lines are allowed. Lines that start with '#' as the first non-whitespace character are treated as comments, and ignored.

Note

No item metadata add commands are included since we can use “extract” to get data and then “delete” and re-“add” with the required arbitrary file if required.

Warning

Filenames in commands cannot contain ':' since it is used as a field delimiter in the <item> description.

The bundle package includes the complete sources for the host tool. eCosPro releases include a pre-built version of the tool for either Linux or Windows as appropriate. If needed the tool can be built from the supplied source, with the only non-standard-library dependency being the “zlib” library. Linux systems will normally provide “zlib” as standard, though it is easily built if required for other host systems.

Chapter 215. Bundle tests

bundle1

The bundle1 test application provides a set of pre-built valid and invalid bundle images, and verifies the bundle run-time support against these “known” images. It provides a method of verifying that any changes to the eCos bundle access sources remain backwards compatible and have not had an adverse effect.

Part LXX. RTT

Table of Contents

Chapter 216. RTT overview

Introduction

The `CYGPKG_RTT` package provides a standard Segger RTT (Real Time Transfer) implementation to eCos applications.

Note

Host access to RTT channels is not limited to the Segger debug tools. Access is supported by 3rd-party tools, including, for example, Ronetix PEEDI and OpenOCD. It is not a feature limited to use with J-Link/J-TracePro H/W debug setups.

This package is covered by an “AS IS” license as distributed in the original RTT package:

Example 216.1. “AS IS” License

USE OF THIS SOFTWARE, EVEN IF ADVISED OF THE POSSIBILITY OF SUCH
DAMAGE.
```

For definitive RTT documentation please refer to the main Segger J-Link RTT website. We do not duplicate that documentation here.

Chapter 217. Configuration

This chapter shows how to incorporate the RTT support into an eCos configuration, and how to configure it once included.

Configuration Overview

The RTT support is contained in a single eCos package `CYGPKG_RTT`. However, some functionality may be dependant on other eCos features. e.g. the Cortex-M HAL.

Quick Start

Incorporating the RTT support into your application is straightforward. The essential starting point is to incorporate the RTT eCos package (`CYGPKG_RTT`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Depending on the RTT package configuration, and the other packages present in the configuration, further package specific configuration **may** be required. For example, the `CYGPKG_HAL_CORTEXM` packages allows for the use of RTT for HAL diagnostics, but the option needs to be explicitly selected.

Options

Various package specific configuration settings define how the RTT world is present.

`CYGNUM_RTT_MAX_UP_BUFFERS`

This option configures the number of UP buffers (Target->Host) available. This value should be at least `2` if also using `CYGPKG_SYSTEMVIEW` for event tracing.

`CYGNUM_RTT_BUFFER_SIZE_UP`

This option configures the size (in bytes) of the buffer used for terminal output (UP channel 0) from the Target to the Host.

`CYGNUM_RTT_MAX_DOWN_BUFFER`

This option configures the number of DOWN buffers (Host->Target) available.

`CYGNUM_RTT_BUFFER_SIZE_DOWN`

This option configures the size (in bytes) of the buffer for terminal input from the Host to the Target. For exampe this could be used for keyboard input. Normally the terminal DOWN buffer can be significantly smaller than the corresponding terminal UP buffer since external tool interaction is going to be less than diagnostics generated.

`CYGNUM_RTT_BUFFER_SIZE_PRINTF`

This option configures the size of the internal buffer used for RTT bulk-send of `printf` characters via RTT.

`CYG_RTT_MODE`

This option sets the default, initial, operation mode for Target->Host buffers. Use `NO_BLOCK_SKIP` for non-blocking TX where data not yet uploaded is overwritten. Use `NO_BLOCK_TRIM` for non-blocking TX where further data is dropped if the upload buffer is full. Use `BLOCK_IF_FIFO_FULL` when the RTT calls should block until space is available in the upload buffer, so no data is lost. The default setting can be over-ridden at run-time by an application if required, via the `SEGGER_RTT_ConfigUpBuffer()` function.

`CYGNUM_RTT_MEMCPY_BYTELOOP`

If required this option replaces the standard `memcpy()` usage with a byte loop. The byte loop can have a lower overhead than `memcpy()` if small amounts of data are being copied, and may be required for some architectures where memory access restrictions are in place.

`CYGNUM_RTT_MAX_INTR_PRI`

The priority for the RTT lock.

`CYGDAT_RTT_SECTION`

This option defines a string with the name of the section to be used for the RTT data objects. If relevent for a target configuration this will allow the explicit placing of the RTT structures into a specific memory area (e.g. SRAM). It is the responsibility of the developer to choose a section name supported by the target architecture linker script. For example, for most target architectures this can be a section named with the prefix "`.sram`", e.g. "`.sram.rtt`". If the option is not enabled then the RTT data structures are linked to the normal data section for the target configuration.

If this option is enabled then the further option `CYGDAT_RTT_BUFFER_SECTION` is available, which can be set to allow the explicit placement of RTT buffers. The `CYGDAT_RTT_BUFFER_SECTION` option defines the string with the name of the section to be used for the RTT up and down "Terminal" buffers. If this option is not enabled, but `CYGDAT_RTT_SECTION` is, then the buffers will be placed in the named `CYGDAT_RTT_SECTION`.

`CYGBLD_RTT_PRINTF`

The `SEGGER_RTT_printf()` implementation is not normally required, since the standard eCos diag_printf() provides similar functionality. This option can be enabled if required by the application.

Chapter 218. eCos port

Overview

The goal for the CYGPKG_RTT package is to avoid, where possible, having to have any core RTT source file changes made specifically for eCos. This is to ensure that re-imports of newer versions of the Segger sources involve minimal effort. The files are as provided in the official JLinkRTT release package as imported, with the following exceptions:

1. Files have been moved, unmodified, to create a standard eCos package tree structure to integrate with the eCosPro build environment

   Only **relevant** files from the original project have been included in the eCos package.

2. The file include/Config/SEGGER_RTT_Conf.h is a wrapper that includes the original, **unmodified**, version of the Segger supplied header. This is done to allow for configuration of the underlying RTT system without having to change the original header source file.

3. Portions of the test source files found in the original Examples directory have been used, but wrapped as eCos test applications. This has been done to avoid inclusion of unnecessary run-time code.

The current RTT version provided by the eCos package is the SEGGER_RTT_V788m release contained within the JLink_Linux_V788m_x86_64.tgz Linux package.

The following table highlights the files taken from the RTT package and their new location within the eCos CYGPKG_RTT package:

Original	eCos package
Config/SEGGER_RTT_Conf.h	include/Config/base/SEGGER_RTT_Conf.h
RTT/SEGGER_RTT.h	include/RTT/SEGGER_RTT.h
RTT/SEGGER_RTT.c	src/SEGGER_RTT.c
RTT/SEGGER_RTT_ASM_ARMv7M.S	src/SEGGER_RTT_ASM_ARMv7M.S
RTT/SEGGER_RTT_printf.c	src/SEGGER_RTT_printf.c
LICENSE.md	doc/LICENSE.md
README.md	doc/README.md

The include structure clunkiness is a side-effect of Segger embedding relative pathnames in their original sources, which we have maintined for the sake of forward maintenance.

Chapter 219. Test Programs

Test Programs

Some RTT specific tests are built and can be used to verify correct operation of the support. The test cases built depend on the configuration options.

1. `rtt_printf`

   This test is built when `CYGBLD_RTT_PRINTF` is enabled. It provides an example of `SEGGER_RTT_printf()` use.

Note

`CYGBLD_RTT_PRINTF` is disabled by default since the standard eCos `diag_printf()` et-al provides for vararg based diagnostics, and so including `SEGGER_RTT_printf()` will just be an increase in the application footprint, since the eCos diagnostic routines are likely to be present from use by other packages.

Part LXXI. eCos Support for Segger SystemView tracing

Table of Contents

Chapter 220. SystemView overview

Introduction

Current version based on `SystemView_Src_V350a.zip` downloaded from the Segger website.

Some of the files in this package are covered by the Segger AS-IS license.

The RTT sample code can also be found in the JLink package. e.g. `JLink_Linux_V695a_x86_64/Samples/RTT/SEGGER_RTT_V695a.tgz`

The following table highlights the files taken from the original `SystemView_Src` release, and their new location within the eCos `CYGPKG_SYSTEMVIEW` package:

Original	**eCos package**
`Config/SEGGER_SYSVIEW_Conf.h`	`include/Config/SEGGER_SYSVIEW_Conf.h`
`Config/Global.h`	`include/Global.h`
`SEGGER/SEGGER.h`	`include/SEGGER.h`
`SEGGER/SEGGER_SYSVIEW_ConfDefaults.h`	`include/SEGGER_SYSVIEW_ConfDefaults.h`
`SEGGER/SEGGER_SYSVIEW.h`	`include/segger_SYSVIEW.h`
`SEGGER/SEGGER_SYSVIEW_Int.h`	`src/3rd_party/SEGGER/SEGGER_SYSVIEW_Int.h`
`SEGGER/SEGGER_SYSVIEW.c`	`src/3rd_party/SEGGER/SEGGER_SYSVIEW.c`

Currently these Segger supplied sources are **unmodified**, which should allow for easier updating to newer releases from Segger if/when required.

The SystemView host application has support for receiving telemetry from: J-Link/RTT H/W debug connection, serial line (UART) or a TCP/IP network connection.

The Segger SystemView documentation (Segger document: UM08027) provides an overview of using the host application, as well as technical details of the target implementation API, of which this eCos package is an example. If required, the developer can embed suitable target side calls into their code as needed (e.g. `SEGGER_SYSVIEW_MarkStart()`) when relying on the support from this package.

Note

In this documentation we refer to the eCos target side implementation as `CYGPKG_SYSTEMVIEW` (the target package), and use SystemView to refer to the host side Segger application.

Chapter 221. SystemView Recording

There are two forms of continuous recording supported. The use of a H/W debugger or a dedicated Recorder communication channel.

H/W debugger

This mechanism records data from an active H/W debugger RTT session, where the H/W debugger directly accesses the target memory to extract the SystemView events. There is no requirement for any (other than the basic core `CYGPKG_SYSTEMVIEW` setup) run-time code on the target being sampled, and normally would provide for the lowest overhead, highest throughput, mechanism for obtaining instrumentation data.

As with all tracing involving target side software (in this case the writing of the event information into the RTT memory buffers), there will be a cost to the performance of the system not experienced when `CYGPKG_SYSTEMVIEW` is not enabled.

Support for receiving RTT recorded events into the host SystemView application can take two forms. Direct J-Link/J-Trace support or a socket based TCP/IP proxy helper service.

J-Link/J-Trace H/W debugger

This direct H/W debugger access is selected by the SystemView application `J-Link` Recorder Configuration option.

svproxy

When using a H/W debugger interface that supports exposing RTT channels via TCP/IP network streams then a proxy helper application can be used to obtain the H/W debugger accessed RTT buffer data for SystemView from the debugger, and present a SystemView application `IP` Recorder channel to the viewer application.

The `host/svproxy.c` source implements a simple BSD socket interface Linux example implementation. It provides a connection between the Segger SystemView application `IP` Recorder support and a non-Segger H/W debugger which presents the data from RTT channel 1 "SystemView" as a network stream (for example Ronetix PEEDI, or OpenOCD).

The proxy provides a service on a specified port allowing the SystemView application to connect and wait for event data to be supplied. The proxy does not need to execute on the same host as the SystemView application.

The target H/W debugger supplied stream should be referenced using its network address and port number as presented by the H/W debugger session. NOTE: The examples below assume that the target H/W debug session has been started, and that the eCos application executed until after the `SEGGER_SYSVIEW_Conf()` function has completed (to initialise the data structure searched for by the H/W debugger). This can be achieved by setting a breakpoint on the function `cyg_hal_invoke_constructors()` as a holding place whilst the H/W debugger network server is started and the `svproxy` tool executed.

For example, assuming a PEEDI configured to expose the RTT channel 1 on port 19112 as follows:

```
rt1064evk_swd> rtt setup 0x80030000 0x10000
rt1064evk_swd> rtt start
++ info: control block found at 0x8003AD1C
rt1064evk_swd> rtt list
target -> host (max 2):
    0: 'Terminal', size 1024
    1: 'SysView', size 8192
host -> target (max 2):
    0: 'Terminal', size 16
    1: 'SysView', size 8
rt1064evk_swd> rtt server_start 19112 1
```

Using OpenOCD is very similar, where via the telnet server exposed via OpenOCD or using the GDB `monitor` command support, a RTT server can be started supplied channel 1 on a network connection. The only difference being that the `rtt setup` requires the Segger identification string when searching for the memory based descriptor. e.g.

```
rtt setup 0x24000000 0x40000 “SEGGER RTT”
rtt start
rtt server start 19112 1
```

I/O Communication

The SystemView application Recorder Configuration allows for `UART` (serial) or `IP` (TCP/IP socket) to be selected as sources for obtaining instrumentation events from the target device.

Note

Currently this eCos package does not yet support the direct provision of the `IP` mechanism. See the proxy support for an `IP` Recorder access to a H/W debugger connection.

These I/O channel based mechanisms, whilst not requiring a H/W debugger to be attached, do require further resources on the target system. Support code is required to provide the necessary I/O transport. Two **mutually exclusive** solutions are provided.

`CYGOPT_SYSTEMVIEW_RECORDER_HAL`

> If the target platform/variant supports the feature then this option can be configured. It is a very simple, low-level, blocking-write transport implementation that will not by itself generate Kernel instrumentation events. This makes it usable if high-frequency Kernel instrumentation is enabled (e.g. detailed ISR, thread and synchronisation object activity).
>
> This approach assumes a UART-style interface is used. The platform supplies an initialisation routine and a pair of routines to read and write data to the host SystemView application. This means that this option is only available on targets where the HAL provides the relevant support (e.g. `mimxrt1xxx_evk`, `stm32f746g_disco`, ...).

`CYGOPT_SYSTEMVIEW_RECORDER`

> When configured this enables a higher-level Recorder approach, where a (normally low-priority) helper thread provides the periodic upload of event data to the host SystemView application.
>
> The `UART` configuration requires a dedicated eCos serial I/O (UART port or USB CDC-ACM) connection. There is a greater run-time overhead to supporting this transport option over and above the J-Link H/W debugger approach or `CYGOPT_SYSTEMVIEW_RECORDER_HAL` approach. At least one helper thread is created, and the eCos I/O API is used. If Kernel instrumentation is enabled then the helper code will also be instrumented, which will greatly increase the instrumentation load.
>
> If Kernel instrumentation is not enabled then this solution is sufficient for tracing the standard eCos thread, ISR and operation activity, along with any application generated SystemView events (e.g. markers).

Support for the Recorder feature can be manually enabled in the package configuration if required.

Performance and Analysis

When performing analysis of data captured by the SystemView application, where a run-time I/O mechanism is in use, the user needs to be aware that the act of recording measurement events **will** affect the overall performance of the system. This needs to be taken into account when checking reported performance.

Note

The following timing measurements were made against a MIMXRT1064-EVK platform (Cortex-M7 clocked at 432MHz) with a simple GPIO driven signal on J23#1 measured using a Saleae LogicPro16. The GPIO line was set and cleared as the first and last operations respectively of the `Cyg_RealTimeClock::isr` which is the ISR handler for the `SysTick` event.

For the following table the `SysTick` ISR was chosen as an example, since it is a high-frequency, common event that is likely to be used when analysing scheduling and thread interactions. On most systems it is configured with a 10ms period.

In the following table, the acronyms used in the headers are:

KIM

Build with Kernel Instrumentation to Memory buffer configured, with interrupt events instrumented. This form of instrumentation has a reasonably low overhead, but is limited to the size of buffer that can be set aside on the target.

KIS

Build with Kernel Instrumentation to SystemView events (RTT memory buffer), with interrupt events instrumented. This approach allows for the possibility of continuous recording over long execution runs depending on the RTT access tools used.

SVHR

SystemView events delivered to the host application via an eCos SystemView HAL Recorder (low-level direct I/O) with the UART using a baud rate of `1000000` (1MHz).

SVRTT

SystemView events delivered to the host application via a J-Trace PRO H/W debugger directly accessing RTT memory buffers, via a 4MHz SWD connection.

Table 221.1. Example Instrumentation “cost”

`Cyg_RealTimeClock::isr()`	**`-O2`**	**`-O0`**	**`-O2`** **KIM**	**`-O0`** **KIM**	**`-O0`** **SVRTT**	**`-O0`** **KIS** **SVRTT**	**`-O0`** **KIS** **SVHR**
Handler function execution time captured as the sampled GPIO SET/CLR period	0.7us	~3us	~8us	~18us	~3us	~4us	~202us
SystemView v3.52a reported `SysTick` execution time (includes ISR entry/exit code)	-	-	-	-	~3.8us	~8.9us	~370us

As can be seen there is a **huge** difference in the time taken to execute that single, relatively simple, ISR function depending on the compiler optimisation level, whether or not memory-buffer based Kernel-instrumentation is enabled, or whether the kernel-instrumentation is directed to a SystemView Recorder (the HAL recorder in the example above) where there is the cost of transmitting the bytes over a UART channel (where the configured baud rate of that channel will also affect the timing reported) or is accessed via H/W debugger background memory accesses. The table highlights that any software based instrumentation solution has a hit on the system throughput.

So tuning of the SystemView captures, and the speed of the underlying transport channel need to be considered when performing anaylsis based on how the data was captured for SystemView.

Overflows

Since the normal target operating mode is to perform non-blocking writes of events into the RTT capture buffer, it is possible (and expected in some cases) that the host read side (whether J-Link or communication channel based Recorder) will detect an `*** Overflow ***`.

This can occur if the volume/rate of events being generated is overloading the available I/O channel, in which case the target configuration can be updated to reduce the quantity of events (by disabling tracking of certain events), or by increasing the buffering available to the target-side `CYGPKG_SYSTEMVIEW` support.

It is also possible for overflow to occur as a side-effect of the host SystemView application not actually recording (i.e. “Start Recording” not being triggered). If the `CYGPKG_SYSTEMVIEW` configuration is using `CYGFUN_SYSTEMVIEW_START_ON_INIT` then the eCos code will be recording events from startup, which may be before the host SystemView application can actually connect to the device when using a communication channel Recorder implemented by the eCos run-time; since before SystemView can attach the eCos target has to initialise and provide the drivers/software-stack needed for the I/O access. e.g. Presenting the `UART` Recorder via a target USB CDC-ACM device.

When configured for `CYGOPT_SYSTEMVIEW_RECORDER_HAL` as the event communication channel, the option `CYGOPT_SYSTEMVIEW_RECORDER_HAL_WAIT` is made available. This option is normally disabled, since when enabled it will cause the run-time to disable interrupts and wait in a **busy** poll waiting to receive the host SystemView application “connect and start a recording” commands. This feature can be used to ensure that all captured events are made available to the SystemView application; which may be critical when instrumenting/analysising application initialisation. The caveat is that the target will appear to be “hung” until it receives a valid hello message from the SystemView application.

Chapter 222. Events

When the `CYGBLD_SYSTEMVIEW_ENABLED` option is enabled the eCos run-time will **always** generate SystemView thread events. This allows basic application flow of control between threads to be analysed.

SystemView Events

The `CYGPKG_SYSTEMVIEW` package also provides for generation of records for some other system events.

The following options are enabled by default, but can be disabled to reduce the instrumentation capture load if overflows are encountered.

`CYGIMP_SYSTEMVIEW_TRACE_ISR`

Used to track ISR (Interrupt Service Routine) entry and exit.

`CYGIMP_SYSTEMVIEW_TRACE_TIMERS`

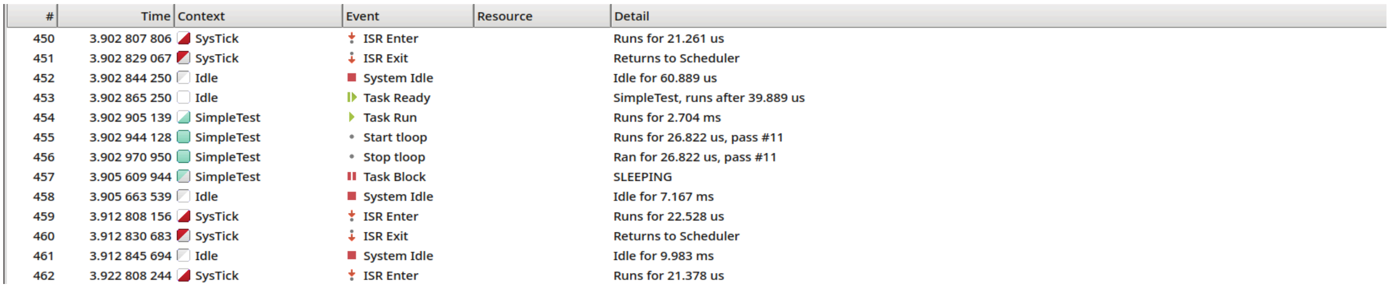
Used to track Kernel alarm function calls. The events wrap the alarm calls within the Kernel `Cyg_Counter::tick()` function.

`CYGIMP_SYSTEMVIEW_TRACE_HEAP`

Used to track `CYGPKG_MEMALLOC` heap creation, allocation and free events. These events can be used to track dynamic memory allocation footprints of an application.

The following image is a screenshot from the SystemView "System" event window highlighting the basic thread and ISR information recorded. It shows a thread named "SimpleTest" being woken, executing for 2.704ms before sleeping and the idle thread executing again.

Figure 222.1. Example from application with `SEGGER_SYSVIEW_Mark()` use



#	Time	Context	Event	Resource	Detail
450	3.902 807 806	SysTick	ISR Enter		Runs for 21.261 us
451	3.902 829 067	SysTick	ISR Exit		Returns to Scheduler
452	3.902 844 250	Idle	System Idle		Idle for 60.889 us
453	3.902 865 250	Idle	Task Ready		SimpleTest, runs after 39.889 us
454	3.902 905 139	SimpleTest	Task Run		Runs for 2.704 ms
455	3.902 944 128	SimpleTest	Start tloop		Runs for 26.822 us, pass #11
456	3.902 970 950	SimpleTest	Stop tloop		Ran for 26.822 us, pass #11
457	3.905 609 944	SimpleTest	Task Block		SLEEPING
458	3.905 663 539	Idle	System Idle		Idle for 7.167 ms
459	3.912 808 156	SysTick	ISR Enter		Runs for 22.528 us
460	3.912 830 683	SysTick	ISR Exit		Returns to Scheduler
461	3.912 845 694	Idle	System Idle		Idle for 9.983 ms
462	3.922 808 244	SysTick	ISR Enter		Runs for 21.378 us

Aside: The above example also highlights the use of an application generated SystemView "marker". The events #`455` and #`456` show the application marked block with the name `tloop` took `26.822us` for the 11th execution of the code covered by the marker.

Kernel Instrumentation

If the eCos Kernel instrumentation (`CYGPKG_KERNEL_INSTRUMENT`) feature is enabled along with the `CYGBLD_SYSTEMVIEW_KERNEL_INSTRUMENT` option then `CYGPKG_SYSTEMVIEW` provides a wrapper header (`CYGBLD_KERNEL_INSTRUMENT_WRAPPER_H`) to replace the Kernel package implementation with code to generate SystemView events.

Note

In this case the normal Kernel instrumentation options `CYGPKG_KERNEL_INSTRUMENT_TIMESTAMPS` and `CYGPKG_KERNEL_INSTRUMENT_BUFFER` are ignored, since the `CYGPKG_SYSTEMVIEW` support is used to record instrumentation. However the `CYGPKG_KERNEL_INSTRUMENT_BUFFER` option should be disabled.

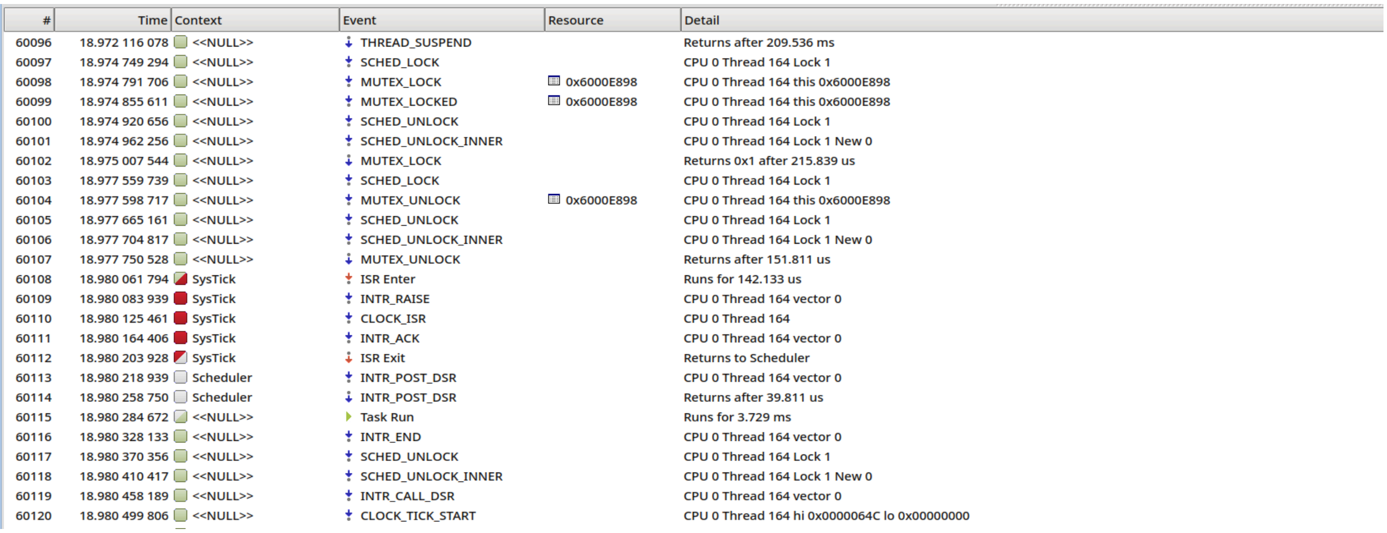
The specific `CYGPKG_KERNEL` instrumentation types can then be manually enabled/disabled as required for the SystemView analysis being performed. e.g. `CYGPKG_KERNEL_SCHED` instrumenting low-level scheduler events can be disabled to save on bandwith; if tracking thread and synchronisation object events is sufficient for the analysis.

Similarly, most packages that make use of Kernel instrumentation do so as eCos configuration conditionals.

These low-level kernel instrumentation events can provide very low-level detail of the inner processing of eCos, and the application use of kernel scheduling objects, but it can generate vast amounts of trace data.

The following image is a screenshot from the SystemView “System” event window which highlights the level of detail available when Kernel instrumentation is enabled. Entry #`60098` is the start of a mutex lock operation, with the lock call completing after `215.839us` as shown by entry #`60102`.

Figure 222.2. Example from application with Kernel instrumentation enabled



#	Time	Context	Event	Resource	Detail
60096	18.972 116 078	<<NULL>>	THREAD_SUSPEND		Returns after 209.536 ms
60097	18.974 749 294	<<NULL>>	SCHED_LOCK		CPU 0 Thread 164 Lock 1
60098	18.974 791 706	<<NULL>>	MUTEX_LOCK	0x6000E898	CPU 0 Thread 164 this 0x6000E898

The above screenshot is from an execution of the `CYGPKG_KERNEL` test `mutex3`, where the created thread has not been given a name, hence the empty thread name being displayed as `<<NULL>>`. This example was captured on the eCos `stm32f746g_disco` target platform (executing at 168MHz and using the UART HAL Recorder with a baud rate of 2MHz).

Warning

When using eCos itself to support the `CYGOPT_SYSTEMVIEW_RECORDER` channel this means that the act of providing support to SystemView will itself add more low-level events, further compounded if the USB CDC-ACM or network stacks are used for the Recorder support, since they will have their own threads and kernel synchronisation objects that will further increase the load. It is more likely that RTT overflows will occur with such a configuration.

It is recommended to use, when available for the selected target, the lower-level `CYGOPT_SYSTEMVIEW_RECORDER_HAL` option when using Kernel instrumentation **if** the use of H/W RTT access is not available.

Infra Trace

In extremis, the Infrastructure (`CYGPKG_INFRA`) package option `CYGDBG_USE_TRACING` can be enabled in conjunction with selecting `CYGDBG_INFRA_DEBUG_TRACE_ASSERT_SYSTEMVIEW` as the trace destination output module.

This feature will provide a trace of the execution of suitably annotated functions. This will mostly be similar in nature to the information that can be obtained from enabling (the lighter weight) Kernel instrumentation, but can be useful for developers wishing to understand the location of the source for the code being executed.

Note

The use of this feature is not normally **recommended**, but can be useful for some investigation/analysis cases.

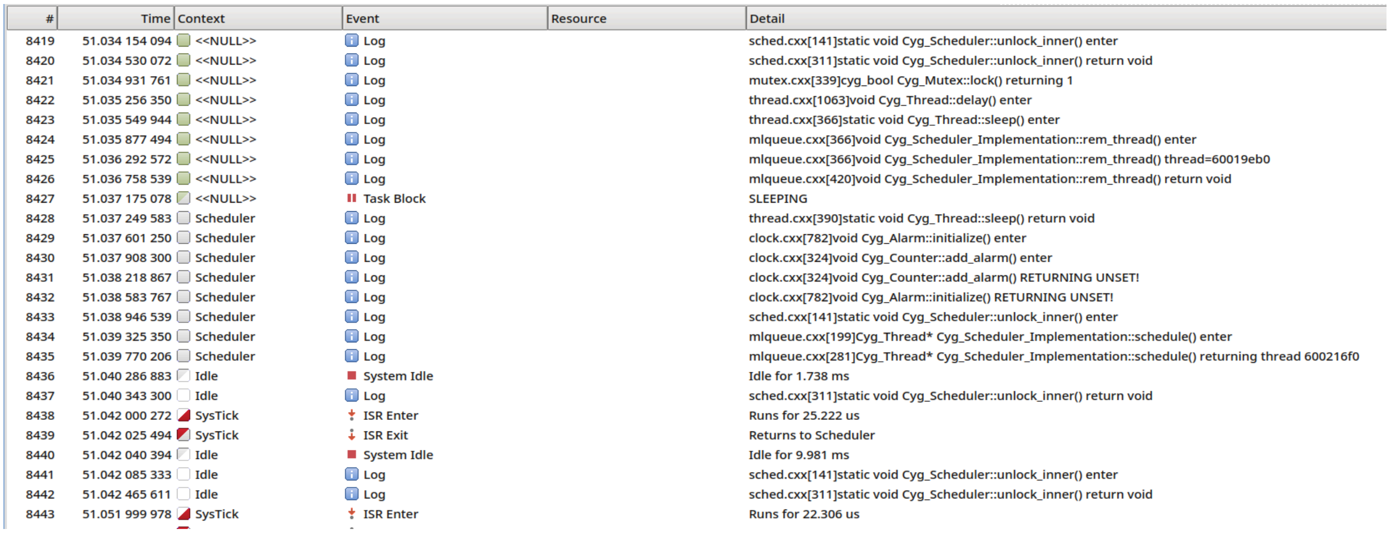
The recording of long strings via the SystemView `Log` mechanism will affect the performance of the application under test, due to the formatting and transfer overhead of long strings.

If detailed eCos operation is required then normally Kernel instrumentation would be sufficient, and whilst it can also generate significant amounts of trace data it will be less than the overhead of the `printf`-style output from the Infrastructure Tracing support.

The following image highlights the style of Tracing output generated.

The `Detail` entries are prefixed with the <*`source-filename`*>[*`source-line#`*]<*`function-name`*> fields, which are then followed by the Tracing specific message text.

Figure 222.3. Example from application using INFRA trace



#	Time	Context	Event	Resource	Detail

8437	51.040 343 300	Idle	Log		sched.cxx[311]static void Cyg_Scheduler::unlock_inner() return void
8438	51.042 000 272	SysTick	ISR Enter		Runs for 25.222 us
8439	51.042 025 494	SysTick	ISR Exit		Returns to Scheduler
8440	51.042 040 394	Idle	System Idle		Idle for 9.981 ms
8441	51.042 085 333	Idle	Log		sched.cxx[141]static void Cyg_Scheduler::unlock_inner() enter
8442	51.042 465 611	Idle	Log		sched.cxx[311]static void Cyg_Scheduler::unlock_inner() return void
8443	51.051 999 978	SysTick	ISR Enter		Runs for 22.306 us

The example above was captured on the eCos `stm32f746g_disco` target platform (executing at 168MHz and using the UART HAL Recorder with a baud rate of 2MHz).

Chapter 223. Configuration

CYGBLD_SYSTEMVIEW_ENABLED

These are the main developer configurable options for controlling `CYGPKG_SYSTEMVIEW` operation when `CYGBLD_SYSTEMVIEW_ENABLED` is enabled.

`CYGBLD_SYSTEMVIEW_KERNEL_INSTRUMENT`

This option allows the Kernel instrumentation to be replaced by SystemView event record generation, without having to explicitly add SystemView support to the existing eCos sources. A wrapper function is used to replace the low-level instrumentation call used by packages configured for Kernel instrumentation.

Note

The Kernel option `CYGPKG_KERNEL_INSTRUMENT_BUFFER` **should** be disabled when using `CYGPKG_SYSTEMVIEW` to capture Kernel instrumentation.

It is also recommended to disable the `CYGDBG_KERNEL_INSTRUMENT_FLAGS` feature, so that instrumentation events are generated unconditionally.

`CYGFUN_SYSTEMVIEW_START_ON_INIT`

If enabled then SystemView tracing is started automatically during application initialisation, so that application initialisation and startup events are captured. When this option is enabled **and** H/W debugging is being used, it is normally useful to have your debug session stop at the entry to the `SEGGER_SYSVIEW_Start()` function so that a host SystemView session can be synchronised to capture all events.

`CYGFUN_SYSTEMVIEW_STOP_ON_EXIT`

If enabled this option provides a `CYG_SYSTRACE` macro that is used by the `cyg_test_exit()` function to stop the SystemView event tracing. Since the normal test application exit implementation does not disable interrupts, it avoids continuing to record events when the main application thread has terminated.

`CYGNUM_SYSTEMVIEW_RTT_BUFFER_SIZE`

This specifies the size in bytes of the SystemView Target->Host buffer. NOTE: Depending on the target CPU frequency, and the enabled trace events a large buffer may be required to avoid capture overflow. The performance of the SystemView tracing to avoid overrun also depends on the other RTT loads on the system (e.g. diagnostics Terminal channel). Some tuning may be required in both the events captured and the RTT buffer sizes to ensure all events are captured in real-time.

`CYGIMP_SYSTEMVIEW_USE_STATIC_BUFFER`

If enabled then a statically allocated buffer for the configured maximum packlet size is used. If disabled then a stack buffer is used, with a lock used to serialise packet writing.

Warning

It is important to ensure that the stack allocations of all threads are sufficient for the extra load of the RTT operations for recording events, and also for the transmission code if a “Recorder” is being used.

`CYGNUM_SYSTEMVIEW_MAX_STRING_LEN`

This option defines the maximum string length that can be passed to the SEGGER_SYSVIEW print and description routines. It also defines the maximum packet size, so will affect stack requirements if `CYGIMP_SYSTEMVIEW_USE_STATIC_BUFFER` is **not** enabled.

`CYGIMP_SYSTEMVIEW_TRACE_ISR`

When enabled this option controls generation of SystemView trace instrumentation for ISR entry/exit events. This is distinct from the extra information recorded when the Kernel instrumentation `INTR` events are being generated.

`CYGIMP_SYSTEMVIEW_TRACE_TIMERS`

When enabled this option controls generation of SystemView trace instrumentation for timer callback function events. This is distinct from the extra information recorded when the Kernel intsrumentation `CLOCK` and `ALARM` events are being generated.

`CYGIMP_SYSTEMVIEW_TRACE_HEAP`

When enabled this option controls generation of SystemView trace instrumentation for memory allocation events from the `CYGPKG_MEMALLOC` package.

`CYGDAT_SYSTEMVIEW_APP_NAME`

This is the string used for the `Name` property recorded for a SystemView trace. It can be used to identify specific applications when working with multiple “SystemView Data” captures.

`CYGDAT_SYSTEMVIEW_CORE_NAME`

This is the string used for the `Core` identificaion property recorded for a SystemView trace. It can identify the hardware architecture used for a capture. Normally this option will have a default value set by the platform architecture support.

`CYGDAT_SYSTEMVIEW_DEVICE_NAME`
