eCosPro Reference Manual

eCosPro Reference Manual

Publication date 18 March 2024

About this reference manual

This reference manual is for eCos and eCosPro. It forms part of the eCosPro Developer's kit and includes documentation of the standard features of eCos as well documentation of eCosPro libraries and runtime features. Not all the eCosPro features or libraries documented in this reference manual may be available in the runtime code due to licensing restrictions. Some eCosPro features are subject to the eCosPro Evaluation License and require seperate licensing exclusively from eCosCentric when included in a product.

Documentation licensing terms

Open Publication License

The document containing or referencing this license was produced in full, or in part if the document contains multiple licensing references, from work that is subject to the terms and conditions set forth in the Open Publication License, v1.0 or later (the latest version is presently available at http://www.opencontent.org/openpub/).

Distribution of the work or derivative of the work in any standard (paper) book form is prohibited unless prior permission is obtained from the copyright holder(s).

eCosPro Non-Commercial Public License

The document containing or referencing these licenses was produced in full, or in part if the document contains multiple licensing references, from work that is subject to the terms and conditions of the eCosPro Non-Commercial Public License.

Distribution of the work or derivative of the work is permitted for Non-Commercial[*] use only.

[*] As defined by the eCosPro Non- Commercial Public License.

eCosPro License

The document containing or referencing these licenses was produced in full, or in part if the document contains multiple licensing references, from work that is subject to the terms and conditions of the eCosPro License.

Distribution of the work or derivative of the work is not permitted.

Apache 2.0 License

The document containing or referencing this license was produced in full, or in part if the document contains multiple licensing references, from work that is subject to the terms and conditions of the Apache 2.0 License.

Microchip “AS IS” License

The document containing or referencing these licenses was produced in full, or in part if the document contains multiple licensing references, from work that is subject to the terms and conditions of the Basic BSD-Style license that accompanies Microchip Software's cryptoauthlib.

Part I. The eCos Kernel

Name

Kernel — Overview of the eCos Kernel

Description

The kernel is one of the key packages in all of eCos. It provides the core functionality needed for developing multi-threaded applications:

1. The ability to create new threads in the system, either during startup or when the system is already running.
2. Control over the various threads in the system, for example manipulating their priorities.
3. A choice of schedulers, determining which thread should currently be running.
4. A range of synchronization primitives, allowing threads to interact and share data safely.
5. Integration with the system's support for interrupts and exceptions.

In some other operating systems the kernel provides additional functionality. For example the kernel may also provide memory allocation functionality, and device drivers may be part of the kernel as well. This is not the case for eCos. Memory allocation is handled by a separate package. Similarly each device driver will typically be a separate package. Various packages are combined and configured using the eCos configuration technology to meet the requirements of the application.

The eCos kernel package is optional. It is possible to write single-threaded applications which do not use any kernel functionality, for example RedBoot. Typically such applications are based around a central polling loop, continually checking all devices and taking appropriate action when I/O occurs. A small amount of calculation is possible every iteration, at the cost of an increased delay between an I/O event occurring and the polling loop detecting the event. When the requirements are straightforward it may well be easier to develop the application using a polling loop, avoiding the complexities of multiple threads and synchronization between threads. As requirements get more complicated a multi-threaded solution becomes more appropriate, requiring the use of the kernel. In fact some of the more advanced packages in eCos, for example the TCP/IP stack, use multi-threading internally. Therefore if the application uses any of those packages then the kernel becomes a required package, not an optional one.

The kernel functionality can be used in one of two ways. The kernel provides its own C API, with functions like `cyg_thread_create` and `cyg_mutex_lock`. These can be called directly from application code or from other packages. Alternatively there are a number of packages which provide compatibility with existing API's, for example POSIX threads or µITRON. These allow application code to call standard functions such as `pthread_create`, and those functions are implemented using the basic functionality provided by the eCos kernel. Using compatibility packages in an eCos application can make it much easier to reuse code developed in other environments, and to share code.

Although the different compatibility packages have similar requirements on the underlying kernel, for example the ability to create a new thread, there are differences in the exact semantics. For example, strict µITRON compliance requires that kernel timeslicing is disabled. This is achieved largely through the configuration technology. The kernel provides a number of configuration options that control the exact semantics that are provided, and the various compatibility packages require particular settings for those options. This has two important consequences. First, it is not usually possible to have two different compatibility packages in one eCos configuration because they will have conflicting requirements on the underlying kernel. Second, the semantics of the kernel's own API are only loosely defined because of the many configuration options. For example `cyg_mutex_lock` will always attempt to lock a mutex, but various configuration options determine the behaviour when the mutex is already locked and there is a possibility of priority inversion.

The optional nature of the kernel package presents some complications for other code, especially device drivers. Wherever possible a device driver should work whether or not the kernel is present. However there are some parts of the system, especially those related to interrupt handling, which should be implemented differently in multi-threaded environments containing the eCos kernel and in single-threaded environments without the kernel. To cope with both scenarios the common HAL package provides a driver API, with functions such as `cyg_drv_interrupt_attach`. When the kernel package is present these driver API functions map directly on to the equivalent kernel functions such as `cyg_interrupt_attach`, using macros to avoid any overheads. When the kernel is absent the common HAL package implements the driver API directly, but this implementation is simpler than the one in the kernel because it can assume a single-threaded environment.

Schedulers

When a system involves multiple threads, a scheduler is needed to determine which thread should currently be running. The eCos kernel can be configured with one of three schedulers, the bitmap scheduler, the multi-level queue (MLQ) scheduler and the SMP scheduler (MLQSMP). The bitmap scheduler is somewhat more efficient, but has a number of limitations. Most systems will instead use the MLQ scheduler, and MLQSMP in SMP configurations. Other schedulers may be added in the future, either as extensions to the kernel package or in separate packages.

Both the bitmap and the MLQ schedulers use a simple numerical priority to determine which thread should be running. The number of priority levels is configurable via the option `CYGNUM_KERNEL_SCHED_PRIORITIES`, but a typical system will have up to 32 priority levels. Therefore thread priorities will be in the range 0 to 31, with 0 being the highest priority and 31 the lowest. Usually only the system's idle thread will run at the lowest priority. Thread priorities are absolute, so the kernel will only run a lower-priority thread if all higher-priority threads are currently blocked.

The bitmap scheduler only allows one thread per priority level, so if the system is configured with 32 priority levels then it is limited to only 32 threads — still enough for many applications. A simple bitmap can be used to keep track of which threads are currently runnable. Bitmaps can also be used to keep track of threads waiting on a mutex or other synchronization primitive. Identifying the highest-priority runnable or waiting thread involves a simple operation on the bitmap, and an array index operation can then be used to get hold of the thread data structure itself. This makes the bitmap scheduler fast and totally deterministic.

The MLQ schedulers (MLQ and MLQSMP) allows multiple threads to run at the same priority. This means that there is no limit on the number of threads in the system, other than the amount of memory available. However operations such as finding the highest priority runnable thread are a little bit more expensive than for the bitmap scheduler.

Optionally the MLQ schedulers support timeslicing, where the scheduler automatically switches from one runnable thread to another when some number of clock ticks have occurred. Timeslicing only comes into play when there are two runnable threads at the same priority and no higher priority runnable threads. If timeslicing is disabled then a thread will not be preempted by another thread of the same priority, and will continue running until either it explicitly yields the processor or until it blocks by, for example, waiting on a synchronization primitive. The configuration options `CYGSEM_KERNEL_SCHED_TIMESLICE` and `CYGNUM_KERNEL_SCHED_TIMESLICE_TICKS` control timeslicing. The bitmap scheduler does not provide timeslicing support. It only allows one thread per priority level, so it is not possible to preempt the current thread in favour of another one with the same priority.

An experimental timeslicing feature is also available in eCosPro, which is "fair" timeslicing, and can be enabled with the `CYGSEM_KERNEL_SCHED_TIMESLICE_FAIR` configuration option. By default, normal timeslicing does not guarantee that different threads get a similar amount of CPU time. In fact, a thread could use most of one of its timeslice ticks allocated to it, but then block shortly before the tick occurs, at which point as far as the kernel is concerned, it effectively used no time at all from that tick. In some applications where some threads may often be operating on small parts of work that take less than a tick, or where there is a periodic event such as an external interrupt that regularly causes a thread to be pre-empted and this can occasionally happen roughly synchronised to the kernel clock, then this can result in other threads at the same priority being starved. The fair timeslicing option seeks to prevent this by using information from the underlying HAL clock to determine a more accurate view of how much CPU time a thread has used. This is naturally at the expense of a slightly greater context switch time. With this option enabled, threads should become more fairly timesliced, although due to the granularity of the kernel clock, there will always be a small error margin of roughly half a kernel clock tick on average. This feature can be tested with the `timeslice_fair` kernel test.

Another important configuration option that affects the MLQ schedulers is `CYGIMP_KERNEL_SCHED_SORTED_QUEUES`. This determines what happens when a thread blocks, for example by waiting on a semaphore which has no pending events. The default behaviour of the system is last-in-first-out queuing. For example if several threads are waiting on a semaphore and an event is posted, the thread that gets woken up is the last one that called `cyg_semaphore_wait`. This allows for a simple and fast implementation of both the queue and dequeue operations. However if there are several queued threads with different priorities, it may not be the highest priority one that gets woken up. In practice this is rarely a problem: usually there will be at most one thread waiting on a queue, or when there are several threads they will be of the same priority. However if the application does require strict priority queueing then the option `CYGIMP_KERNEL_SCHED_SORTED_QUEUES` should be enabled. There are disadvantages: more work is needed whenever a thread is queued, and the scheduler needs to be locked for this operation so the system's dispatch latency is worse. If the bitmap scheduler is used then priority queueing is automatic and does not involve any penalties.

Some kernel functionality is currently only supported with the MLQ schedulers, not the bitmap scheduler. This includes support for SMP systems, and protection against priority inversion using either mutex priority ceilings or priority inheritance.

The MLQSMP scheduler is a derivative of the MLQ scheduler that has some additional features for controlling thread affinity and CPU activation. The MLQ scheduler can support SMP operation, but does not support the additional features. By default, eCosPro uses the MLQSMP scheduler when configured for SMP operation.

Synchronization Primitives

The eCos kernel provides a number of different synchronization primitives: mutexes, condition variables, counting semaphores, mail boxes and event flags.

Mutexes serve a very different purpose from the other primitives. A mutex allows multiple threads to share a resource safely: a thread locks a mutex, manipulates the shared resource, and then unlocks the mutex again. The other primitives are used to communicate information between threads, or alternatively from a DSR associated with an interrupt handler to a thread.

When a thread that has locked a mutex needs to wait for some condition to become true, it should use a condition variable. A condition variable is essentially just a place for a thread to wait, and which another thread, or DSR, can use to wake it up. When a thread waits on a condition variable it releases the mutex before waiting, and when it wakes up it reacquires it before proceeding. These operations are atomic so that synchronization race conditions cannot be introduced.

A counting semaphore is used to indicate that a particular event has occurred. A consumer thread can wait for this event to occur, and a producer thread or a DSR can post the event. There is a count associated with the semaphore so if the event occurs multiple times in quick succession this information is not lost, and the appropriate number of semaphore wait operations will succeed.

Mail boxes are also used to indicate that a particular event has occurred, and allows for one item of data to be exchanged per event. Typically this item of data would be a pointer to some data structure. Because of the need to store this extra data, mail boxes have a finite capacity. If a producer thread generates mail box events faster than they can be consumed then, to avoid overflow, it will be blocked until space is again available in the mail box. This means that mail boxes usually cannot be used by a DSR to wake up a thread. Instead mail boxes are typically only used between threads.

Event flags can be used to wait on some number of different events, and to signal that one or several of these events have occurred. This is achieved by associating bits in a bit mask with the different events. Unlike a counting semaphore no attempt is made to keep track of the number of events that have occurred, only the fact that an event has occurred at least once. Unlike a mail box it is not possible to send additional data with the event, but this does mean that there is no possibility of an overflow and hence event flags can be used between a DSR and a thread as well as between threads.

The eCos common HAL package provides its own device driver API which contains some of the above synchronization primitives. These allow the DSR for an interrupt handler to signal events to higher-level code. If the configuration includes the eCos kernel package then the driver API routines map directly on to the equivalent kernel routines, allowing interrupt handlers to interact with threads. If the kernel package is not included and the application consists of just a single thread running in polled mode then the driver API is implemented entirely within the common HAL, and with no need to worry about multiple threads the implementation can obviously be rather simpler.

Threads and Interrupt Handling

During normal operation the processor will be running one of the threads in the system. This may be an application thread, a system thread running inside say the TCP/IP stack, or the idle thread. From time to time a hardware interrupt will occur, causing control to be transferred briefly to an interrupt handler. When the interrupt has been completed the system's scheduler will decide whether to return control to the interrupted thread or to some other runnable thread.

Threads and interrupt handlers must be able to interact. If a thread is waiting for some I/O operation to complete, the interrupt handler associated with that I/O must be able to inform the thread that the operation has completed. This can be achieved in a number of ways. One very simple approach is for the interrupt handler to set a volatile variable. A thread can then poll continuously until this flag is set, possibly sleeping for a clock tick in between. Polling continuously means that the CPU time is not available for other activities, which may be acceptable for some but not all applications. Polling once every clock tick imposes much less overhead, but means that the thread may not detect that the I/O event has occurred until an entire clock tick has elapsed. In typical systems this could be as long as 10 milliseconds. Such a delay might be acceptable for some applications, but not all.

A better solution would be to use one of the synchronization primitives. The interrupt handler could signal a condition variable, post to a semaphore, or use one of the other primitives. The thread would perform a wait operation on the same primitive. It would not consume any CPU cycles until the I/O event had occurred, and when the event does occur the thread can start running again immediately (subject to any higher priority threads that might also be runnable).

Synchronization primitives constitute shared data, so care must be taken to avoid problems with concurrent access. If the thread that was interrupted was just performing some calculations then the interrupt handler could manipulate the synchronization primitive quite safely. However if the interrupted thread happened to be inside some kernel call then there is a real possibility that some kernel data structure will be corrupted.

One way of avoiding such problems would be for the kernel functions to disable interrupts when executing any critical region. On most architectures this would be simple to implement and very fast, but it would mean that interrupts would be disabled often and for quite a long time. For some applications that might not matter, but many embedded applications require that the interrupt handler run as soon as possible after the hardware interrupt has occurred. If the kernel relied on disabling interrupts then it would not be able to support such applications.

Instead the kernel uses a two-level approach to interrupt handling. Associated with every interrupt vector is an Interrupt Service Routine or ISR, which will run as quickly as possible so that it can service the hardware. However an ISR can make only a small number of kernel calls, mostly related to the interrupt subsystem, and it cannot make any call that would cause a thread to wake up. If an ISR detects that an I/O operation has completed and hence that a thread should be woken up, it can cause the associated Deferred Service Routine or DSR to run. A DSR is allowed to make more kernel calls, for example it can signal a condition variable or post to a semaphore.

Disabling interrupts prevents ISRs from running, but very few parts of the system disable interrupts and then only for short periods of time. The main reason for a thread to disable interrupts is to manipulate some state that is shared with an ISR. For example if a thread needs to add another buffer to a linked list of free buffers and the ISR may remove a buffer from this list at any time, the thread would need to disable interrupts for the few instructions needed to manipulate the list. If the hardware raises an interrupt at this time, it remains pending until interrupts are reenabled.

Analogous to interrupts being disabled or enabled, the kernel has a scheduler lock. The various kernel functions such as `cyg_mutex_lock` and `cyg_semaphore_post` will claim the scheduler lock, manipulate the kernel data structures, and then release the scheduler lock. If an interrupt results in a DSR being requested and the scheduler is currently locked, the DSR remains pending. When the scheduler lock is released any pending DSRs will run. These may post events to synchronization primitives, causing other higher priority threads to be woken up.

For an example, consider the following scenario. The system has a high priority thread A, responsible for processing some data coming from an external device. This device will raise an interrupt when data is available. There are two other threads B and C which spend their time performing calculations and occasionally writing results to a display of some sort. This display is a shared resource so a mutex is used to control access.

At a particular moment in time thread A is likely to be blocked, waiting on a semaphore or another synchronization primitive until data is available. Thread B might be running performing some calculations, and thread C is runnable waiting for its next timeslice. Interrupts are enabled, and the scheduler is unlocked because none of the threads are in the middle of a kernel operation. At this point the device raises an interrupt. The hardware transfers control to a low-level interrupt handler provided by eCos which works out exactly which interrupt occurs, and then the corresponding ISR is run. This ISR manipulates the hardware as appropriate, determines that there is now data available, and wants to wake up thread A by posting to the semaphore. However ISR's are not allowed to call `cyg_semaphore_post` directly, so instead the ISR requests that its associated DSR be run and returns. There are no more interrupts to be processed, so the kernel next checks for DSR's. One DSR is pending and the scheduler is currently unlocked, so the DSR can run immediately and post the semaphore. This will have the effect of making thread A runnable again, so the scheduler's data structures are adjusted accordingly. When the DSR returns thread B is no longer the highest priority runnable thread so it will be suspended, and instead thread A gains control over the CPU.

In the above example no kernel data structures were being manipulated at the exact moment that the interrupt happened. However that cannot be assumed. Suppose that thread B had finished its current set of calculations and wanted to write the results to the display. It would claim the appropriate mutex and manipulate the display. Now suppose that thread B was timesliced in favour of thread C, and that thread C also finished its calculations and wanted to write the results to the display. It would call `cyg_mutex_lock`. This kernel call locks the scheduler, examines the current state of the mutex, discovers that the mutex is already owned by another thread, suspends the current thread, and switches control to another runnable thread. Another interrupt happens in the middle of this `cyg_mutex_lock` call, causing the ISR to run immediately. The ISR decides that thread A should be woken up so it requests that its DSR be run and returns back to the kernel. At this point there is a pending DSR, but the scheduler is still locked by the call to `cyg_mutex_lock` so the DSR cannot run immediately. Instead the call to `cyg_mutex_lock` is allowed to continue, which at some point involves unlocking the scheduler. The pending DSR can now run, safely post the semaphore, and thus wake up thread A.

If the ISR had called `cyg_semaphore_post` directly rather than leaving it to a DSR, it is likely that there would have been some sort of corruption of a kernel data structure. For example the kernel might have completely lost track of one of the threads, and that thread would never have run again. The two-level approach to interrupt handling, ISR's and DSR's, prevents such problems with no need to disable interrupts.

Calling Contexts

eCos defines a number of contexts. Only certain calls are allowed from inside each context, for example most operations on threads or synchronization primitives are not allowed from ISR context. The different contexts are initialization, thread, ISR and DSR.

When eCos starts up it goes through a number of phases, including setting up the hardware and invoking C++ static constructors. During this time interrupts are disabled and the scheduler is locked. When a configuration includes the kernel package the final operation is a call to `cyg_scheduler_start`. At this point interrupts are enabled, the scheduler is unlocked, and control is transferred to the highest priority runnable thread. If the configuration also includes the C library package then usually the C library startup package will have created a thread which will call the application's `main` entry point.

Some application code can also run before the scheduler is started, and this code runs in initialization context. If the application is written partly or completely in C++ then the constructors for any static objects will be run. Alternatively application code can define a function `cyg_user_start` which gets called after any C++ static constructors. This allows applications to be written entirely in C.

```
void
cyg_user_start(void)
{
    /* Perform application-specific initialization here */
}
```

It is not necessary for applications to provide a `cyg_user_start` function since the system will provide a default implementation which does nothing.

Typical operations that are performed from inside static constructors or `cyg_user_start` include creating threads, synchronization primitives, setting up alarms, and registering application-specific interrupt handlers. In fact for many applications all such creation operations happen at this time, using statically allocated data, avoiding any need for dynamic memory allocation or other overheads.

Code running in initialization context runs with interrupts disabled and the scheduler locked. It is not permitted to reenable interrupts or unlock the scheduler because the system is not guaranteed to be in a totally consistent state at this point. A consequence is that initialization code cannot use synchronization primitives such as `cyg_semaphore_wait` to wait for an external event. It is permitted to lock and unlock a mutex: there are no other threads running so it is guaranteed that the mutex is not yet locked, and therefore the lock operation will never block; this is useful when making library calls that may use a mutex internally.

At the end of the startup sequence the system will call `cyg_scheduler_start` and the various threads will start running. In thread context nearly all of the kernel functions are available. There may be some restrictions on interrupt-related operations, depending on the target hardware. For example the hardware may require that interrupts be acknowledged in the ISR or DSR before control returns to thread context, in which case `cyg_interrupt_acknowledge` should not be called by a thread.

At any time the processor may receive an external interrupt, causing control to be transferred from the current thread. Typically a VSR provided by eCos will run and determine exactly which interrupt occurred. Then the VSR will switch to the appropriate ISR, which can be provided by a HAL package, a device driver, or by the application. During this time the system is running at ISR context, and most of the kernel function calls are disallowed. This includes the various synchronization primitives, so for example an ISR is not allowed to post to a semaphore to indicate that an event has happened. Usually the only operations that should be performed from inside an ISR are ones related to the interrupt subsystem itself, for example masking an interrupt or acknowledging that an interrupt has been processed. On SMP systems it is also possible to use spinlocks from ISR context.

When an ISR returns it can request that the corresponding DSR be run as soon as it is safe to do so, and that will run in DSR context. This context is also used for running alarm functions, and threads can switch temporarily to DSR context by locking the scheduler. Only certain kernel functions can be called from DSR context, although more than in ISR context. In particular it is possible to use any synchronization primitives which cannot block. These include `cyg_semaphore_post`, `cyg_cond_signal`, `cyg_cond_broadcast`, `cyg_flag_setbits`, and `cyg_mbox_tryput`. It is not possible to use any primitives that may block such as `cyg_semaphore_wait`, `cyg_mutex_lock`, or `cyg_mbox_put`. Calling such functions from inside a DSR may cause the system to hang.

The specific documentation for the various kernel functions gives more details about valid contexts.

Error Handling and Assertions

In many APIs each function is expected to perform some validation of its parameters and possibly of the current state of the system. This is supposed to ensure that each function is used correctly, and that application code is not attempting to perform a semaphore operation on a mutex or anything like that. If an error is detected then a suitable error code is returned, for example the POSIX function `pthread_mutex_lock` can return various error codes including `EINVAL` and `EDEADLK`. There are a number of problems with this approach, especially in the context of deeply embedded systems:

1. Performing these checks inside the mutex lock and all the other functions requires extra CPU cycles and adds significantly to the code size. Even if the application is written correctly and only makes system function calls with sensible arguments and under the right conditions, these overheads still exist.

2. Returning an error code is only useful if the calling code detects these error codes and takes appropriate action. In practice the calling code will often ignore any errors because the programmer *“knows”* that the function is being used correctly. If the programmer is mistaken then an error condition may be detected and reported, but the application continues running anyway and is likely to fail some time later in mysterious ways.

3. If the calling code does always check for error codes, that adds yet more CPU cycles and code size overhead.

4. Usually there will be no way to recover from certain errors, so if the application code detected an error such as `EINVAL` then all it could do is abort the application somehow.

The approach taken within the eCos kernel is different. Functions such as `cyg_mutex_lock` will not return an error code. Instead they contain various assertions, which can be enabled or disabled. During the development process assertions are normally left enabled, and the various kernel functions will perform parameter checks and other system consistency checks. If a problem is detected then an assertion failure will be reported and the application will be terminated. In a typical debug session a suitable breakpoint will have been installed and the developer can now examine the state of the system and work out exactly what is going on. Towards the end of the development cycle assertions will be disabled by manipulating configuration options within the eCos infrastructure package, and all assertions will be eliminated at compile-time. The assumption is that by this time the application code has been mostly debugged: the initial version of the code might have tried to perform a semaphore operation on a mutex, but any problems like that will have been fixed some time ago. This approach has a number of advantages:

1. In the final application there will be no overheads for checking parameters and other conditions. All that code will have been eliminated at compile-time.

2. Because the final application will not suffer any overheads, it is reasonable for the system to do more work during the development process. In particular the various assertions can test for more error conditions and more complicated errors. When an error is detected it is possible to give a text message describing the error rather than just return an error code.

3. There is no need for application programmers to handle error codes returned by various kernel function calls. This simplifies the application code.

4. If an error is detected then an assertion failure will be reported immediately and the application will be halted. There is no possibility of an error condition being ignored because application code did not check for an error code.

Although none of the kernel functions return an error code, many of them do return a status condition. For example the function `cyg_semaphore_timed_wait` waits until either an event has been posted to a semaphore, or until a certain number of clock ticks have occurred. Usually the calling code will need to know whether the wait operation succeeded or whether a timeout occurred. `cyg_semaphore_timed_wait` returns a boolean: a return value of zero or false indicates a timeout, a non-zero return value indicates that the wait succeeded.

In conventional APIs one common error conditions is lack of memory. For example the POSIX function `pthread_create` usually has to allocate some memory dynamically for the thread stack and other per-thread data. If the target hardware does not have enough memory to meet all demands, or more commonly if the application contains a memory leak, then there may not be enough memory available and the function call would fail. The eCos kernel avoids such problems by never performing any dynamic memory allocation. Instead it is the responsibility of the application code to provide all the memory required for kernel data structures and other needs. In the case of `cyg_thread_create` this means a cyg_thread data structure to hold the thread details, and a char array for the thread stack.

In many applications this approach results in all data structures being allocated statically rather than dynamically. This has several advantages. If the application is in fact too large for the target hardware's memory then there will be an error at link-time rather than at run-time, making the problem much easier to diagnose. Static allocation does not involve any of the usual overheads associated with dynamic allocation, for example there is no need to keep track of the various free blocks in the system, and it may be possible to eliminate `malloc` from the system completely. Problems such as fragmentation and memory leaks cannot occur if all data is allocated statically. However, some applications are sufficiently complicated that dynamic memory allocation is required, and the various kernel functions do not distinguish between statically and dynamically allocated memory. It still remains the responsibility of the calling code to ensure that sufficient memory is available, and passing null pointers to the kernel will result in assertions or system failure.

Name

SMP — Support Symmetric Multiprocessing Systems

Description

eCos contains support for limited Symmetric Multi-Processing (SMP). This is only available on selected architectures and platforms. The implementation has a number of restrictions on the kind of hardware supported. These are described in the section called "SMP Support".

The aim for eCos SMP is to support embedded and real time applications on the class of hardware that is the likely target. This means being able to allocate threads to specific CPUs and manage the CPUs that are active. eCos does not support the kind of load balancing scheduler epitomized by the Linux Fair Scheduler, which is oriented to running massively parallel servers. Instead eCos allows deliberately unbalanced scheduling to improve real time latency.

The following sections describe the changes that have been made to the eCos kernel to support SMP operation.

System Startup

The system startup sequence needs to be somewhat different on an SMP system, although this is largely transparent to application code. The main startup takes place on only one CPU, called the primary CPU. All other CPUs, the secondary CPUs, are either placed in suspended state at reset, or are captured by the HAL and put into a spin as they start up. The primary CPU is responsible for copying the DATA segment and zeroing the BSS (if required), calling HAL variant and platform initialization routines and invoking constructors. It then calls `cyg_start` to enter the application. The application may then create extra threads and other objects.

It is only when the application calls `cyg_scheduler_start` that the secondary CPUs are initialized. This routine scans the list of available secondary CPUs and invokes `HAL_SMP_CPU_START` to start each CPU. Finally it calls an internal function `Cyg_Scheduler::start_cpu` to enter the scheduler for the primary CPU.

Each secondary CPU starts in the HAL, where it completes any per-CPU initialization before calling into the kernel at `cyg_kernel_cpu_startup`. Here it claims the scheduler lock and calls `Cyg_Scheduler::start_cpu`.

`Cyg_Scheduler::start_cpu` is common to both the primary and secondary CPUs. The first thing this code does is to install an interrupt object for this CPU's inter-CPU interrupt. From this point on the code is the same as for the single CPU case: an initial thread is chosen and entered.

From this point on the CPUs are all equal, eCos makes no further distinction between the primary and secondary CPUs. However, the hardware may still distinguish between them as far as interrupt delivery is concerned.

Scheduling

To function correctly an operating system kernel must protect its vital data structures, such as the run queues, from concurrent access. In a single CPU system the only concurrent activities to worry about are asynchronous interrupts. The kernel can easily guard its data structures against these by disabling interrupts. However, in a multi-CPU system, this is inadequate since it does not block access by other CPUs.

The eCos kernel protects its vital data structures using the scheduler lock. In single CPU systems this is a simple counter that is atomically incremented to acquire the lock and decremented to release it. If the lock is decremented to zero then the scheduler may be invoked to choose a different thread to run. Because interrupts may continue to be serviced while the scheduler lock is claimed, ISRs are not allowed to access kernel data structures, or call kernel routines that can. Instead all such operations are deferred to an associated DSR routine that is run during the lock release operation, when the data structures are in a consistent state.

By choosing a kernel locking mechanism that does not rely on interrupt manipulation to protect data structures, it is easier to convert eCos to SMP than would otherwise be the case. The principal change needed to make eCos SMP-safe is to convert the scheduler lock into a nestable spin lock. This is done by adding a spinlock and a CPU id to the original counter.

The algorithm for acquiring the scheduler lock is very simple. If the scheduler lock's CPU id matches the current CPU then it can just increment the counter and continue. If it does not match, the CPU must spin on the spinlock, after which it may increment the counter and store its own identity in the CPU id.

To release the lock, the counter is decremented. If it goes to zero the CPU id value must be set to NONE and the spinlock cleared.

To protect these sequences against interrupts, they must be performed with interrupts disabled. However, since these are very short code sequences, they will not have an adverse effect on the interrupt latency.

Beyond converting the scheduler lock, further preparing the kernel for SMP is a relatively minor matter. The main changes are to convert various scalar housekeeping variables into arrays indexed by CPU id. These include the current thread pointer, the need_reschedule flag and the timeslice counter.

At present only the Multi-Level Queue (MLQ) schedulers are capable of supporting SMP configurations. The main change made to this scheduler is to cope with having several threads in execution at the same time. Running threads are marked with the CPU that they are executing on. When scheduling a thread, the scheduler skips past any running threads until it finds a thread that is pending. While not a constant-time algorithm, as in the single CPU case, this is still deterministic, since the worst case time is bounded by the number of CPUs in the system.

A second change to the scheduler is in the code used to decide when the scheduler should be called to choose a new thread. The scheduler attempts to keep the n CPUs running the n highest priority threads. Since an event or interrupt on one CPU may require a reschedule on another CPU, there must be a mechanism for deciding this. The algorithm currently implemented is very simple. Given a thread that has just been awakened (or had its priority changed), the scheduler scans the CPUs, starting with the one it is currently running on, for a current thread that is of lower priority than the new one. If one is found then a reschedule interrupt is sent to that CPU and the scan continues, but now using the current thread of the rescheduled CPU as the candidate thread. In this way the new thread gets to run as quickly as possible, hopefully on the current CPU, and the remaining CPUs will pick up the remaining highest priority threads as a consequence of processing the reschedule interrupt.

The final change to the scheduler is in the handling of timeslicing. Only one CPU receives timer interrupts, although all CPUs must handle timeslicing. To make this work, the CPU that receives the timer interrupt decrements the timeslice counter for all CPUs, not just its own. If the counter for a CPU reaches zero, then it sends a timeslice interrupt to that CPU. On receiving the interrupt the destination CPU enters the scheduler and looks for another thread at the same priority to run. This is somewhat more efficient than distributing clock ticks to all CPUs, since the interrupt is only needed when a timeslice occurs.

In addition to the standard MLQ scheduler, eCosPro also contains an MLQSMP scheduler. This is a derivative of the MLQ scheduler that has some additional features. The main change is to implement a CPU affinity mechanism. This is implemented by adding a CPU affinity map to each thread, indicating which CPUs this thread is allowed to run on. When choosing which thread to run a CPU will only look for threads that have its bit set in their affinity maps. In the future this scheduler will be extended with support for CPU activation and deactivation. By default, eCosPro uses the MLQSMP scheduler when configured for SMP operation.

All existing synchronization mechanisms work as before in an SMP system. Additional synchronization mechanisms have been added to provide explicit synchronization for SMP, in the form of spinlocks.

New functions have also been added to support CPU affinity.

SMP Interrupt Handling

The main area where the SMP nature of a system requires special attention is in device drivers and especially interrupt handling. It is quite possible for the ISR, DSR and thread components of a device driver to execute on different CPUs. For this reason it is much more important that SMP-capable device drivers use the interrupt-related functions correctly. Typically a device driver would use the driver API rather than call the kernel directly, but it is unlikely that anybody would attempt to use a multiprocessor system without the kernel package.

Two new functions have been added to the Kernel API to do interrupt routing: `cyg_interrupt_set_cpu` and `cyg_interrupt_get_cpu`. Once a vector has been routed to a new CPU, all other interrupt masking and configuration operations are relative to that CPU, where relevant.

There are more details of how interrupts should be handled in SMP systems in the section called “SMP Support”.

Name

cyg_thread_create — Create a new thread

Synopsis

#include <cyg/kernel/kapi.h>

`void` **`cyg_thread_create`** `(`*`sched_info`*`,` *`entry`*`,` *`entry_data`*`,` *`name`*`,` *`stack_base`*`,` *`stack_size`*`,` *`handle`*`,` *`thread`*`);`

Description

The `cyg_thread_create` function allows application code and eCos packages to create new threads. In many applications this only happens during system initialization and all required data is allocated statically. However additional threads can be created at any time, if necessary. A newly created thread is always in suspended state and will not start running until it has been resumed via a call to `cyg_thread_resume`. Also, if threads are created during system initialization then they will not start running until the eCos scheduler has been started.

The *`name`* argument is used primarily for debugging purposes, making it easier to keep track of which cyg_thread structure is associated with which application-level thread. The kernel configuration option `CYGVAR_KERNEL_THREADS_NAME` controls whether or not this name is actually used.

On creation each thread is assigned a unique handle, and this will be stored in the location pointed at by the *`handle`* argument. Subsequent operations on this thread including the required `cyg_thread_resume` should use this handle to identify the thread.

The kernel requires a small amount of space for each thread, in the form of a cyg_thread data structure, to hold information such as the current state of that thread. To avoid any need for dynamic memory allocation within the kernel this space has to be provided by higher-level code, typically in the form of a static variable. The *`thread`* argument provides this space.

Thread Entry Point

The entry point for a thread takes the form:

```
void thread_entry_function(cyg_addrword_t data)
{
    …
}
```

The second argument to `cyg_thread_create` is a pointer to such a function. The third argument *`entry_data`* is used to pass additional data to the function. Typically this takes the form of a pointer to some static data, or a small integer, or `0` if the thread does not require any additional data.

If the thread entry function ever returns then this is equivalent to the thread calling `cyg_thread_exit`. Even though the thread will no longer run again, it remains registered with the scheduler. If the application needs to re-use the cyg_thread data structure then a call to `cyg_thread_delete` is required first.

Thread Priorities

The *`sched_info`* argument provides additional information to the scheduler. The exact details depend on the scheduler being used. For the bitmap and mlqueue schedulers it is a small integer, typically in the range 0 to 31, with 0 being the highest priority. The lowest priority is normally used only by the system's idle thread. The exact number of priorities is controlled by the kernel configuration option `CYGNUM_KERNEL_SCHED_PRIORITIES`.

It is the responsibility of the application developer to be aware of the various threads in the system, including those created by eCos packages, and to ensure that all threads run at suitable priorities. For threads created by other packages the documentation provided by those packages should indicate any requirements.

The functions `cyg_thread_set_priority`, `cyg_thread_get_priority`, and `cyg_thread_get_current_priority` can be used to manipulate a thread's priority.

Stacks and Stack Sizes

Each thread needs its own stack for local variables and to keep track of function calls and returns. Again it is expected that this stack is provided by the calling code, usually in the form of static data, so that the kernel does not need any dynamic memory allocation facilities. `cyg_thread_create` takes two arguments related to the stack, a pointer to the base of the stack and the total size of this stack. On many processors stacks actually descend from the top down, so the kernel will add the stack size to the base address to determine the starting location.

The exact stack size requirements for any given thread depend on a number of factors. The most important is of course the code that will be executed in the context of this code: if this involves significant nesting of function calls, recursion, or large local arrays, then the stack size needs to be set to a suitably high value. There are some architectural issues, for example the number of CPU registers and the calling conventions will have some effect on stack usage. Also, depending on the configuration, it is possible that some other code such as interrupt handlers will occasionally run on the current thread's stack. This depends in part on configuration options such as `CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK` and `CYGSEM_HAL_COMMON_INTERRUPTS_ALLOW_NESTING`.

Determining an application's actual stack size requirements is the responsibility of the application developer, since the kernel cannot know in advance what code a given thread will run. However, the system does provide some hints about reasonable stack sizes in the form of two constants: `CYGNUM_HAL_STACK_SIZE_MINIMUM` and `CYGNUM_HAL_STACK_SIZE_TYPICAL`. These are defined by the appropriate HAL package. The `MINIMUM` value is appropriate for a thread that just runs a single function and makes very simple system calls. Trying to create a thread with a smaller stack than this is illegal. The `TYPICAL` value is appropriate for applications where application calls are nested no more than half a dozen or so levels, and there are no large arrays on the stack.

If the stack sizes are not estimated correctly and a stack overflow occurs, the probably result is some form of memory corruption. This can be very hard to track down. The kernel does contain some code to help detect stack overflows, controlled by the configuration option `CYGFUN_KERNEL_THREADS_STACK_CHECKING`: a small amount of space is reserved at the stack limit and filled with a special signature: every time a thread context switch occurs this signature is checked, and if invalid that is a good indication (but not absolute proof) that a stack overflow has occurred. This form of stack checking is enabled by default when the system is built with debugging enabled. A related configuration option is `CYGFUN_KERNEL_THREADS_STACK_MEASUREMENT`: enabling this option means that a thread can call the function `cyg_thread_measure_stack_usage` to find out the maximum stack usage to date. Note that this is not necessarily the true maximum because, for example, it is possible that in the current run no interrupt occurred at the worst possible moment.

Valid contexts

`cyg_thread_create` may be called during initialization and from within thread context. It may not be called from inside a DSR.

Example

A simple example of thread creation is shown below. This involves creating five threads, one producer and four consumers or workers. The threads are created in the system's `cyg_user_start`: depending on the configuration it might be more appropriate to do this elsewhere, for example inside `main`.

```
#include <cyg/hal/hal_arch.h>
#include <cyg/kernel/kapi.h>

// These numbers depend entirely on your application
#define NUMBER_OF_WORKERS    4
```

```
#define PRODUCER_PRIORITY   10
#define WORKER_PRIORITY     11
#define PRODUCER_STACKSIZE  CYGNUM_HAL_STACK_SIZE_TYPICAL
#define WORKER_STACKSIZE    (CYGNUM_HAL_STACK_SIZE_MINIMUM + 1024)

static unsigned char producer_stack[PRODUCER_STACKSIZE];
static unsigned char worker_stacks[NUMBER_OF_WORKERS][WORKER_STACKSIZE];
static cyg_handle_t producer_handle, worker_handles[NUMBER_OF_WORKERS];
static cyg_thread   producer_thread, worker_threads[NUMBER_OF_WORKERS];

static void
producer(cyg_addrword_t data)
{
    …
}

static void
worker(cyg_addrword_t data)
{
    …
}

void
cyg_user_start(void)
{
    int i;

    cyg_thread_create(PRODUCER_PRIORITY, &producer, 0, "producer",
    producer_stack, PRODUCER_STACKSIZE,
    &producer_handle, &producer_thread);
    cyg_thread_resume(producer_handle);
    for (i = 0; i < NUMBER_OF_WORKERS; i++) {
        cyg_thread_create(WORKER_PRIORITY, &worker, i, "worker",
        worker_stacks[i], WORKER_STACKSIZE,
        &(worker_handles[i]), &(worker_threads[i]));
        cyg_thread_resume(worker_handles[i]);
    }
}
```

Thread Entry Points and C++

For code written in C++ the thread entry function must be either a static member function of a class or an ordinary function outside any class. It cannot be a normal member function of a class because such member functions take an implicit additional argument `this`, and the kernel has no way of knowing what value to use for this argument. One way around this problem is to make use of a special static member function, for example:

```
class fred {
    public:
        void thread_function();
        static void static_thread_aux(cyg_addrword_t);
};

void
fred::static_thread_aux(cyg_addrword_t objptr)
{
    fred* object = static_cast<fred*>(objptr);
    object->thread_function();
}

static fred instance;

extern "C" void
cyg_start( void )
{
    …
    cyg_thread_create(  …,
                        &fred::static_thread_aux,
                        reinterpret_cast<cyg_addrword_t>(&instance),
                        …);
    …
}
```

Effectively this uses the *`entry_data`* argument to `cyg_thread_create` to hold the `this` pointer. Unfortunately this approach does require the use of some C++ casts, so some of the type safety that can be achieved when programming in C++ is lost.

Name

cyg_thread_self, cyg_thread_idle_thread, cyg_thread_get_stack_base, cyg_thread_get_stack_size, cyg_thread_measure_stack_usage, cyg_thread_get_next, cyg_thread_get_info, cyg_thread_get_id and cyg_thread_find — Get basic thread information

Synopsis

#include <cyg/kernel/kapi.h>

`cyg_handle_t` **`cyg_thread_self`** `();`

`cyg_handle_t` **`cyg_thread_idle_thread`** `();`

`cyg_addrword_t` **`cyg_thread_get_stack_base`** `(`*`thread`*`);`

`cyg_uint32` **`cyg_thread_get_stack_size`** `(`*`thread`*`);`

`cyg_uint32` **`cyg_thread_measure_stack_usage`** `(`*`thread`*`);`

`cyg_bool` **`cyg_thread_get_next`** `(`*`thread`*`, `*`id`*`);`

`cyg_bool` **`cyg_thread_get_info`** `(`*`thread`*`, `*`id`*`, `*`info`*`);`

`cyg_uint16` **`cyg_thread_get_id`** `(`*`thread`*`);`

`cyg_handle_t` **`cyg_thread_find`** `(`*`id`*`);`

Description

These functions can be used to obtain some basic information about various threads in the system. Typically they serve little or no purpose in real applications, but they can be useful during debugging.

`cyg_thread_self` returns a handle corresponding to the current thread. It will be the same as the value filled in by `cyg_thread_create` when the current thread was created. This handle can then be passed to other functions such as `cyg_thread_get_priority`.

`cyg_thread_idle_thread` returns the handle corresponding to the idle thread. This thread is created automatically by the kernel, so application-code has no other way of getting hold of this information.

`cyg_thread_get_stack_base` and `cyg_thread_get_stack_size` return information about a specific thread's stack. The values returned will match the values passed to `cyg_thread_create` when this thread was created.

`cyg_thread_measure_stack_usage` is only available if the configuration option `CYGFUN_KERNEL_THREADS_STACK_MEASUREMENT` is enabled. The return value is the maximum number of bytes of stack space used so far by the specified thread. Note that this should not be considered a true upper bound, for example it is possible that in the current test run the specified thread has not yet been interrupted at the deepest point in the function call graph. Never the less the value returned can give some useful indication of the thread's stack requirements.

`cyg_thread_get_next` is used to enumerate all the current threads in the system. It should be called initially with the locations pointed to by *`thread`* and *`id`* set to zero. On return these will be set to the handle and ID of the first thread. On subsequent calls, these parameters should be left set to the values returned by the previous call. The handle and ID of the next thread in the system will be installed each time, until a `false` return value indicates the end of the list.

`cyg_thread_get_info` fills in the cyg_thread_info structure with information about the thread described by the *`thread`* and *`id`* arguments. The information returned includes the thread's handle and id, its state and name, priorities and stack parameters. If the thread does not exist the function returns `false`.

The cyg_thread_info structure is defined as follows by <cyg/kernel/kapi.h>, but may be extended in future with additional members, and so its size should not be relied upon:

```
typedef struct
{
    cyg_handle_t        handle;
    cyg_uint16          id;
    cyg_uint32          state;
    char                *name;
    cyg_priority_t      set_pri;
    cyg_priority_t      cur_pri;
    cyg_addrword_t      stack_base;
    cyg_uint32          stack_size;
    cyg_uint32          stack_used;
} cyg_thread_info;
```

cyg_thread_get_id returns the unique thread ID for the thread identified by *thread*.

cyg_thread_find returns a handle for the thread whose ID is *id*. If no such thread exists, a zero handle is returned.

Valid contexts

cyg_thread_self may only be called from thread context. cyg_thread_idle_thread may be called from thread or DSR context, but only after the system has been initialized. cyg_thread_get_stack_base, cyg_thread_get_stack_size and cyg_thread_measure_stack_usage may be called any time after the specified thread has been created, but measuring stack usage involves looping over at least part of the thread's stack so this should normally only be done from thread context. cyg_thread_get_id may be called from any context as long as the caller can guarantee that the supplied thread handle remains valid.

Examples

A simple example of the use of the cyg_thread_get_next and cyg_thread_get_info follows:

```
#include <cyg/kernel/kapi.h>
#include <stdio.h>

void show_threads(void)
{
    cyg_handle_t thread = 0;
    cyg_uint16 id = 0;

    while( cyg_thread_get_next( &thread, &id ) )
    {
        cyg_thread_info info;

        if( !cyg_thread_get_info( thread, id, &info ) )
            break;

        printf("ID: %04x name: %10s pri: %d\n",
        info.id, info.name?info.name:"----", info.set_pri );
    }
}
```

Name

cyg_thread_yield, cyg_thread_delay, cyg_thread_suspend, cyg_thread_resume, cyg_thread_release, cyg_thread_set_affinity and cyg_thread_get_affinity — Control whether or not a thread is running

Synopsis

```
#include <cyg/kernel/kapi.h>
```

void **cyg_thread_yield** ();

void **cyg_thread_delay** (*delay*);

void **cyg_thread_suspend** (*thread*);

void **cyg_thread_resume** (*thread*);

void **cyg_thread_release** (*thread*);

void **cyg_thread_set_affinity** (*thread*, *mask*);

void **cyg_thread_get_affinity** (*thread*, **mask*);

Description

These functions provide some control over whether or not a particular thread can run. Apart from the required use of `cyg_thread_resume` to start a newly-created thread, application code should normally use proper synchronization primitives such as condition variables or mail boxes.

Yield

`cyg_thread_yield` allows a thread to relinquish control of the processor to some other runnable thread which has the same priority. This can have no effect on any higher-priority thread since, if such a thread were runnable, the current thread would have been preempted in its favour. Similarly it can have no effect on any lower-priority thread because the current thread will always be run in preference to those. As a consequence this function is only useful in configurations with a scheduler that allows multiple threads to run at the same priority, for example the mlqueue scheduler. If instead the bitmap scheduler was being used then `cyg_thread_yield()` would serve no purpose.

Even if a suitable scheduler such as the mlqueue scheduler has been configured, `cyg_thread_yield` will still rarely prove useful: instead timeslicing will be used to ensure that all threads of a given priority get a fair slice of the available processor time. However it is possible to disable timeslicing via the configuration option `CYGSEM_KERNEL_SCHED_TIMESLICE`, in which case `cyg_thread_yield` can be used to implement a form of cooperative multitasking.

Delay

`cyg_thread_delay` allows a thread to suspend until the specified number of clock ticks have occurred. For example, if a value of 1 is used and the system clock runs at a frequency of 100Hz then the thread will sleep for up to 10 milliseconds. This functionality depends on the presence of a real-time system clock, as controlled by the configuration option `CYGVAR_KERNEL_COUNTERS_CLOCK`.

If the application requires delays measured in milliseconds or similar units rather than in clock ticks, some calculations are needed to convert between these units as described in Clocks. Usually these calculations can be done by the application developer, or at compile-time. Performing such calculations prior to every call to `cyg_thread_delay` adds unnecessary overhead to the system.

Suspend and Resume

Associated with each thread is a suspend counter. When a thread is first created this counter is initialized to 1. cyg_thread_suspend can be used to increment the suspend counter, and cyg_thread_resume decrements it. The scheduler will never run a thread with a non-zero suspend counter. Therefore a newly created thread will not run until it has been resumed.

An occasional problem with the use of suspend and resume functionality is that a thread gets suspended more times than it is resumed and hence never becomes runnable again. This can lead to very confusing behaviour. To help with debugging such problems the kernel provides a configuration option CYGNUM_KERNEL_MAX_SUSPEND_COUNT_ASSERT which imposes an upper bound on the number of suspend calls without matching resumes, with a reasonable default value. This functionality depends on infrastructure assertions being enabled.

Releasing a Blocked Thread

When a thread is blocked on a synchronization primitive such as a semaphore or a mutex, or when it is waiting for an alarm to trigger, it can be forcibly woken up using cyg_thread_release. Typically this will call the affected synchronization primitive to return false, indicating that the operation was not completed successfully. This function has to be used with great care, and in particular it should only be used on threads that have been designed appropriately and check all return codes. If instead it were to be used on, say, an arbitrary thread that is attempting to claim a mutex then that thread might not bother to check the result of the mutex lock operation - usually there would be no reason to do so. Therefore the thread will now continue running in the false belief that it has successfully claimed a mutex lock, and the resulting behaviour is undefined. If the system has been built with assertions enabled then it is possible that an assertion will trigger when the thread tries to release the mutex it does not actually own.

The main use of cyg_thread_release is in the POSIX compatibility layer, where it is used in the implementation of per-thread signals and cancellation handlers.

Thread Affinity

In SMP configurations, using the MLQSMP scheduler, it is possible to control the set of CPUs on which a thread can be run. This can be controlled by using cyg_thread_set_affinity. In addition to the thread handle, this function takes a bitmask that has bit n set if that thread can run on CPU n and clear if it cannot. Bits corresponding to CPUs that are not present are ignored. A mask of all ones allows the thread to run on any CPU and is the default setting. A value of all zeroes will prevent the thread running at all. The function cyg_thread_get_affinity returns the current setting of the thread's affinity mask.

These functions are also present in non-SMP configurations to retain compatibility. In this case cyg_thread_set_affinity is a no-op, and cyg_thread_get_affinity returns a mask with just the bit for CPU 0 set.

Valid contexts

cyg_thread_yield can only be called from thread context, A DSR must always run to completion and cannot yield the processor to some thread. cyg_thread_suspend, cyg_thread_resume, and cyg_thread_release may be called from thread or DSR context.

Name

cyg_thread_exit, cyg_thread_kill and cyg_thread_delete — Allow threads to terminate

Synopsis

#include <cyg/kernel/kapi.h>

void **cyg_thread_exit** ();

void **cyg_thread_kill** (*thread*);

cyg_bool_t **cyg_thread_delete** (*thread*);

Description

In many embedded systems the various threads are allocated statically, created during initialization, and never need to terminate. This avoids any need for dynamic memory allocation or other resource management facilities. However if a given application does have a requirement that some threads be created dynamically, must terminate, and their resources such as the stack be reclaimed, then the kernel provides the functions `cyg_thread_exit`, `cyg_thread_kill`, and `cyg_thread_delete`.

`cyg_thread_exit` allows a thread to terminate itself, thus ensuring that it will not be run again by the scheduler. However the cyg_thread data structure passed to `cyg_thread_create` remains in use, and the handle returned by `cyg_thread_create` remains valid. This allows other threads to perform certain operations on the terminated thread, for example to determine its stack usage via `cyg_thread_measure_stack_usage`. When the handle and cyg_thread structure are no longer required, `cyg_thread_delete` should be called to release these resources. If the stack was dynamically allocated then this should not be freed until after the call to `cyg_thread_delete`.

Alternatively, one thread may use `cyg_thread_kill` on another This has much the same effect as the affected thread calling `cyg_thread_exit`. However killing a thread is generally rather dangerous because no attempt is made to unlock any synchronization primitives currently owned by that thread or release any other resources that thread may have claimed. Therefore use of this function should be avoided, and `cyg_thread_exit` is preferred. `cyg_thread_kill` cannot be used by a thread to kill itself.

`cyg_thread_delete` should be used on a thread after it has exited and is no longer required. After this call the thread handle is no longer valid, and both the cyg_thread structure and the thread stack can be re-used or freed. If `cyg_thread_delete` is invoked on a thread that is still running then there is an implicit call to `cyg_thread_kill`. This function returns `true` if the delete was successful, and `false` if the delete did not happen. The delete may not happen for example if the thread being destroyed is a lower priority thread than the running thread, and will thus not wake up in order to exit until it is rescheduled.

Valid contexts

`cyg_thread_exit`, `cyg_thread_kill` and `cyg_thread_delete` can only be called from thread context.

Name

cyg_thread_get_priority, cyg_thread_get_current_priority and cyg_thread_set_priority — Examine and manipulate thread priorities

Synopsis

#include <cyg/kernel/kapi.h>

```
cyg_priority_t cyg_thread_get_priority (thread);
```

```
cyg_priority_t cyg_thread_get_current_priority (thread);
```

```
void cyg_thread_set_priority (thread, priority);
```

Description

Typical schedulers use the concept of a thread priority to determine which thread should run next. Exactly what this priority consists of will depend on the scheduler, but a typical implementation would be a small integer in the range 0 to 31, with 0 being the highest priority. Usually only the idle thread will run at the lowest priority. The exact number of priority levels available depends on the configuration, typically the option `CYGNUM_KERNEL_SCHED_PRIORITIES`.

`cyg_thread_get_priority` can be used to determine the priority of a thread, or more correctly the value last used in a `cyg_thread_set_priority` call or when the thread was first created. In some circumstances it is possible that the thread is actually running at a higher priority. For example, if it owns a mutex and priority ceilings or inheritance is being used to prevent priority inversion problems, then the thread's priority may have been boosted temporarily. `cyg_thread_get_current_priority` returns the real current priority.

In many applications appropriate thread priorities can be determined and allocated statically. However, if it is necessary for a thread's priority to change at run-time then the `cyg_thread_set_priority` function provides this functionality.

Valid contexts

`cyg_thread_get_priority` and `cyg_thread_get_current_priority` can be called from thread or DSR context, although the latter is rarely useful. `cyg_thread_set_priority` should also only be called from thread context.

Name

cyg_thread_new_data_index, cyg_thread_free_data_index, cyg_thread_get_data, cyg_thread_get_data_ptr and cyg_thread_set_data — Manipulate per-thread data

Synopsis

#include <cyg/kernel/kapi.h>

cyg_ucount32 **cyg_thread_new_data_index** ();

void **cyg_thread_free_data_index** (*index*);

cyg_addrword_t **cyg_thread_get_data** (*index*);

cyg_addrword_t* **cyg_thread_get_data_ptr** (*index*);

void **cyg_thread_set_data** (*index*, *data*);

Description

In some applications and libraries it is useful to have some data that is specific to each thread. For example, many of the functions in the POSIX compatibility package return -1 to indicate an error and store additional information in what appears to be a global variable errno. However, if multiple threads make concurrent calls into the POSIX library and if errno were really a global variable then a thread would have no way of knowing whether the current errno value really corresponded to the last POSIX call it made, or whether some other thread had run in the meantime and made a different POSIX call which updated the variable. To avoid such confusion errno is instead implemented as a per-thread variable, and each thread has its own instance.

The support for per-thread data can be disabled via the configuration option CYGVAR_KERNEL_THREADS_DATA. If enabled, each cyg_thread data structure holds a small array of words. The size of this array is determined by the configuration option CYGNUM_KERNEL_THREADS_DATA_MAX. When a thread is created the array is filled with zeroes.

If an application needs to use per-thread data then it needs an index into this array which has not yet been allocated to other code. This index can be obtained by calling cyg_thread_new_data_index, and then used in subsequent calls to cyg_thread_get_data. Typically indices are allocated during system initialization and stored in static variables. If for some reason a slot in the array is no longer required and can be re-used then it can be released by calling cyg_thread_free_data_index. When a slot index is allocated, then if the CYGVAR_KERNEL_THREADS_LIST option is enabled, the corresponding array entry for all threads will be reset back to zero in case that slot had been previously used.

The current per-thread data in a given slot can be obtained using cyg_thread_get_data. This implicitly operates on the current thread, and its single argument should be an index as returned by cyg_thread_new_data_index. The per-thread data can be updated using cyg_thread_set_data. If a particular item of per-thread data is needed repeatedly then cyg_thread_get_data_ptr can be used to obtain the address of the data, and indirecting through this pointer allows the data to be examined and updated efficiently.

Some packages, for example the error and POSIX packages, have pre-allocated slots in the array of per-thread data. These slots should not normally be used by application code, and instead slots should be allocated during initialization by a call to cyg_thread_new_data_index. If it is known that, for example, the configuration will never include the POSIX compatibility package then application code may instead decide to re-use the slot allocated to that package, CYGNUM_KERNEL_THREADS_DATA_POSIX, but obviously this does involve a risk of strange and subtle bugs if the application's requirements ever change.

Valid contexts

Typically cyg_thread_new_data_index is only called during initialization, but may also be called at any time in thread context. cyg_thread_free_data_index, if used at all, can also be called during initialization or from thread context.

`cyg_thread_get_data`, `cyg_thread_get_data_ptr`, and `cyg_thread_set_data` may only be called from thread context because they implicitly operate on the current thread.

Name

cyg_thread_add_destructor and cyg_thread_rem_destructor — Call functions on thread termination

Synopsis

#include <cyg/kernel/kapi.h> typedef void (*cyg_thread_destructor_fn)(cyg_addrword_t);

`cyg_bool_t` **`cyg_thread_add_destructor`** `(`*`fn`*`, `*`data`*`);`

`cyg_bool_t` **`cyg_thread_rem_destructor`** `(`*`fn`*`, `*`data`*`);`

Description

These functions are provided for cases when an application requires a function to be automatically called when a thread exits. This is often useful when, for example, freeing up resources allocated by the thread.

This support must be enabled with the configuration option `CYGPKG_KERNEL_THREADS_DESTRUCTORS`. When enabled, you may register a function of type cyg_thread_destructor_fn to be called on thread termination using `cyg_thread_add_destructor`. You may also provide it with a piece of arbitrary information in the *`data`* argument which will be passed to the destructor function *`fn`* when the thread terminates. If you no longer wish to call a function previous registered with `cyg_thread_add_destructor`, you may call `cyg_thread_rem_destructor` with the same parameters used to register the destructor function. Both these functions return `true` on success and `false` on failure.

By default, thread destructors are per-thread, which means that registering a destructor function only registers that function for the current thread. In other words, each thread has its own list of destructors. Alternatively you may disable the configuration option `CYGSEM_KERNEL_THREADS_DESTRUCTORS_PER_THREAD` in which case any registered destructors will be run when *any* threads exit. In other words, the thread destructor list is global and all threads have the same destructors.

There is a limit to the number of destructors which may be registered, which can be controlled with the `CYGNUM_KERNEL_THREADS_DESTRUCTORS` configuration option. Increasing this value will very slightly increase the amount of memory in use, and when `CYGSEM_KERNEL_THREADS_DESTRUCTORS_PER_THREAD` is enabled, the amount of memory used per thread will increase. When the limit has been reached, `cyg_thread_add_destructor` will return `false`.

Valid contexts

When `CYGSEM_KERNEL_THREADS_DESTRUCTORS_PER_THREAD` is enabled, these functions must only be called from a thread context as they implicitly operate on the current thread. When `CYGSEM_KERNEL_THREADS_DESTRUCTORS_PER_THREAD` is disabled, these functions may be called from thread or DSR context, or at initialization time.

Name

cyg_exception_set_handler, cyg_exception_clear_handler and cyg_exception_call_handler — Handle processor exceptions

Synopsis

#include <cyg/kernel/kapi.h>

`void` **`cyg_exception_set_handler`** `(`*`exception_number`*`,` *`new_handler`*`,` *`new_data`*`,` *`old_handler`*`,` *`old_data`*`);`

`void` **`cyg_exception_clear_handler`** `(`*`exception_number`*`);`

`void` **`cyg_exception_call_handler`** `(`*`thread`*`,` *`exception_number`*`,` *`exception_info`*`);`

Description

Sometimes code attempts operations that are not legal on the current hardware, for example dividing by zero, or accessing data through a pointer that is not properly aligned. When this happens the hardware will raise an exception. This is very similar to an interrupt, but happens synchronously with code execution rather than asynchronously and hence can be tied to the thread that is currently running.

The exceptions that can be raised depend very much on the hardware, especially the processor. The corresponding documentation should be consulted for more details. Alternatively the architectural HAL header file `hal_intr.h`, or one of the variant or platform header files it includes, will contain appropriate definitions. The details of how to handle exceptions, including whether or not it is possible to recover from them, also depend on the hardware.

Exception handling is optional, and can be disabled through the configuration option `CYGPKG_KERNEL_EXCEPTIONS`. If an application has been exhaustively tested and is trusted never to raise a hardware exception then this option can be disabled and code and data sizes will be reduced somewhat. If exceptions are left enabled then the system will provide default handlers for the various exceptions, but these do nothing. Even the specific type of exception is ignored, so there is no point in attempting to decode this and distinguish between say a divide-by-zero and an unaligned access. If the application installs its own handlers and wants details of the specific exception being raised then the configuration option `CYGSEM_KERNEL_EXCEPTIONS_DECODE` has to be enabled.

An alternative handler can be installed using `cyg_exception_set_handler`. This requires a code for the exception, a function pointer for the new exception handler, and a parameter to be passed to this handler. Details of the previously installed exception handler will be returned via the remaining two arguments, allowing that handler to be reinstated, or null pointers can be used if this information is of no interest. An exception handling function should take the following form:

```
void
my_exception_handler(cyg_addrword_t data, cyg_code_t exception, cyg_addrword_t info)
{
    …
}
```

The data argument corresponds to the *`new_data`* parameter supplied to `cyg_exception_set_handler`. The exception code is provided as well, in case a single handler is expected to support multiple exceptions. The *`info`* argument will depend on the hardware and on the specific exception.

`cyg_exception_clear_handler` can be used to restore the default handler, if desired. It is also possible for software to raise an exception and cause the current handler to be invoked, but generally this is useful only for testing.

By default the system maintains a single set of global exception handlers. However, since exceptions occur synchronously it is sometimes useful to handle them on a per-thread basis, and have a different set of handlers for each thread. This behaviour can be obtained by disabling the configuration option `CYGSEM_KERNEL_EXCEPTIONS_GLOBAL`. If per-thread exception handlers are being used then `cyg_exception_set_handler` and `cyg_exception_clear_handler` apply to the current thread. Otherwise they apply to the global set of handlers.

Caution

In the current implementation `cyg_exception_call_handler` can only be used on the current thread. There is no support for delivering an exception to another thread.

Note

Exceptions at the eCos kernel level refer specifically to hardware-related events such as unaligned accesses to memory or division by zero. There is no relation with other concepts that are also known as exceptions, for example the `throw` and `catch` facilities associated with C++.

Valid contexts

If the system is configured with a single set of global exception handlers then `cyg_exception_set_handler` and `cyg_exception_clear_handler` may be called during initialization or from thread context. If instead per-thread exception handlers are being used then it is not possible to install new handlers during initialization because the functions operate implicitly on the current thread, so they can only be called from thread context. `cyg_exception_call_handler` should only be called from thread context.

Name

cyg_counter_create, cyg_counter_delete, cyg_counter_current_value, cyg_counter_set_value and cyg_counter_tick — Count event occurrences

Synopsis

#include <cyg/kernel/kapi.h>

```
void cyg_counter_create (handle, counter);

void cyg_counter_delete (counter);

cyg_tick_count_t cyg_counter_current_value (counter);

void cyg_counter_set_value (counter, new_value);

void cyg_counter_tick (counter);
```

Description

Kernel counters can be used to keep track of how many times a particular event has occurred. Usually this event is an external signal of some sort. The most common use of counters is in the implementation of clocks, but they can be useful with other event sources as well. Application code can attach alarms to counters, causing a function to be called when some number of events have occurred.

A new counter is initialized by a call to `cyg_counter_create`. The first argument is used to return a handle to the new counter which can be used for subsequent operations. The second argument allows the application to provide the memory needed for the object, thus eliminating any need for dynamic memory allocation within the kernel. If a counter is no longer required and does not have any alarms attached then `cyg_counter_delete` can be used to release the resources, allowing the cyg_counter data structure to be re-used.

Initializing a counter does not automatically attach it to any source of events. Instead some other code needs to call `cyg_counter_tick` whenever a suitable event occurs, which will cause the counter to be incremented and may cause alarms to trigger. The current value associated with the counter can be retrieved using `cyg_counter_current_value` and modified with `cyg_counter_set_value`. Typically the latter function is only used during initialization, for example to set a clock to wallclock time, but it can be used to reset a counter if necessary. However `cyg_counter_set_value` will never trigger any alarms. A newly initialized counter has a starting value of 0.

The kernel provides two different implementations of counters. The default is `CYGIMP_KERNEL_COUNTERS_SINGLE_LIST` which stores all alarms attached to the counter on a single list. This is simple and usually efficient. However when a tick occurs the kernel code has to traverse this list, typically at DSR level, so if there are a significant number of alarms attached to a single counter this will affect the system's dispatch latency. The alternative implementation, `CYGIMP_KERNEL_COUNTERS_MULTI_LIST`, stores each alarm in one of an array of lists such that at most one of the lists needs to be searched per clock tick. This involves extra code and data, but can improve real-time responsiveness in some circumstances. Another configuration option that is relevant here is `CYGIMP_KERNEL_COUNTERS_SORT_LIST`, which is disabled by default. This provides a trade off between doing work whenever a new alarm is added to a counter and doing work whenever a tick occurs. It is application-dependent which of these is more appropriate.

Valid contexts

`cyg_counter_create` is typically called during system initialization but may also be called in thread context. Similarly `cyg_counter_delete` may be called during initialization or in thread context. `cyg_counter_current_value`, `cyg_counter_set_value` and `cyg_counter_tick` may be called during initialization or from thread or DSR context. In fact, `cyg_counter_tick` is usually called from inside a DSR in response to an external event of some sort.

Name

cyg_clock_create, cyg_clock_delete, cyg_clock_to_counter, cyg_clock_set_resolution, cyg_clock_get_resolution, cyg_real_time_clock and cyg_current_time — Provide system clocks

Synopsis

#include <cyg/kernel/kapi.h>

```
void cyg_clock_create (resolution, handle, clock);

void cyg_clock_delete (clock);

void cyg_clock_to_counter (clock, counter);

void cyg_clock_set_resolution (clock, resolution);

cyg_resolution_t cyg_clock_get_resolution (clock);

cyg_handle_t cyg_real_time_clock ();

cyg_tick_count_t cyg_current_time ();
```

Description

In the eCos kernel clock objects are a special form of counter objects. They are attached to a specific type of hardware, clocks that generate ticks at very specific time intervals, whereas counters can be used with any event source.

In a default configuration the kernel provides a single clock instance, the real-time clock. This gets used for timeslicing and for operations that involve a timeout, for example `cyg_semaphore_timed_wait`. If this functionality is not required it can be removed from the system using the configuration option `CYGVAR_KERNEL_COUNTERS_CLOCK`. Otherwise the real-time clock can be accessed by a call to `cyg_real_time_clock`, allowing applications to attach alarms, and the current counter value can be obtained using `cyg_current_time`.

Applications can create and destroy additional clocks if desired, using `cyg_clock_create` and `cyg_clock_delete`. The first argument to `cyg_clock_create` specifies the resolution this clock will run at. The second argument is used to return a handle for this clock object, and the third argument provides the kernel with the memory needed to hold this object. This clock will not actually tick by itself. Instead it is the responsibility of application code to initialize a suitable hardware timer to generate interrupts at the appropriate frequency, install an interrupt handler for this, and call `cyg_counter_tick` from inside the DSR. Associated with each clock is a kernel counter, a handle for which can be obtained using `cyg_clock_to_counter`.

Clock Resolutions and Ticks

At the kernel level all clock-related operations including delays, timeouts and alarms work in units of clock ticks, rather than in units of seconds or milliseconds. If the calling code, whether the application or some other package, needs to operate using units such as milliseconds then it has to convert from these units to clock ticks.

The main reason for this is that it accurately reflects the hardware: calling something like `nanosleep` with a delay of ten nanoseconds will not work as intended on any real hardware because timer interrupts simply will not happen that frequently; instead calling `cyg_thread_delay` with the equivalent delay of 0 ticks gives a much clearer indication that the application is attempting something inappropriate for the target hardware. Similarly, passing a delay of five ticks to `cyg_thread_delay` makes it fairly obvious that the current thread will be suspended for somewhere between four and five clock periods, as opposed to passing 50000000 to `nanosleep` which suggests a granularity that is not actually provided.

A secondary reason is that conversion between clock ticks and units such as milliseconds can be somewhat expensive, and whenever possible should be done at compile-time or by the application developer rather than at run-time. This saves code size and CPU cycles.

The information needed to perform these conversions is the clock resolution. This is a structure with two fields, a dividend and a divisor, and specifies the number of nanoseconds between clock ticks. For example a clock that runs at 100Hz will have 10 milliseconds between clock ticks, or 10000000 nanoseconds. The ratio between the resolution's dividend and divisor will therefore be 10000000 to 1, and typical values for these might be 1000000000 and 100. If the clock runs at a different frequency, say 60Hz, the numbers could be 1000000000 and 60 respectively. Given a delay in nanoseconds, this can be converted to clock ticks by multiplying with the the divisor and then dividing by the dividend. For example a delay of 50 milliseconds corresponds to 50000000 nanoseconds, and with a clock frequency of 100Hz this can be converted to ((50000000 * 100) / 1000000000) = 5 clock ticks. Given the large numbers involved this arithmetic normally has to be done using 64-bit precision and the long long data type, but allows code to run on hardware with unusual clock frequencies.

The default frequency for the real-time clock on any platform is usually about 100Hz, but platform-specific documentation should be consulted for this information. Usually it is possible to override this default by configuration options, but again this depends on the capabilities of the underlying hardware. The resolution for any clock can be obtained using `cyg_clock_get_resolution`. For clocks created by application code, there is also a function `cyg_clock_set_resolution`. This does not affect the underlying hardware timer in any way, it merely updates the information that will be returned in subsequent calls to `cyg_clock_get_resolution`: changing the actual underlying clock frequency will require appropriate manipulation of the timer hardware.

Valid contexts

`cyg_clock_create` is usually only called during system initialization (if at all), but may also be called from thread context. The same applies to `cyg_clock_delete`. The remaining functions may be called during initialization, from thread context, or from DSR context, although it should be noted that there is no locking between `cyg_clock_get_resolution` and `cyg_clock_set_resolution` so theoretically it is possible that the former returns an inconsistent data structure.

Name

cyg_alarm_create, cyg_alarm_delete, cyg_alarm_initialize, cyg_alarm_enable and cyg_alarm_disable — Run an alarm function when a number of events have occurred

Synopsis

#include <cyg/kernel/kapi.h>

void **cyg_alarm_create** (*counter*, *alarmfn*, *data*, *handle*, *alarm*);

void **cyg_alarm_delete** (*alarm*);

void **cyg_alarm_initialize** (*alarm*, *trigger*, *interval*);

void **cyg_alarm_enable** (*alarm*);

void **cyg_alarm_disable** (*alarm*);

Description

Kernel alarms are used together with counters and allow for action to be taken when a certain number of events have occurred. If the counter is associated with a clock then the alarm action happens when the appropriate number of clock ticks have occurred, in other words after a certain period of time.

Setting up an alarm involves a two-step process. First the alarm must be created with a call to `cyg_alarm_create`. This takes five arguments. The first identifies the counter to which the alarm should be attached. If the alarm should be attached to the system's real-time clock then `cyg_real_time_clock` and `cyg_clock_to_counter` can be used to get hold of the appropriate handle. The next two arguments specify the action to be taken when the alarm is triggered, in the form of a function pointer and some data. This function should take the form:

```
void
alarm_handler(cyg_handle_t alarm, cyg_addrword_t data)
{
    …
}
```

The data argument passed to the alarm function corresponds to the third argument passed to `cyg_alarm_create`. The fourth argument to `cyg_alarm_create` is used to return a handle to the newly-created alarm object, and the final argument provides the memory needed for the alarm object and thus avoids any need for dynamic memory allocation within the kernel.

Once an alarm has been created a further call to `cyg_alarm_initialize` is needed to activate it. The first argument specifies the alarm. The second argument indicates the number of events, for example clock ticks, that need to occur before the alarm triggers. If the third argument is 0 then the alarm will only trigger once. A non-zero value specifies that the alarm should trigger repeatedly, with an interval of the specified number of events.

Alarms can be temporarily disabled and reenabled using `cyg_alarm_disable` and `cyg_alarm_enable`. Alternatively another call to `cyg_alarm_initialize` can be used to modify the behaviour of an existing alarm. If an alarm is no longer required then the associated resources can be released using `cyg_alarm_delete`.

If two or more alarms are registered for precisely the same counter tick, the order of execution of the alarm functions is unspecified.

Handler context

The alarm function is invoked when a counter tick occurs, in other words when there is a call to `cyg_counter_tick`, and will happen in the same context. If the alarm is associated with the system's real-time clock then by default this will be DSR context, following a clock interrupt. If the alarm is associated with some other application-specific counter then the details will depend on how that counter is updated.

It is also possible to configure the kernel to call kernel RTC alarms in a thread context, instead of a DSR context. This is enabled with the option "Call RTC events from a thread" (`CYGIMP_KERNEL_COUNTERS_RTC_TICK_THREAD`). When enabled, a dedicated thread is created for running kernel alarm handlers. This can be useful in improving deterministic real-time behaviour as lengthy alarm handlers in a DSR context could disrupt normal scheduling.

As an additional variation, normally the scheduler is locked while running all the alarm handlers, preventing DSRs (and any higher priority threads) from running. However if the "Reduce DSR latency" option is enabled, the scheduler will briefly be unlocked at a safe point between each alarm handler call, in order to allow DSRs to run. This reduces the worst case DSR latency to that of the longest single running alarm handler. However note that if enabled, this option effects *all* counters and clocks in the system, not just those associated with the kernel RTC.

Valid calling contexts

`cyg_alarm_createcyg_alarm_initialize` is typically called during system initialization but may also be called in thread context. The same applies to `cyg_alarm_delete`. `cyg_alarm_initialize`, `cyg_alarm_disable` and `cyg_alarm_enable` may be called during initialization or from thread or DSR context, but `cyg_alarm_enable` and `cyg_alarm_initialize` may be expensive operations and should only be called when necessary.

Name

cyg_mutex_init, cyg_mutex_destroy, cyg_mutex_lock, cyg_mutex_timed_lock, cyg_mutex_trylock, cyg_mutex_unlock, cyg_mutex_release, cyg_mutex_set_ceiling and cyg_mutex_set_protocol — Synchronization primitive

Synopsis

#include <cyg/kernel/kapi.h>

`void` **`cyg_mutex_init`** `(`*`mutex`*`);`

`void` **`cyg_mutex_destroy`** `(`*`mutex`*`);`

`cyg_bool_t` **`cyg_mutex_lock`** `(`*`mutex`*`);`

`cyg_bool_t` **`cyg_mutex_timed_lock`** `(`*`mutex`*`,` *`abstime`*`);`

`cyg_bool_t` **`cyg_mutex_trylock`** `(`*`mutex`*`);`

`void` **`cyg_mutex_unlock`** `(`*`mutex`*`);`

`void` **`cyg_mutex_release`** `(`*`mutex`*`);`

`void` **`cyg_mutex_set_ceiling`** `(`*`mutex`*`,` *`priority`*`);`

`void` **`cyg_mutex_set_protocol`** `(`*`mutex`*`,` *`protocol/`*`);`

Description

The purpose of mutexes is to let threads share resources safely. If two or more threads attempt to manipulate a data structure with no locking between them then the system may run for quite some time without apparent problems, but sooner or later the data structure will become inconsistent and the application will start behaving strangely and is quite likely to crash. The same can apply even when manipulating a single variable or some other resource. For example, consider:

```
static volatile int counter = 0;

void
process_event(void)
{
    …

    counter++;
}
```

Assume that after a certain period of time `counter` has a value of 42, and two threads A and B running at the same priority call `process_event`. Typically thread A will read the value of `counter` into a register, increment this register to 43, and write this updated value back to memory. Thread B will do the same, so usually `counter` will end up with a value of 44. However if thread A is timesliced after reading the old value 42 but before writing back 43, thread B will still read back the old value and will also write back 43. The net result is that the counter only gets incremented once, not twice, which depending on the application may prove disastrous.

Sections of code like the above which involve manipulating shared data are generally known as critical regions. Code should claim a lock before entering a critical region and release the lock when leaving. Mutexes provide an appropriate synchronization primitive for this.

```
static volatile int counter = 0;
static cyg_mutex_t  lock;

void
```

```
process_event(void)
{
    …

    cyg_mutex_lock(&lock);
    counter++;
    cyg_mutex_unlock(&lock);
}
```

A mutex must be initialized before it can be used, by calling `cyg_mutex_init`. This takes a pointer to a cyg_mutex_t data structure which is typically statically allocated, and may be part of a larger data structure. If a mutex is no longer required and there are no threads waiting on it then `cyg_mutex_destroy` can be used.

The main functions for using a mutex are `cyg_mutex_lock` and `cyg_mutex_unlock`. In normal operation `cyg_mutex_lock` will return success after claiming the mutex lock, blocking if another thread currently owns the mutex. However the lock operation may fail if other code calls `cyg_mutex_release` or `cyg_thread_release`, so if these functions may get used then it is important to check the return value. The current owner of a mutex should call `cyg_mutex_unlock` when a lock is no longer required. This operation must be performed by the owner, not by another thread.

The kernel supplies a variant of `cyg_mutex_lock`, `cyg_mutex_timed_wait`, which can be used to wait for the lock or until some number of clock ticks have passed. The number of ticks is specified as an absolute, not relative, tick count and so in order to wait for a relative number of ticks, the return value of the `cyg_current_time()` function should be added to determine the absolute number of ticks. If this function returns `true` then the mutex has been claimed, if it returns `false` then either a timeout has occurred or the thread has been released.

`cyg_mutex_trylock` is a variant of `cyg_mutex_lock` that will always return immediately, returning success or failure as appropriate. This function is rarely useful. Typical code locks a mutex just before entering a critical region, so if the lock cannot be claimed then there may be nothing else for the current thread to do. Use of this function may also cause a form of priority inversion if the owner runs at a lower priority, because the priority inheritance code will not be triggered. Instead the current thread continues running, preventing the owner from getting any CPU time, completing the critical region, and releasing the mutex.

`cyg_mutex_release` can be used to wake up all threads that are currently blocked inside a call to `cyg_mutex_lock` for a specific mutex. These lock calls will return failure. The current mutex owner is not affected.

Priority Inversion

The use of mutexes gives rise to a problem known as priority inversion. In a typical scenario this requires three threads A, B, and C, running at high, medium and low priority respectively. Thread A and thread B are temporarily blocked waiting for some event, so thread C gets a chance to run, needs to enter a critical region, and locks a mutex. At this point threads A and B are woken up - the exact order does not matter. Thread A needs to claim the same mutex but has to wait until C has left the critical region and can release the mutex. Meanwhile thread B works on something completely different and can continue running without problems. Because thread C is running a lower priority than B it will not get a chance to run until B blocks for some reason, and hence thread A cannot run either. The overall effect is that a high-priority thread A cannot proceed because of a lower priority thread B, and priority inversion has occurred.

In simple applications it may be possible to arrange the code such that priority inversion cannot occur, for example by ensuring that a given mutex is never shared by threads running at different priority levels. However this may not always be possible even at the application level. In addition mutexes may be used internally by underlying code, for example the memory allocation package, so careful analysis of the whole system would be needed to be sure that priority inversion cannot occur. Instead it is common practice to use one of two techniques: priority ceilings and priority inheritance.

Priority ceilings involve associating a priority with each mutex. Usually this will match the highest priority thread that will ever lock the mutex. When a thread running at a lower priority makes a successful call to `cyg_mutex_lock` or `cyg_mutex_trylock` its priority will be boosted to that of the mutex. For example, given the previous example the priority associated with the mutex would be that of thread A, so for as long as it owns the mutex thread C will run in preference to thread B. When C releases the mutex its priority drops to the normal value again, allowing A to run and claim the mutex. Setting the priority for a mutex involves a call to `cyg_mutex_set_ceiling`, which is typically called during initialization. It is possible to change the ceiling dynamically but this will only affect subsequent lock operations, not the current owner of the mutex.

Priority ceilings are very suitable for simple applications, where for every thread in the system it is possible to work out which mutexes will be accessed. For more complicated applications this may prove difficult, especially if thread priorities change at run-time. An additional problem occurs for any mutexes outside the application, for example used internally within eCos packages. A typical eCos package will be unaware of the details of the various threads in the system, so it will have no way of setting suitable ceilings for its internal mutexes. If those mutexes are not exported to application code then using priority ceilings may not be viable. The kernel does provide a configuration option `CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL_DEFAULT_PRIORITY` that can be used to set the default priority ceiling for all mutexes, which may prove sufficient.

The alternative approach is to use priority inheritance: if a thread calls `cyg_mutex_lock` for a mutex that it currently owned by a lower-priority thread, then the owner will have its priority raised to that of the current thread. Often this is more efficient than priority ceilings because priority boosting only happens when necessary, not for every lock operation, and the required priority is determined at run-time rather than by static analysis. However there are complications when multiple threads running at different priorities try to lock a single mutex, or when the current owner of a mutex then tries to lock additional mutexes, and this makes the implementation significantly more complicated than priority ceilings.

There are a number of configuration options associated with priority inversion. First, if after careful analysis it is known that priority inversion cannot arise then the component `CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL` can be disabled. More commonly this component will be enabled, and one of either `CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL_INHERIT` or `CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL_CEILING` will be selected, so that one of the two protocols is available for all mutexes. It is possible to select multiple protocols, so that some mutexes can have priority ceilings while others use priority inheritance or no priority inversion protection at all. Obviously this flexibility will add to the code size and to the cost of mutex operations. The default for all mutexes will be controlled by `CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL_DEFAULT`, and can be changed at run-time using `cyg_mutex_set_protocol`.

Priority inversion problems can also occur with other synchronization primitives such as semaphores. For example there could be a situation where a high-priority thread A is waiting on a semaphore, a low-priority thread C needs to do just a little bit more work before posting the semaphore, but a medium priority thread B is running and preventing C from making progress. However a semaphore does not have the concept of an owner, so there is no way for the system to know that it is thread C which would next post to the semaphore. Hence there is no way for the system to boost the priority of C automatically and prevent the priority inversion. Instead situations like this have to be detected by application developers and appropriate precautions have to be taken, for example making sure that all the threads run at suitable priorities at all times.

Warning

The default implementation of priority inheritance within the eCos kernel has been simplified in a way that may cause behaviour which is unexpected for developers. Problems will only arise if a thread owns one mutex, then attempts to claim another mutex, and there are other threads attempting to lock these same mutexes. Although the system will continue running, the current owners of the various mutexes involved may not run at the priority they should.

The reason for this is that, with the default implementation of priority inheritance, a thread which has its priority boosted due to it having locked *two or more* mutexes will not have its priority reduced until *both* mutexes are unlocked. In other words, that thread will continue running at the highest priority of any of the threads waiting for a mutex it holds, and will keep running at that priority until it has unlocked all the mutexes which it holds.

This situation rarely arises in real-world code because a mutex should generally only be locked for a small critical region, and there is no need to manipulate other shared resources inside this region. However eCosPro offers an alternative implementation which does allow priorities to be reduced in a fair and accurate way when mutexes are unlocked. This alternative is not enabled by default, but can be enabled with the "Fair priority inheritance semantics" (`CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL_INHERIT_ACCURATE`) CDL configuration option. However the trade-off of providing a fair and accurate behaviour of priority inheritance is that mutex unlock operations then have a non-deterministic element as each mutex held by a thread must be examined to determine the priority of the highest waiting thread. Fortunately, it is unlikely in real-world applications that more than a few mutexes will be held simultaneously, so that list should be short; and therefore this trade-off may be acceptable for many developers.

Warning

Support for priority ceilings and priority inheritance is not implemented for all schedulers. In particular neither priority ceilings nor priority inheritance are currently available for the bitmap scheduler.

Alternatives

In nearly all circumstances, if two or more threads need to share some data then protecting this data with a mutex is the correct thing to do. Mutexes are the only primitive that combine a locking mechanism and protection against priority inversion problems. However this functionality is achieved at a cost, and in exceptional circumstances such as an application's most critical inner loop it may be desirable to use some other means of locking.

When a critical region is very very small it is possible to lock the scheduler, thus ensuring that no other thread can run until the scheduler is unlocked again. This is achieved with calls to `cyg_scheduler_lock` and `cyg_scheduler_unlock`. If the critical region is sufficiently small then this can actually improve both performance and dispatch latency because `cyg_mutex_lock` also locks the scheduler for a brief period of time. This approach will not work on SMP systems because another thread may already be running on a different processor and accessing the critical region.

Another way of avoiding the use of mutexes is to make sure that all threads that access a particular critical region run at the same priority and configure the system with timeslicing disabled (`CYGSEM_KERNEL_SCHED_TIMESLICE`). Without timeslicing a thread can only be preempted by a higher-priority one, or if it performs some operation that can block. This approach requires that none of the operations in the critical region can block, so for example it is not legal to call `cyg_semaphore_wait`. It is also vulnerable to any changes in the configuration or to the various thread priorities: any such changes may now have unexpected side effects. It will not work on SMP systems.

Recursive Mutexes

The implementation of mutexes within the eCos kernel does not support recursive locks. If a thread has locked a mutex and then attempts to lock the mutex again, typically as a result of some recursive call in a complicated call graph, then either an assertion failure will be reported or the thread will deadlock. This behaviour is deliberate. When a thread has just locked a mutex associated with some data structure, it can assume that that data structure is in a consistent state. Before unlocking the mutex again it must ensure that the data structure is again in a consistent state. Recursive mutexes allow a thread to make arbitrary changes to a data structure, then in a recursive call lock the mutex again while the data structure is still inconsistent. The net result is that code can no longer make any assumptions about data structure consistency, which defeats the purpose of using mutexes.

Valid contexts

`cyg_mutex_init`, `cyg_mutex_set_ceiling` and `cyg_mutex_set_protocol` are normally called during initialization but may also be called from thread context. The remaining functions should only be called from thread context. Mutexes serve as a mutual exclusion mechanism between threads, and cannot be used to synchronize between threads and the interrupt handling subsystem. If a critical region is shared between a thread and a DSR then it must be protected using `cyg_scheduler_lock` and `cyg_scheduler_unlock`. If a critical region is shared between a thread and an ISR, it must be protected by disabling or masking interrupts. Obviously these operations must be used with care because they can affect dispatch and interrupt latencies.

Name

cyg_cond_init, cyg_cond_destroy, cyg_cond_wait, cyg_cond_timed_wait, cyg_cond_signal and cyg_cond_broadcast — Synchronization primitive

Synopsis

#include <cyg/kernel/kapi.h>

void **cyg_cond_init** (*cond*, *mutex*);

void **cyg_cond_destroy** (*cond*);

cyg_bool_t **cyg_cond_wait** (*cond*);

cyg_bool_t **cyg_cond_timed_wait** (*cond*, *abstime*);

void **cyg_cond_signal** (*cond*);

void **cyg_cond_broadcast** (*cond*);

Description

Condition variables are used in conjunction with mutexes to implement long-term waits for some condition to become true. For example consider a set of functions that control access to a pool of resources:

```
cyg_mutex_t res_lock;
res_t res_pool[RES_MAX];
int res_count = RES_MAX;

void res_init(void)
{
    cyg_mutex_init(&res_lock);
    <fill pool with resources>
}

res_t res_allocate(void)
{
    res_t res;

    cyg_mutex_lock(&res_lock);               // lock the mutex

    if( res_count == 0 )                     // check for free resource
        res = RES_NONE;                      // return RES_NONE if none
    else
    {
        res_count--;                         // allocate a resources
        res = res_pool[res_count];
    }

    cyg_mutex_unlock(&res_lock);             // unlock the mutex

    return res;
}

void res_free(res_t res)
{
    cyg_mutex_lock(&res_lock);               // lock the mutex

    res_pool[res_count] = res;               // free the resource
    res_count++;
    cyg_mutex_unlock(&res_lock);             // unlock the mutex
}
```

These routines use the variable `res_count` to keep track of the resources available. If there are none then `res_allocate` returns `RES_NONE`, which the caller must check for and take appropriate error handling actions.

Now suppose that we do not want to return `RES_NONE` when there are no resources, but want to wait for one to become available. This is where a condition variable can be used:

```
cyg_mutex_t res_lock;
cyg_cond_t res_wait;
res_t res_pool[RES_MAX];
int res_count = RES_MAX;

void res_init(void)
{
    cyg_mutex_init(&res_lock);
    cyg_cond_init(&res_wait, &res_lock);
    <fill pool with resources>
}

res_t res_allocate(void)
{
    res_t res;

    cyg_mutex_lock(&res_lock);               // lock the mutex

    while( res_count == 0 )                  // wait for a resources
        cyg_cond_wait(&res_wait);

    res_count--;                             // allocate a resource
    res = res_pool[res_count];

    cyg_mutex_unlock(&res_lock);             // unlock the mutex

    return res;
}

void res_free(res_t res)
{
    cyg_mutex_lock(&res_lock);               // lock the mutex

    res_pool[res_count] = res;               // free the resource
    res_count++;

    cyg_cond_signal(&res_wait);              // wake up any waiting allocators

    cyg_mutex_unlock(&res_lock);             // unlock the mutex
}
```

In this version of the code, when `res_allocate` detects that there are no resources it calls `cyg_cond_wait`. This does two things: it unlocks the mutex, and puts the calling thread to sleep on the condition variable. When `res_free` is eventually called, it puts a resource back into the pool and calls `cyg_cond_signal` to wake up any thread waiting on the condition variable. When the waiting thread eventually gets to run again, it will re-lock the mutex before returning from `cyg_cond_wait`.

There are two important things to note about the way in which this code works. The first is that the mutex unlock and wait in `cyg_cond_wait` are atomic: no other thread can run between the unlock and the wait. If this were not the case then a call to `res_free` by that thread would release the resource but the call to `cyg_cond_signal` would be lost, and the first thread would end up waiting when there were resources available.

The second feature is that the call to `cyg_cond_wait` is in a `while` loop and not a simple `if` statement. This is because of the need to re-lock the mutex in `cyg_cond_wait` when the signalled thread reawakens. If there are other threads already queued to claim the lock then this thread must wait. Depending on the scheduler and the queue order, many other threads may have entered the critical section before this one gets to run. So the condition that it was waiting for may have been rendered false. Using a loop around all condition variable wait operations is the only way to guarantee that the condition being waited for is still true after waiting.

Before a condition variable can be used it must be initialized with a call to `cyg_cond_init`. This requires two arguments, memory for the data structure and a pointer to an existing mutex. This mutex will not be initialized by `cyg_cond_init`, instead a separate call to `cyg_mutex_init` is required. If a condition variable is no longer required and there are no threads waiting on it then `cyg_cond_destroy` can be used.

When a thread needs to wait for a condition to be satisfied it can call `cyg_cond_wait`. The thread must have already locked the mutex that was specified in the `cyg_cond_init` call. This mutex will be unlocked and the current thread will be suspended in an atomic operation. When some other thread performs a signal or broadcast operation the current thread will be woken up and automatically reclaim ownership of the mutex again, allowing it to examine global state and determine whether or not the condition is now satisfied.

The kernel supplies a variant of this function, `cyg_cond_timed_wait`, which can be used to wait on the condition variable or until some number of clock ticks have occurred. The number of ticks is specified as an absolute, not relative tick count, and so in order to wait for a relative number of ticks, the return value of the `cyg_current_time()` function should be added to determine the absolute number of ticks. The mutex will always be reclaimed before `cyg_cond_timed_wait` returns, regardless of whether it was a result of a signal operation or a timeout.

There is no `cyg_cond_trywait` function because this would not serve any purpose. If a thread has locked the mutex and determined that the condition is satisfied, it can just release the mutex and return. There is no need to perform any operation on the condition variable.

When a thread changes shared state that may affect some other thread blocked on a condition variable, it should call either `cyg_cond_signal` or `cyg_cond_broadcast`. These calls do not require ownership of the mutex, but usually the mutex will have been claimed before updating the shared state. A signal operation only wakes up the first thread that is waiting on the condition variable, while a broadcast wakes up all the threads. If there are no threads waiting on the condition variable at the time, then the signal or broadcast will have no effect: past signals are not counted up or remembered in any way. Typically a signal should be used when all threads will check the same condition and at most one thread can continue running. A broadcast should be used if threads check slightly different conditions, or if the change to the global state might allow multiple threads to proceed.

Valid contexts

`cyg_cond_init` is typically called during system initialization but may also be called in thread context. The same applies to `cyg_cond_delete`. `cyg_cond_wait` and `cyg_cond_timedwait` may only be called from thread context since they may block. `cyg_cond_signal` and `cyg_cond_broadcast` may be called from thread or DSR context.

Name

cyg_semaphore_init, cyg_semaphore_destroy, cyg_semaphore_wait, cyg_semaphore_timed_wait, cyg_semaphore_post and cyg_semaphore_peek — Synchronization primitive

Synopsis

#include <cyg/kernel/kapi.h>

```
void cyg_semaphore_init (sem, val);

void cyg_semaphore_peek (sem, val);
```

Description

Counting semaphores are a synchronization primitive that allow threads to wait until an event has occurred. The event may be generated by a producer thread, or by a DSR in response to a hardware interrupt. Associated with each semaphore is an integer counter that keeps track of the number of events that have not yet been processed. If this counter is zero, an attempt by a consumer thread to wait on the semaphore will block until some other thread or a DSR posts a new event to the semaphore. If the counter is greater than zero then an attempt to wait on the semaphore will consume one event, in other words decrement the counter, and return immediately. Posting to a semaphore will wake up the first thread that is currently waiting, which will then resume inside the semaphore wait operation and decrement the counter again.

Another use of semaphores is for certain forms of resource management. The counter would correspond to how many of a certain type of resource are currently available, with threads waiting on the semaphore to claim a resource and posting to release the resource again. In practice condition variables are usually much better suited for operations like this.

`cyg_semaphore_init` is used to initialize a semaphore. It takes two arguments, a pointer to a cyg_sem_t structure and an initial value for the counter. Note that semaphore operations, unlike some other parts of the kernel API, use pointers to data structures rather than handles. This makes it easier to embed semaphores in a larger data structure. The initial counter value can be any number, zero, positive or negative, but typically a value of zero is used to indicate that no events have occurred yet.

`cyg_semaphore_wait` is used by a consumer thread to wait for an event. If the current counter is greater than 0, in other words if the event has already occurred in the past, then the counter will be decremented and the call will return immediately. Otherwise the current thread will be blocked until there is a `cyg_semaphore_post` call.

`cyg_semaphore_post` is called when an event has occurs. This increments the counter and wakes up the first thread waiting on the semaphore (if any). Usually that thread will then continue running inside `cyg_semaphore_wait` and decrement the counter again. However other scenarios are possible. For example the thread calling `cyg_semaphore_post` may be running at high priority, some other thread running at medium priority may be about to call `cyg_semaphore_wait` when it next gets a chance to run, and a low priority thread may be waiting on the semaphore. What will happen is that the current high priority thread continues running until it is descheduled for some reason, then the medium priority thread runs and its call to `cyg_semaphore_wait` succeeds immediately, and later on the low priority thread runs again, discovers a counter value of 0, and blocks until another event is posted. If there are multiple threads blocked on a semaphore then the configuration option `CYGIMP_KERNEL_SCHED_SORTED_QUEUES` determines which one will be woken up by a post operation.

cyg_semaphore_wait returns a boolean. Normally it will block until it has successfully decremented the counter, retrying as necessary, and return success. However the wait operation may be aborted by a call to cyg_thread_release, and cyg_semaphore_wait will then return false.

cyg_semaphore_timed_wait is a variant of cyg_semaphore_wait. It can be used to wait until either an event has occurred or a number of clock ticks have happened. The number of ticks is specified as an absolute, not relative tick count, and so in order to wait for a relative number of ticks, the return value of the cyg_current_time() function should be added to determine the absolute number of ticks. The function returns success if the semaphore wait operation succeeded, or false if the operation timed out or was aborted by cyg_thread_release. If support for the real-time clock has been removed from the current configuration then this function will not be available. cyg_semaphore_trywait is another variant which will always return immediately rather than block, again returning success or failure. If cyg_semaphore_timedwait is given a timeout in the past, it operates like cyg_semaphore_trywait.

cyg_semaphore_peek can be used to get hold of the current counter value. This function is rarely useful except for debugging purposes since the counter value may change at any time if some other thread or a DSR performs a semaphore operation.

Valid contexts

cyg_semaphore_init is normally called during initialization but may also be called from thread context. cyg_semaphore_wait and cyg_semaphore_timed_wait may only be called from thread context because these operations may block. cyg_semaphore_trywait, cyg_semaphore_post and cyg_semaphore_peek may be called from thread or DSR context.

Description

Mail boxes are a synchronization primitive. Like semaphores they can be used by a consumer thread to wait until a certain event has occurred, but the producer also has the ability to transmit some data along with each event. This data, the message, is normally a pointer to some data structure. It is stored in the mail box itself, so the producer thread that generates the event and provides the data usually does not have to block until some consumer thread is ready to receive the event. However a mail box will only have a finite capacity, typically ten slots. Even if the system is balanced and events are typically consumed at least as fast as they are generated, a burst of events can cause the mail box to fill up and the generating thread will block until space is available again. This behaviour is very different from semaphores, where it is only necessary to maintain a counter and hence an overflow is unlikely.

Before a mail box can be used it must be created with a call to `cyg_mbox_create`. Each mail box has a unique handle which will be returned via the first argument and which should be used for subsequent operations. `cyg_mbox_create` also requires an area of memory for the kernel structure, which is provided by the cyg_mbox second argument. If a mail box is no longer required then `cyg_mbox_delete` can be used. This will simply discard any messages that remain posted.

The main function for waiting on a mail box is `cyg_mbox_get`. If there is a pending message because of a call to `cyg_mbox_put` then `cyg_mbox_get` will return immediately with the message that was put into the mail box. Otherwise this function will block until there is a put operation. Exceptionally the thread can instead be unblocked by a call to `cyg_thread_release`, in which case `cyg_mbox_get` will return a null pointer. It is assumed that there will never be a call to `cyg_mbox_put` with a null pointer, because it would not be possible to distinguish between that and a release operation. Messages are always retrieved in the order in which they were put into the mail box, and there is no support for messages with different priorities.

There are two variants of cyg_mbox_get. The first, cyg_mbox_timed_get will wait until either a message is available or until a number of clock ticks have occurred. The number of ticks is specified as an absolute, not relative tick count, and so in order to wait for a relative number of ticks, the return value of the cyg_current_time() function should be added to determine the absolute number of ticks. If no message is posted within the timeout then a null pointer will be returned. cyg_mbox_tryget is a non-blocking operation which will either return a message if one is available or a null pointer.

New messages are placed in the mail box by calling cyg_mbox_put or one of its variants. The main put function takes two arguments, a handle to the mail box and a pointer for the message itself. If there is a spare slot in the mail box then the new message can be placed there immediately, and if there is a waiting thread it will be woken up so that it can receive the message. If the mail box is currently full then cyg_mbox_put will block until there has been a get operation and a slot is available. The cyg_mbox_timed_put variant imposes a time limit on the put operation, returning false if the operation cannot be completed within the specified number of clock ticks and as for cyg_mbox_timed_get this is an absolute tick count. The cyg_mbox_tryput variant is non-blocking, returning false if there are no free slots available and the message cannot be posted without blocking.

There are a further four functions available for examining the current state of a mailbox. The results of these functions must be used with care because usually the state can change at any time as a result of activity within other threads, but they may prove occasionally useful during debugging or in special situations. cyg_mbox_peek returns a count of the number of messages currently stored in the mail box. cyg_mbox_peek_item retrieves the first message, but it remains in the mail box until a get operation is performed. cyg_mbox_waiting_to_get and cyg_mbox_waiting_to_put indicate whether or not there are currently threads blocked in a get or a put operation on a given mail box.

The number of slots in each mail box is controlled by a configuration option CYGNUM_KERNEL_SYNCH_MBOX_QUEUE_SIZE, with a default value of 10. All mail boxes are the same size.

Valid contexts

cyg_mbox_create is typically called during system initialization but may also be called in thread context. The remaining functions are normally called only during thread context. Of special note is cyg_mbox_put which can be a blocking operation when the mail box is full, and which therefore must never be called from DSR context. It is permitted to call cyg_mbox_tryput, cyg_mbox_tryget, and the information functions from DSR context but this is rarely useful.

Name

Description

Event flags allow a consumer thread to wait for one of several different types of event to occur. Alternatively it is possible to wait for some combination of events. The implementation is relatively straightforward. Each event flag contains a 32-bit integer. Application code associates these bits with specific events, so for example bit 0 could indicate that an I/O operation has completed and data is available, while bit 1 could indicate that the user has pressed a start button. A producer thread or a DSR can cause one or more of the bits to be set, and a consumer thread currently waiting for these bits will be woken up.

Unlike semaphores no attempt is made to keep track of event counts. It does not matter whether a given event occurs once or multiple times before being consumed, the corresponding bit in the event flag will change only once. However semaphores cannot easily be used to handle multiple event sources. Event flags can often be used as an alternative to condition variables, although they cannot be used for completely arbitrary conditions and they only support the equivalent of condition variable broadcasts, not signals.

Before an event flag can be used it must be initialized by a call to `cyg_flag_init`. This takes a pointer to a cyg_flag_t data structure, which can be part of a larger structure. All 32 bits in the event flag will be set to 0, indicating that no events have yet occurred. If an event flag is no longer required it can be cleaned up with a call to `cyg_flag_destroy`, allowing the memory for the *`cyg_flag_t`* structure to be re-used.

A consumer thread can wait for one or more events by calling `cyg_flag_wait`. This takes three arguments. The first identifies a particular event flag. The second is some combination of bits, indicating which events are of interest. The final argument should be one of the following:

`CYG_FLAG_WAITMODE_AND`

> The call to `cyg_flag_wait` will block until all the specified event bits are set. The event flag is not cleared when the wait succeeds, in other words all the bits remain set.

`CYG_FLAG_WAITMODE_OR`

> The call will block until at least one of the specified event bits is set. The event flag is not cleared on return.

CYG_FLAG_WAITMODE_AND | CYG_FLAG_WAITMODE_CLR

The call will block until all the specified event bits are set, and the entire event flag is cleared when the call succeeds. Note that if this mode of operation is used then a single event flag cannot be used to store disjoint sets of events, even though enough bits might be available. Instead each disjoint set of events requires its own event flag.

CYG_FLAG_WAITMODE_OR | CYG_FLAG_WAITMODE_CLR

The call will block until at least one of the specified event bits is set, and the entire flag is cleared when the call succeeds.

A call to `cyg_flag_wait` normally blocks until the required condition is satisfied. It will return the value of the event flag at the point that the operation succeeded, which may be a superset of the requested events. If `cyg_thread_release` is used to unblock a thread that is currently in a wait operation, the `cyg_flag_wait` call will instead return 0.

`cyg_flag_timed_wait` is a variant of `cyg_flag_wait` which adds a timeout: the wait operation must succeed within the specified number of ticks, or it will fail with a return value of 0. The number of ticks is specified as an absolute, not relative tick count, and so in order to wait for a relative number of ticks, the return value of the `cyg_current_time()` function should be added to determine the absolute number of ticks. `cyg_flag_poll` is a non-blocking variant: if the wait operation can succeed immediately it acts like `cyg_flag_wait`, otherwise it returns immediately with a value of 0.

`cyg_flag_setbits` is called by a producer thread or from inside a DSR when an event occurs. The specified bits are or'd into the current event flag value. This may cause one or more waiting threads to be woken up, if their conditions are now satisfied. How many threads are awoken depends on the use of `CYG_FLAG_WAITMODE_CLR`. The queue of threads waiting on the flag is walked to find threads which now have their wake condition fulfilled. If the awoken thread has passed `CYG_FLAG_WAITMODE_CLR` the walking of the queue is terminated, otherwise the walk continues. Thus if no threads have passed `CYG_FLAG_WAITMORE_CLR` all threads with fulfilled conditions will be awoken. If `CYG_FLAG_WAITMODE_CLR` is passed by threads with fulfilled conditions, the number of awoken threads will depend on the order the threads are in the queue.

`cyg_flag_maskbits` can be used to clear one or more bits in the event flag. This can be called from a producer when a particular condition is no longer satisfied, for example when the user is no longer pressing a particular button. It can also be used by a consumer thread if `CYG_FLAG_WAITMODE_CLR` was not used as part of the wait operation, to indicate that some but not all of the active events have been consumed. If there are multiple consumer threads performing wait operations without using `CYG_FLAG_WAITMODE_CLR` then typically some additional synchronization such as a mutex is needed to prevent multiple threads consuming the same event.

Two additional functions are provided to query the current state of an event flag. `cyg_flag_peek` returns the current value of the event flag, and `cyg_flag_waiting` can be used to find out whether or not there are any threads currently blocked on the event flag. Both of these functions must be used with care because other threads may be operating on the event flag.

Valid contexts

`cyg_flag_init` is typically called during system initialization but may also be called in thread context. The same applies to `cyg_flag_destroy`. `cyg_flag_wait` and `cyg_flag_timed_wait` may only be called from thread context. The remaining functions may be called from thread or DSR context.

void **cyg_spinlock_clear_intsave** (*lock*, *istate*);

Description

Spinlocks provide an additional synchronization primitive for applications running on SMP systems. They operate at a lower level than the other primitives such as mutexes, and for most purposes the higher-level primitives should be preferred. However there are some circumstances where a spinlock is appropriate, especially when interrupt handlers and threads need to share access to hardware, and on SMP systems the kernel implementation itself depends on spinlocks.

Essentially a spinlock is just a simple flag. When code tries to claim a spinlock it checks whether or not the flag is already set. If not then the flag is set and the operation succeeds immediately. The exact implementation of this is hardware-specific, for example it may use a test-and-set instruction to guarantee the desired behaviour even if several processors try to access the spinlock at the exact same time. If it is not possible to claim a spinlock then the current thread spins in a tight loop, repeatedly checking the flag until it is clear. This behaviour is very different from other synchronization primitives such as mutexes, where contention would cause a thread to be suspended. The assumption is that a spinlock will only be held for a very short time. If claiming a spinlock could cause the current thread to be suspended then spinlocks could not be used inside interrupt handlers, which is not acceptable.

This does impose a constraint on any code which uses spinlocks. Specifically it is important that spinlocks are held only for a short period of time, typically just some dozens of instructions. Otherwise another processor could be blocked on the spinlock for a long time, unable to do any useful work. It is also important that a thread which owns a spinlock does not get preempted because that might cause another processor to spin for a whole timeslice period, or longer. One way of achieving this is to disable interrupts on the current processor, and the function `cyg_spinlock_spin_intsave` is provided to facilitate this.

Spinlocks should not be used on single-processor systems. Consider a high priority thread which attempts to claim a spinlock already held by a lower priority thread: it will just loop forever and the lower priority thread will never get another chance to run and release the spinlock. Even if the two threads were running at the same priority, the one attempting to claim the spinlock would spin until it was timesliced and a lot of CPU time would be wasted. If an interrupt handler tried to claim a spinlock owned by a thread, the interrupt handler would loop forever. Therefore spinlocks are only appropriate for SMP systems where the current owner of a spinlock can continue running on a different processor.

Before a spinlock can be used it must be initialized by a call to `cyg_spinlock_init`. This takes two arguments, a pointer to a `cyg_spinlock_t` data structure, and a flag to specify whether the spinlock starts off locked or unlocked. If a spinlock is no longer required then it can be destroyed by a call to `cyg_spinlock_destroy`.

There are two routines for claiming a spinlock: `cyg_spinlock_spin` and `cyg_spinlock_spin_intsave`. The former can be used when it is known the current code will not be preempted, for example because it is running in an interrupt handler or because interrupts are disabled. The latter will disable interrupts in addition to claiming the spinlock, so is safe to use in all circumstances. The previous interrupt state is returned via the second argument, and should be used in a subsequent call to `cyg_spinlock_clear_intsave`.

Similarly there are two routines for releasing a spinlock: `cyg_spinlock_clear` and `cyg_spinlock_clear_intsave`. Typically the former will be used if the spinlock was claimed by a call to `cyg_spinlock_spin`, and the latter when `cyg_spinlock_intsave` was used.

There are two additional routines. `cyg_spinlock_try` is a non-blocking version of `cyg_spinlock_spin`: if possible the lock will be claimed and the function will return `true`; otherwise the function will return immediately with failure. `cyg_spinlock_test` can be used to find out whether or not the spinlock is currently locked. This function must be used with care because, especially on a multiprocessor system, the state of the spinlock can change at any time.

Spinlocks should only be held for a short period of time, and attempting to claim a spinlock will never cause a thread to be suspended. This means that there is no need to worry about priority inversion problems, and concepts such as priority ceilings and inheritance do not apply.

Valid contexts

All of the spinlock functions can be called from any context, including ISR and DSR context. Typically `cyg_spinlock_init` is only called during system initialization.

Name

cyg_scheduler_start, cyg_scheduler_lock, cyg_scheduler_unlock, cyg_scheduler_safe_lock, cyg_scheduler_read_lock, cyg_thread_lock_preemption, cyg_thread_unlock_preemption and cyg_thread_get_preemption_lock — Control the state of the scheduler

Synopsis

#include <cyg/kernel/kapi.h>

void **cyg_scheduler_start** ();

void **cyg_scheduler_lock** ();

void **cyg_scheduler_unlock** ();

cyg_ucount32 **cyg_scheduler_read_lock** ();

void **cyg_thread_lock_preemption** ();

void **cyg_thread_unlock_preemption** ();

cyg_ucount32 **cyg_thread_get_preemption_lock** ();

Description

`cyg_scheduler_start` should only be called once, to mark the end of system initialization. In typical configurations it is called automatically by the system startup, but some applications may bypass the standard startup in which case `cyg_scheduler_start` will have to be called explicitly. The call will enable system interrupts, allowing I/O operations to commence. Then the scheduler will be invoked and control will be transferred to the highest priority runnable thread. The call will never return.

The various data structures inside the eCos kernel must be protected against concurrent updates. Consider a call to `cyg_semaphore_post` which causes a thread to be woken up: the semaphore data structure must be updated to remove the thread from its queue; the scheduler data structure must also be updated to mark the thread as runnable; it is possible that the newly runnable thread has a higher priority than the current one, in which case preemption is required. If in the middle of the semaphore post call an interrupt occurred and the interrupt handler tried to manipulate the same data structures, for example by making another thread runnable, then it is likely that the structures will be left in an inconsistent state and the system will fail.

To prevent such problems the kernel contains a special lock known as the scheduler lock. A typical kernel function such as `cyg_semaphore_post` will claim the scheduler lock, do all its manipulation of kernel data structures, and then release the scheduler lock. The current thread cannot be preempted while it holds the scheduler lock. If an interrupt occurs and a DSR is supposed to run to signal that some event has occurred, that DSR is postponed until the scheduler unlock operation. This prevents concurrent updates of kernel data structures.

The kernel exports three routines for manipulating the scheduler lock. `cyg_scheduler_lock` can be called to claim the lock. On return it is guaranteed that the current thread will not be preempted, and that no other code is manipulating any kernel data structures. `cyg_scheduler_unlock` can be used to release the lock, which may cause the current thread to be preempted. `cyg_scheduler_read_lock` can be used to query the current state of the scheduler lock. This function should never be needed because well-written code should always know whether or not the scheduler is currently locked, but may prove useful during debugging.

The implementation of the scheduler lock involves a simple counter. Code can call `cyg_scheduler_lock` multiple times, causing the counter to be incremented each time, as long as `cyg_scheduler_unlock` is called the same number of times. This behaviour is different from mutexes where an attempt by a thread to lock a mutex multiple times will result in deadlock or an assertion failure.

Typical application code should not use the scheduler lock. Instead other synchronization primitives such as mutexes and semaphores should be used. While the scheduler is locked the current thread cannot be preempted, so any higher priority threads will not be able to run. Also no DSRs can run, so device drivers may not be able to service I/O requests. However there is one situation where locking the scheduler is appropriate: if some data structure needs to be shared between an application thread and a DSR associated with some interrupt source, the thread can use the scheduler lock to prevent concurrent invocations of the DSR and then safely manipulate the structure. It is desirable that the scheduler lock is held for only a short period of time, typically some tens of instructions. In exceptional cases there may also be some performance-critical code where it is more appropriate to use the scheduler lock rather than a mutex, because the former is more efficient.

Valid contexts

`cyg_scheduler_start` can only be called during system initialization, since it marks the end of that phase. The remaining functions may be called from thread or DSR context. Locking the scheduler from inside the DSR has no practical effect because the lock is claimed automatically by the interrupt subsystem before running DSRs, but allows functions to be shared between normal thread code and DSRs.

Pre-emption lock

Separate but similar to the scheduler lock is the thread pre-emption lock. This provides a more light-weight method of preventing pre-emption by higher priority threads. So even if a higher priority thread becomes runnable (on this CPU, if SMP) the current thread will not be descheduled until the pre-emption lock has been released. While the pre-emption lock is held, DSRs (and ISRs) are still permitted to run.

Like the scheduler lock, the pre-emption lock is a count and so it can be called multiple times, and only when the final level is unlocked will pre-emption become possible again. A thread should only invoke the lock for itself, not on another thread, as the lock is not protected from access by multiple threads. If a thread blocks or goes to sleep, then it will be descheduled in the normal way and another thread can run. Although, once it is rescheduled, its pre-emption lock state will be preserved; so if pre-emption was disabled before, it will become disabled again when rescheduled. In an SMP system, locking pre-emption will only affect operations on the current CPU, it will not affect threads on other CPUs.

If timeslicing is enabled and the current thread has locked pre-emption, then even if the thread has run out of time in its timeslice, it will still not be descheduled. Instead, it will run until it unlocks pre-emption.

Clearly, as with the scheduler lock, the pre-emption lock can severely affect proper real-time operation and so it should be avoided if other synchronization methods, such as mutexes, semaphores etc. can be used instead. If it is used, the length of time pre-emption is disabled should be kept to a minimum.

The availability of pre-emption locking can be controlled with the CDL configuration option `CYGFUN_KERNEL_THREAD_PREEMPTION_LOCK`, which defaults to enabled.

Description

The kernel provides an interface for installing interrupt handlers and controlling when interrupts occur. This functionality is used primarily by eCos device drivers and by any application code that interacts directly with hardware. However in most cases it is better to avoid using this kernel functionality directly, and instead the device driver API provided by the common HAL package should be used. Use of the kernel package is optional, and some applications such as RedBoot work with no need for multiple threads or synchronization primitives. Any code which calls the kernel directly rather than the device driver API will not function in such a configuration. When the kernel package is present the device driver API is implemented as `#define`'s to the equivalent kernel calls, otherwise it is implemented inside the common HAL package. The latter implementation can be simpler than the kernel one because there is no need to consider thread preemption and similar issues.

The exact details of interrupt handling vary widely between architectures. The functionality provided by the kernel abstracts away from many of the details of the underlying hardware, thus simplifying application development. However this is not always successful. For example, if some hardware does not provide any support at all for masking specific interrupts then calling `cyg_interrupt_mask` may not behave as intended: instead of masking just the one interrupt source it might disable all interrupts, because that is as close to the desired behaviour as is possible given the hardware restrictions. Another possibility is that masking a given interrupt source also affects all lower-priority interrupts, but still allows higher-priority ones. The documentation for the appropriate HAL packages should be consulted for more information about exactly how interrupts are handled on any given hardware. The HAL header files will also contain useful information.

Interrupt Handlers

Interrupt handlers are created by a call to `cyg_interrupt_create`. This takes the following arguments:

cyg_vector_t *`vector`*

The interrupt vector, a small integer, identifies the specific interrupt source. The appropriate hardware documentation or HAL header files should be consulted for details of which vector corresponds to which device.

cyg_priority_t *`priority`*

Some hardware may support interrupt priorities, where a low priority interrupt handler can in turn be interrupted by a higher priority one. Again hardware-specific documentation should be consulted for details about what the valid interrupt priority levels are.

cyg_addrword_t *`data`*

When an interrupt occurs eCos will first call the associated interrupt service routine or ISR, then optionally a deferred service routine or DSR. The *`data`* argument to `cyg_interrupt_create` will be passed to both these functions. Typically it will be a pointer to some data structure.

cyg_ISR_t *`isr`*

When an interrupt occurs the hardware will transfer control to the appropriate vector service routine or VSR, which is usually provided by eCos. This performs any appropriate processing, for example to work out exactly which interrupt occurred, and then as quickly as possible transfers control the installed ISR. An ISR is a C function which takes the following form:

```
cyg_uint32
isr_function(cyg_vector_t vector, cyg_addrword_t data)
{
    cyg_bool_t dsr_required = 0;

    …

    return dsr_required ?
        (CYG_ISR_CALL_DSR | CYG_ISR_HANDLED) :
        CYG_ISR_HANDLED;
}
```

The first argument identifies the particular interrupt source, especially useful if there multiple instances of a given device and a single ISR can be used for several different interrupt vectors. The second argument is the *`data`* field passed to `cyg_interrupt_create`, usually a pointer to some data structure. The exact conditions under which an ISR runs will depend partly on the hardware and partly on configuration options. Interrupts may currently be disabled globally, especially if the hardware does not support interrupt priorities. Alternatively interrupts may be enabled such that higher priority interrupts are allowed through. The ISR may be running on a separate interrupt stack, or on the stack of whichever thread was running at the time the interrupt happened.

A typical ISR will do as little work as possible, just enough to meet the needs of the hardware and then acknowledge the interrupt by calling `cyg_interrupt_acknowledge`. This ensures that interrupts will be quickly reenabled, so higher priority devices can be serviced. For some applications there may be one device which is especially important and whose ISR can take much longer than normal. However eCos device drivers usually will not assume that they are especially important, so their ISRs will be as short as possible.

The return value of an ISR is normally a bit mask containing zero, one or both of the following bits: `CYG_ISR_CALL_DSR` or `CYG_ISR_HANDLED`. The former indicates that further processing is required at DSR level, and the interrupt handler's DSR will be run as soon as possible. The latter indicates that the interrupt was handled by this ISR so there is no need to call other interrupt handlers which might be chained on this interrupt vector. If this ISR did not handle the interrupt it should not set the CYG_ISR_HANDLED bit so that other chained interrupt handlers may handle the interrupt.

An ISR is allowed to make very few kernel calls. It can manipulate the interrupt mask, and on SMP systems it can use spinlocks. However an ISR must not make higher-level kernel calls such as posting to a semaphore, instead any such calls must be made from the DSR. This avoids having to disable interrupts throughout the kernel and thus improves interrupt latency.

cyg_DSR_t *`dsr`*

If an interrupt has occurred and the ISR has returned a value with `CYG_ISR_CALL_DSR` bit being set, the system will call the DSR associated with this interrupt handler. If the scheduler is not currently locked then the DSR will run immediately. However if the interrupted thread was in the middle of a kernel call and had locked the scheduler, then the DSR will be deferred until the scheduler is again unlocked. This allows the DSR to make certain kernel calls safely, for example posting to a semaphore or signalling a condition variable. A DSR is a C function which takes the following form:

```
void
dsr_function(cyg_vector_t vector,
    cyg_ucount32 count,
    cyg_addrword_t data)
{
    …
}
```

The first argument identifies the specific interrupt that has caused the DSR to run. The second argument indicates the number of these interrupts that have occurred and for which the ISR requested a DSR. Usually this will be `1`, unless the system is suffering from a very heavy load. The third argument is the *`data`* field passed to `cyg_interrupt_create`.

cyg_handle_t* *`handle`*

The kernel will return a handle to the newly created interrupt handler via this argument. Subsequent operations on the interrupt handler such as attaching it to the interrupt source will use this handle.

cyg_interrupt* *`intr`*

This provides the kernel with an area of memory for holding this interrupt handler and associated data.

The call to `cyg_interrupt_create` simply fills in a kernel data structure. A typical next step is to call `cyg_interrupt_attach` using the handle returned by the create operation. This makes it possible to have several different interrupt handlers for a given vector, attaching whichever one is currently appropriate. Replacing an interrupt handler requires a call to `cyg_interrupt_detach`, followed by another call to `cyg_interrupt_attach` for the replacement handler. `cyg_interrupt_delete` can be used if an interrupt handler is no longer required.

Some hardware may allow for further control over specific interrupts, for example whether an interrupt is level or edge triggered. Any such hardware functionality can be accessed using `cyg_interrupt_configure`: the *`level`* argument selects between level versus edge triggered; the *`up`* argument selects between high and low level, or between rising and falling edges.

Usually interrupt handlers are created, attached and configured during system initialization, while global interrupts are still disabled. On most hardware it will also be necessary to call `cyg_interrupt_unmask`, since the sensible default for interrupt masking is to ignore any interrupts for which no handler is installed.

Controlling Interrupts

eCos provides two ways of controlling whether or not interrupts happen. It is possible to disable and reenable all interrupts globally, using `cyg_interrupt_disable` and `cyg_interrupt_enable`. Typically this works by manipulating state inside the

CPU itself, for example setting a flag in a status register or executing special instructions. Alternatively it may be possible to mask a specific interrupt source by writing to one or to several interrupt mask registers. Hardware-specific documentation should be consulted for the exact details of how interrupt masking works, because a full implementation is not possible on all hardware.

The primary use for these functions is to allow data to be shared between ISRs and other code such as DSRs or threads. If both a thread and an ISR need to manipulate either a data structure or the hardware itself, there is a possible conflict if an interrupt happens just when the thread is doing such manipulation. Problems can be avoided by the thread either disabling or masking interrupts during the critical region. If this critical region requires only a few instructions then usually it is more efficient to disable interrupts. For larger critical regions it may be more appropriate to use interrupt masking, allowing other interrupts to occur. There are other uses for interrupt masking. For example if a device is not currently being used by the application then it may be desirable to mask all interrupts generated by that device.

There are two functions for masking a specific interrupt source, `cyg_interrupt_mask` and `cyg_interrupt_mask_intunsafe`. On typical hardware masking an interrupt is not an atomic operation, so if two threads were to perform interrupt masking operations at the same time there could be problems. `cyg_interrupt_mask` disables all interrupts while it manipulates the interrupt mask. In situations where interrupts are already known to be disabled, `cyg_interrupt_mask_intunsafe` can be used instead. There are matching functions `cyg_interrupt_unmask` and `cyg_interrupt_unmask_intsafe`.

If an interrupt handler is no longer required, it can be deleted from the interrupt system with `cyg_interrupt_delete`, but it is up to the user to ensure that the interrupt source can no longer be generating interrupts, and there are no as-yet-unhandled pending interrupts or DSRs. Calling `cyg_interrupt_mask` before `cyg_interrupt_delete` will be sufficient to ensure that no more interrupts are delivered. The interrupt may be checked for pending DSRs by calling `cyg_interrupt_dsr_count`, which will return a non-zero result if there are DSRs pending. The application can cause pending DSRs to be delivered by making a kernel call, for example to `cyg_thread_yield`. The following code example shows the sequence that might be used to delete an interrupt handler:

```
        cyg_interrupt_mask( vector );
        while( cyg_interrupt_dsr_count( interrupt ) )
        {
            cyg_thread_yield();
        }
        cyg_interrupt_delete( interrupt );
```

If an interrupt handler is deleted but the interrupt is subsequently raised and is not masked, then the HAL will treat this as a spurious interrupt which, depending on the HAL and the configuration, may result in an assertion failure, an exception or it may simply be ignored albeit wasting the CPU resources to handle the interrupt.

SMP Support

On SMP systems the kernel provides an additional two functions related to interrupt handling. `cyg_interrupt_set_cpu` specifies that a particular hardware interrupt should always be handled on a specified set of processors in the system. In other words when the interrupt triggers it is only one of those processors which detects it, and it is only on those processors that the VSR and ISR will run. If a DSR is requested then it will also run on the same CPU. The function `cyg_interrupt_get_cpu` can be used to find out which interrupts are handled on which processors.

VSR Support

When an interrupt occurs the hardware will transfer control to a piece of code known as the VSR, or Vector Service Routine. By default this code is provided by eCos. Usually it is written in assembler, but on some architectures it may be possible to implement VSRs in C by specifying an interrupt attribute. Compiler documentation should be consulted for more information on this. The default eCos VSR will work out which ISR function should process the interrupt, and set up a C environment suitable for this ISR.

For some applications it may be desirable to replace the default eCos VSR and handle some interrupts directly. This minimizes interrupt latency, but it requires application developers to program at a lower level. Usually the best way to write a custom VSR is to copy the existing one supplied by eCos and then make appropriate modifications. The function `cyg_interrupt_get_vsr` can be used to get hold of the current VSR for a given interrupt vector, allowing it to be restored if the custom VSR is no longer required. `cyg_interrupt_set_vsr` can be used to install a replacement VSR. Usually the *`vsr`* argument will correspond to an exported label in an assembler source file.

Note

On some eCos platforms, possibly only in certain configurations, the table of VSRs resides in read-only memory and `cyg_interrupt_set_vsr` will not be available. Portable code can test for this condition by including the header file `cyg/hal/hal_intr.h` and testing for the macro `HAL_VSR_SET`.

Valid contexts

In a typical configuration interrupt handlers are created and attached during system initialization, and never detached or deleted. However it is possible to perform these operations at thread level, if desired. Similarly `cyg_interrupt_configure`, `cyg_interrupt_set_vsr`, and `cyg_interrupt_set_cpu` are usually called only during system initialization, but on typical hardware may be called at any time. `cyg_interrupt_get_vsr` and `cyg_interrupt_get_cpu` may be called at any time.

The functions for enabling, disabling, masking and unmasking interrupts can be called in any context, when appropriate. It is the responsibility of application developers to determine when the use of these functions is appropriate.

Name

tm_basic — Measure the performance of the eCos kernel

Description

When building a real-time system, care must be taken to ensure that the system will be able to perform properly within the constraints of that system. One of these constraints may be how fast certain operations can be performed. Another might be how deterministic the overall behavior of the system is. Lastly the memory footprint (size) and unit cost may be important.

One of the major problems encountered while evaluating a system will be how to compare it with possible alternatives. Most manufacturers of real-time systems publish performance numbers, ostensibly so that users can compare the different offerings. However, what these numbers mean and how they were gathered is often not clear. The values are typically measured on a particular piece of hardware, so in order to truly compare, one must obtain measurements for exactly the same set of hardware that were gathered in a similar fashion.

Two major items need to be present in any given set of measurements. First, the raw values for the various operations; these are typically quite easy to measure and will be available for most systems. Second, the determinacy of the numbers; in other words how much the value might change depending on other factors within the system. This value is affected by a number of factors: how long interrupts might be masked, whether or not the function can be interrupted, even very hardware-specific effects such as cache locality and pipeline usage. It is very difficult to measure the determinacy of any given operation, but that determinacy is fundamentally important to proper overall characterization of a system.

In the discussion and numbers that follow, three key measurements are provided. The first measurement is an estimate of the interrupt latency: this is the length of time from when a hardware interrupt occurs until its Interrupt Service Routine (ISR) is called. The second measurement is an estimate of overall interrupt overhead: this is the length of time average interrupt processing takes, as measured by the real-time clock interrupt (other interrupt sources will certainly take a different amount of time, but this data cannot be easily gathered). The third measurement consists of the timings for the various kernel primitives.

Methodology

Key operations in the kernel were measured by using a simple test program which exercises the various kernel primitive operations. A hardware timer, normally the one used to drive the real-time clock, was used for these measurements. In most cases this timer can be read with quite high resolution, typically in the range of a few microseconds. For each measurement, the operation was repeated a number of times. Time stamps were obtained directly before and after the operation was performed. The data gathered for the entire set of operations was then analyzed, generating average (mean), maximum and minimum values. The sample variance (a measure of how close most samples are to the mean) was also calculated. The cost of obtaining the real-time clock timer values was also measured, and was subtracted from all other times.

Most kernel functions can be measured separately. In each case, a reasonable number of iterations are performed. Where the test case involves a kernel object, for example creating a task, each iteration is performed on a different object. There is also a set of tests which measures the interactions between multiple tasks and certain kernel primitives. Most functions are tested in such a way as to determine the variations introduced by varying numbers of objects in the system. For example, the mailbox tests measure the cost of a 'peek' operation when the mailbox is empty, has a single item, and has multiple items present. In this way, any effects of the state of the object or how many items it contains can be determined.

There are a few things to consider about these measurements. Firstly, they are quite micro in scale and only measure the operation in question. These measurements do not adequately describe how the timings would be perturbed in a real system with multiple interrupting sources. Secondly, the possible aberration incurred by the real-time clock (system heartbeat tick) is explicitly avoided. Virtually all kernel functions have been designed to be interruptible. Thus the times presented are typical, but best case, since any particular function may be interrupted by the clock tick processing. This number is explicitly calculated so that the value may be included in any deadline calculations required by the end user. Lastly, the reported measurements were obtained from a system built with all options at their default values. Kernel instrumentation and asserts are also disabled for these measurements. Any number of configuration options can change the measured results, sometimes quite dramatically. For example, mutexes are using priority inheritance in these measurements. The numbers will change if the system is built with priority inheritance on mutex variables turned off.

The final value that is measured is an estimate of interrupt latency. This particular value is not explicitly calculated in the test program used, but rather by instrumenting the kernel itself. The raw number of timer ticks that elapse between the time the timer generates an interrupt and the start of the timer ISR is kept in the kernel. These values are printed by the test program after all other operations have been tested. Thus this should be a reasonable estimate of the interrupt latency over time.

Using these Measurements

These measurements can be used in a number of ways. The most typical use will be to compare different real-time kernel offerings on similar hardware, another will be to estimate the cost of implementing a task using eCos (applications can be examined to see what effect the kernel operations will have on the total execution time). Another use would be to observe how the tuning of the kernel affects overall operation.

Influences on Performance

A number of factors can affect real-time performance in a system. One of the most common factors, yet most difficult to characterize, is the effect of device drivers and interrupts on system timings. Different device drivers will have differing requirements as to how long interrupts are suppressed, for example. The eCos system has been designed with this in mind, by separating the management of interrupts (ISR handlers) and the processing required by the interrupt (DSR—Deferred Service Routine— handlers). However, since there is so much variability here, and indeed most device drivers will come from the end users themselves, these effects cannot be reliably measured. Attempts have been made to measure the overhead of the single interrupt that eCos relies on, the real-time clock timer. This should give you a reasonable idea of the cost of executing interrupt handling for devices.

Measured Items

This section describes the various tests and the numbers presented. All tests use the C kernel API (available by way of `cyg/kernel/kapi.h`). There is a single main thread in the system that performs the various tests. Additional threads may be created as part of the testing, but these are short lived and are destroyed between tests unless otherwise noted. The terminology “lower priority” means a priority that is less important, not necessarily lower in numerical value. A higher priority thread will run in preference to a lower priority thread even though the priority value of the higher priority thread may be numerically less than that of the lower priority thread.

Thread Primitives

Create thread

> This test measures the `cyg_thread_create()` call. Each call creates a totally new thread. The set of threads created by this test will be reused in the subsequent thread primitive tests.

Yield thread

> This test measures the `cyg_thread_yield()` call. For this test, there are no other runnable threads, thus the test should just measure the overhead of trying to give up the CPU.

Suspend [suspended] thread

> This test measures the `cyg_thread_suspend()` call. A thread may be suspended multiple times; each thread is already suspended from its initial creation, and is suspended again.

Resume thread

> This test measures the `cyg_thread_resume()` call. All of the threads have a suspend count of 2, thus this call does not make them runnable. This test just measures the overhead of resuming a thread.

Set priority

This test measures the `cyg_thread_set_priority()` call. Each thread, currently suspended, has its priority set to a new value.

Get priority

This test measures the `cyg_thread_get_priority()` call.

Kill [suspended] thread

This test measures the `cyg_thread_kill()` call. Each thread in the set is killed. All threads are known to be suspended before being killed.

Yield [no other] thread

This test measures the `cyg_thread_yield()` call again. This is to demonstrate that the `cyg_thread_yield()` call has a fixed overhead, regardless of whether there are other threads in the system.

Resume [suspended low priority] thread

This test measures the `cyg_thread_resume()` call again. In this case, the thread being resumed is lower priority than the main thread, thus it will simply become ready to run but not be granted the CPU. This test measures the cost of making a thread ready to run.

Resume [runnable low priority] thread

This test measures the `cyg_thread_resume()` call again. In this case, the thread being resumed is lower priority than the main thread and has already been made runnable, so in fact the resume call has no effect.

Suspend [runnable] thread

This test measures the `cyg_thread_suspend()` call again. In this case, each thread has already been made runnable (by previous tests).

Yield [only low priority] thread

This test measures the `cyg_thread_yield()` call. In this case, there are many other runnable threads, but they are all lower priority than the main thread, thus no thread switches will take place.

Suspend [runnable->not runnable] thread

This test measures the `cyg_thread_suspend()` call again. The thread being suspended will become non-runnable by this action.

Kill [runnable] thread

This test measures the `cyg_thread_kill()` call again. In this case, the thread being killed is currently runnable, but lower priority than the main thread.

Resume [high priority] thread

This test measures the `cyg_thread_resume()` call. The thread being resumed is higher priority than the main thread, thus a thread switch will take place on each call. In fact there will be two thread switches; one to the new higher priority thread and a second back to the test thread. The test thread exits immediately.

Thread switch

This test attempts to measure the cost of switching from one thread to another. Two equal priority threads are started and they will each yield to the other for a number of iterations. A time stamp is gathered in one thread before the `cyg_thread_yield()` call and after the call in the other thread.

Scheduler Primitives

Scheduler lock

This test measures the `cyg_scheduler_lock()` call.

Scheduler unlock [0 threads]

This test measures the `cyg_scheduler_unlock()` call. There are no other threads in the system and the unlock happens immediately after a lock so there will be no pending DSR,s to run.

Scheduler unlock [1 suspended thread]

This test measures the `cyg_scheduler_unlock()` call. There is one other thread in the system which is currently suspended.

Scheduler unlock [many suspended threads]

This test measures the `cyg_scheduler_unlock()` call. There are many other threads in the system which are currently suspended. The purpose of this test is to determine the cost of having additional threads in the system when the scheduler is activated by way of `cyg_scheduler_unlock()`.

Scheduler unlock [many low priority threads]

This test measures the `cyg_scheduler_unlock()` call. There are many other threads in the system which are runnable but are lower priority than the main thread. The purpose of this test is to determine the cost of having additional threads in the system when the scheduler is activated by way of `cyg_scheduler_unlock()`.

Mutex Primitives

Init mutex

This test measures the `cyg_mutex_init()` call. A number of separate mutex variables are created. The purpose of this test is to measure the cost of creating a new mutex and introducing it to the system.

Lock [unlocked] mutex

This test measures the `cyg_mutex_lock()` call. The purpose of this test is to measure the cost of locking a mutex which is currently unlocked. There are no other threads executing in the system while this test runs.

Unlock [locked] mutex

This test measures the `cyg_mutex_unlock()` call. The purpose of this test is to measure the cost of unlocking a mutex which is currently locked. There are no other threads executing in the system while this test runs.

Trylock [unlocked] mutex

This test measures the `cyg_mutex_trylock()` call. The purpose of this test is to measure the cost of locking a mutex which is currently unlocked. There are no other threads executing in the system while this test runs.

Trylock [locked] mutex

This test measures the `cyg_mutex_trylock()` call. The purpose of this test is to measure the cost of locking a mutex which is currently locked. There are no other threads executing in the system while this test runs.

Destroy mutex

This test measures the `cyg_mutex_destroy()` call. The purpose of this test is to measure the cost of deleting a mutex from the system. There are no other threads executing in the system while this test runs.

Unlock/Lock mutex

This test attempts to measure the cost of unlocking a mutex for which there is another higher priority thread waiting. When the mutex is unlocked, the higher priority waiting thread will immediately take the lock. The time from when the unlock is issued until after the lock succeeds in the second thread is measured, thus giving the round-trip or circuit time for this type of synchronizer.

Mailbox Primitives

Create mbox

This test measures the `cyg_mbox_create()` call. A number of separate mailboxes is created. The purpose of this test is to measure the cost of creating a new mailbox and introducing it to the system.

Peek [empty] mbox

This test measures the `cyg_mbox_peek()` call. An attempt is made to peek the value in each mailbox, which is currently empty. The purpose of this test is to measure the cost of checking a mailbox for a value without blocking.

Put [first] mbox

This test measures the `cyg_mbox_put()` call. One item is added to a currently empty mailbox. The purpose of this test is to measure the cost of adding an item to a mailbox. There are no other threads currently waiting for mailbox items to arrive.

Peek [1 msg] mbox

This test measures the `cyg_mbox_peek()` call. An attempt is made to peek the value in each mailbox, which contains a single item. The purpose of this test is to measure the cost of checking a mailbox which has data to deliver.

Put [second] mbox

This test measures the `cyg_mbox_put()` call. A second item is added to a mailbox. The purpose of this test is to measure the cost of adding an additional item to a mailbox. There are no other threads currently waiting for mailbox items to arrive.

Peek [2 msgs] mbox

This test measures the `cyg_mbox_peek()` call. An attempt is made to peek the value in each mailbox, which contains two items. The purpose of this test is to measure the cost of checking a mailbox which has data to deliver.

Get [first] mbox

This test measures the `cyg_mbox_get()` call. The first item is removed from a mailbox that currently contains two items. The purpose of this test is to measure the cost of obtaining an item from a mailbox without blocking.

Get [second] mbox

This test measures the `cyg_mbox_get()` call. The last item is removed from a mailbox that currently contains one item. The purpose of this test is to measure the cost of obtaining an item from a mailbox without blocking.

Tryput [first] mbox

This test measures the `cyg_mbox_tryput()` call. A single item is added to a currently empty mailbox. The purpose of this test is to measure the cost of adding an item to a mailbox.

Peek item [non-empty] mbox

This test measures the `cyg_mbox_peek_item()` call. A single item is fetched from a mailbox that contains a single item. The purpose of this test is to measure the cost of obtaining an item without disturbing the mailbox.

Tryget [non-empty] mbox

This test measures the `cyg_mbox_tryget()` call. A single item is removed from a mailbox that contains exactly one item. The purpose of this test is to measure the cost of obtaining one item from a non-empty mailbox.

Peek item [empty] mbox

This test measures the `cyg_mbox_peek_item()` call. An attempt is made to fetch an item from a mailbox that is empty. The purpose of this test is to measure the cost of trying to obtain an item when the mailbox is empty.

Tryget [empty] mbox

This test measures the `cyg_mbox_tryget()` call. An attempt is made to fetch an item from a mailbox that is empty. The purpose of this test is to measure the cost of trying to obtain an item when the mailbox is empty.

Waiting to get mbox

This test measures the `cyg_mbox_waiting_to_get()` call. The purpose of this test is to measure the cost of determining how many threads are waiting to obtain a message from this mailbox.

Waiting to put mbox

This test measures the `cyg_mbox_waiting_to_put()` call. The purpose of this test is to measure the cost of determining how many threads are waiting to put a message into this mailbox.

Delete mbox

This test measures the `cyg_mbox_delete()` call. The purpose of this test is to measure the cost of destroying a mailbox and removing it from the system.

Put/Get mbox

In this round-trip test, one thread is sending data to a mailbox that is being consumed by another thread. The time from when the data is put into the mailbox until it has been delivered to the waiting thread is measured. Note that this time will contain a thread switch.

Semaphore Primitives

Init semaphore

This test measures the `cyg_semaphore_init()` call. A number of separate semaphore objects are created and introduced to the system. The purpose of this test is to measure the cost of creating a new semaphore.

Post [0] semaphore

This test measures the `cyg_semaphore_post()` call. Each semaphore currently has a value of 0 and there are no other threads in the system. The purpose of this test is to measure the overhead cost of posting to a semaphore. This cost will differ if there is a thread waiting for the semaphore.

Wait [1] semaphore

This test measures the `cyg_semaphore_wait()` call. The semaphore has a current value of 1 so the call is non-blocking. The purpose of the test is to measure the overhead of “taking” a semaphore.

Trywait [0] semaphore

This test measures the `cyg_semaphore_trywait()` call. The semaphore has a value of 0 when the call is made. The purpose of this test is to measure the cost of seeing if a semaphore can be “taken” without blocking. In this case, the answer would be no.

Trywait [1] semaphore

This test measures the `cyg_semaphore_trywait()` call. The semaphore has a value of 1 when the call is made. The purpose of this test is to measure the cost of seeing if a semaphore can be “taken” without blocking. In this case, the answer would be yes.

Peek semaphore

This test measures the `cyg_semaphore_peek()` call. The purpose of this test is to measure the cost of obtaining the current semaphore count value.

Destroy semaphore

This test measures the `cyg_semaphore_destroy()` call. The purpose of this test is to measure the cost of deleting a semaphore from the system.

Post/Wait semaphore

In this round-trip test, two threads are passing control back and forth by using a semaphore. The time from when one thread calls `cyg_semaphore_post()` until the other thread completes its `cyg_semaphore_wait()` is measured. Note that each iteration of this test will involve a thread switch.

Counters

Create counter

This test measures the `cyg_counter_create()` call. A number of separate counters are created. The purpose of this test is to measure the cost of creating a new counter and introducing it to the system.

Get counter value

This test measures the `cyg_counter_current_value()` call. The current value of each counter is obtained.

Set counter value

This test measures the `cyg_counter_set_value()` call. Each counter is set to a new value.

Tick counter

This test measures the `cyg_counter_tick()` call. Each counter is “ticked” once.

Delete counter

This test measures the `cyg_counter_delete()` call. Each counter is deleted from the system. The purpose of this test is to measure the cost of deleting a counter object.

Alarms

Create alarm

> This test measures the `cyg_alarm_create()` call. A number of separate alarms are created, all attached to the same counter object. The purpose of this test is to measure the cost of creating a new counter and introducing it to the system.

Initialize alarm

> This test measures the `cyg_alarm_initialize()` call. Each alarm is initialized to a small value.

Disable alarm

> This test measures the `cyg_alarm_disable()` call. Each alarm is explicitly disabled.

Enable alarm

> This test measures the `cyg_alarm_enable()` call. Each alarm is explicitly enabled.

Delete alarm

> This test measures the `cyg_alarm_delete()` call. Each alarm is destroyed. The purpose of this test is to measure the cost of deleting an alarm and removing it from the system.

Tick counter [1 alarm]

> This test measures the `cyg_counter_tick()` call. A counter is created that has a single alarm attached to it. The purpose of this test is to measure the cost of "ticking" a counter when it has a single attached alarm. In this test, the alarm is not activated (fired).

Tick counter [many alarms]

> This test measures the `cyg_counter_tick()` call. A counter is created that has multiple alarms attached to it. The purpose of this test is to measure the cost of "ticking" a counter when it has many attached alarms. In this test, the alarms are not activated (fired).

Tick & fire counter [1 alarm]

> This test measures the `cyg_counter_tick()` call. A counter is created that has a single alarm attached to it. The purpose of this test is to measure the cost of "ticking" a counter when it has a single attached alarm. In this test, the alarm is activated (fired). Thus the measured time will include the overhead of calling the alarm callback function.

Tick & fire counter [many alarms]

> This test measures the `cyg_counter_tick()` call. A counter is created that has multiple alarms attached to it. The purpose of this test is to measure the cost of "ticking" a counter when it has many attached alarms. In this test, the alarms are activated (fired). Thus the measured time will include the overhead of calling the alarm callback function.

Alarm latency [0 threads]

> This test attempts to measure the latency in calling an alarm callback function. The time from the clock interrupt until the alarm function is called is measured. In this test, there are no threads that can be run, other than the system idle thread, when the clock interrupt occurs (all threads are suspended).

Alarm latency [2 threads]

> This test attempts to measure the latency in calling an alarm callback function. The time from the clock interrupt until the alarm function is called is measured. In this test, there are exactly two threads which are running when the clock interrupt occurs.

They are simply passing back and forth by way of the `cyg_thread_yield()` call. The purpose of this test is to measure the variations in the latency when there are executing threads.

Alarm latency [many threads]

This test attempts to measure the latency in calling an alarm callback function. The time from the clock interrupt until the alarm function is called is measured. In this test, there are a number of threads which are running when the clock interrupt occurs. They are simply passing back and forth by way of the `cyg_thread_yield()` call. The purpose of this test is to measure the variations in the latency when there are many executing threads.

Name

Thread Debugging — Overview of eCos Kernel thread-aware debugging

Description

Thread-aware debugging refers to the ability to interrogate the list of threads active within an application when the system is stopped (halted). This is normally when the code has either stopped at a breakpoint, or when execution is interrupted via a hosted debug session (e.g. from GDB).

Helper Symbols

For eCosPro to aid external host-based debug tools, a set of helper symbols are defined to provide information on the size (width) and offset of useful fields, or relevant constant values, instead of addresses. The majority of these symbols are named to avoid possible namespace clashes with applications, but for historical reasons some architecture specific symbols are valid in the C/C++ namespace. Similarly different architectures export their own symbols.

An external tool that wishes to interpret thread information can check for the presence of the specifically named symbol, and add support accordingly.

These symbols are held in the symbol table of the ELF file, but have no cost impact (code or data size) on the actual binary loaded into the target (either via a debugger, or if an application binary is stored on the target). Obviously a stripped executable will lose the helper symbols, but debugging using a stripped ELF file would always pose some restrictions.

Required

These symbols are required for accessing the list of threads and the currently active thread. If they are **not** present in the symbol table then it indicates an eCos build without a thread scheduler, and hence there is no need for thread-aware debug support.

`Cyg_Thread::thread_list`

Pointer to the first thread descriptor in the chain of created threads.

`Cyg_Scheduler_Base::current_thread`

Pointer to the thread context for the currently active thread.

Common

When an eCos scheduler is configured, information describing the thread context is provided to enable generic scanning code to be implemented in an external tool regardless whether some eCos features are enabled or disabled. Since individual eCos configurations can have features present that change the shape of the actual thread descriptor structure, we need the important fields for scanning a list of threads to be available in each ELF file.

`__ecospro_syminfo.size.cyg_thread.list_next`
`__ecospro_syminfo.size.cyg_thread.state`
`__ecospro_syminfo.size.cyg_thread.sleep_reason`
`__ecospro_syminfo.size.cyg_thread.wake_reason`
`__ecospro_syminfo.size.cyg_thread.unique_id`
`__ecospro_syminfo.size.cyg_thread.name`
`__ecospro_syminfo.size.cyg_thread.priority`
`__ecospro_syminfo.size.cyg_thread.stack_ptr`

The **presence** of a field in the thread descriptor structure can be determined by a **non-zero** size symbol being provided. These symbols give the size, in bytes, of the relevant field at the offset specified by the corresponding `__ecospro_syminfo.off.*` symbol. This allows any host tool to provide features based on the conditional presence of fields.

`__ecospro_syminfo.off.cyg_thread.list_next`

Offset to field that points to the next thread descriptor.

`__ecospro_syminfo.off.cyg_thread.state`
`__ecospro_syminfo.off.cyg_thread.sleep_reason`
`__ecospro_syminfo.off.cyg_thread.wake_reason`
`__ecospro_syminfo.off.cyg_thread.unique_id`
`__ecospro_syminfo.off.cyg_thread.name`
`__ecospro_syminfo.off.cyg_thread.priority`

Offsets for useful fields in a thread descriptor structure.

`__ecospro_syminfo.off.cyg_thread.stack_ptr`

This symbol is the offset for the field containing the address of the stacked register context for inactive threads.

Cortex-M

Cortex-M Base

For Cortex-M targets the following symbols describe the main CPU register state. The presence of the symbol `__ecospro_syminfo.cortexm.thread.saved` can be used as indicator of an eCos Cortex-M application.

`__ecospro_syminfo.cortexm.thread.saved`

This symbol provides the actual `PC` address of the point in the code where a switch actually occurs, It may be useful depending on how the external tool interprets the stacked context information.

`__ecospro_syminfo.value.HAL_SAVEDREGISTERS.THREAD`
`__ecospro_syminfo.value.HAL_SAVEDREGISTERS.EXCEPTION`
`__ecospro_syminfo.value.HAL_SAVEDREGISTERS.INTERRUPT`

These symbols provide the values in the type field used to identify the shape of the stacked context. Since only threads will be accessed by the `Cyg_Thread::thread_list` list the host tools should only ever encounter `__ecospro_syminfo.value.HAL_SAVEDREGISTERS.THREAD` type contexts (with the optional FPU register state indicator flag). The values for the other types of Cortex-M contexts are provided for completeness only.

`__ecospro_syminfo.size.HAL_SavedRegisters.Thread`

This symbol provides the total size, in bytes, of a stacked CPU context for contexts of type `__ecospro_syminfo.value.HAL_SAVEDREGISTERS.THREAD`.

`__ecospro_syminfo.size.HAL_SavedRegisters.u.thread.r`

Total size, in bytes, of all the core CPU registers present in a stacked context.

`__ecospro_syminfo.size.HAL_SavedRegisters.u.thread.type`

Size, in bytes, of the field that encodes the type of stacked context. Since for Cortex-M targets the actual context stored (and its size) depends on whether the individual thread has any hardware FPU context saved. This is needed to ensure only valid information is used when dealing with lazy per-thread hardware FPU support.

`__ecospro_syminfo.size.HAL_SavedRegisters.u.thread.basepri`
`__ecospro_syminfo.size.HAL_SavedRegisters.u.thread.sp`
`__ecospro_syminfo.size.HAL_SavedRegisters.u.thread.pc`

Size of individual context fields referenced by the corresponding offset symbol.

`__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.type`
`__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.basepri`
`__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.sp`
`__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.r`
`__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.pc`

Offsets into the stacked context for the core register values.

Cortex-M FPU

When a Cortex-M configuration with hardware FPU support configured is used then the following optional symbols will be present with **non-zero** values where appropriate.

`__ecospro_syminfo.value.HAL_SAVEDREGISTERS.WITH_FPU`

This value provides the bitmask flag `OR`-ed into the type field provided at the `__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.type` offset used to identify individual thread contexts that contain FPU state.

`__ecospro_syminfo.size.HAL_SavedRegisters.u.thread.fpscr`

Size, in bytes, of the `FPSCR` register stacked in the context.

`__ecospro_syminfo.size.HAL_SavedRegisters.u.thread.s`

Total size, in bytes, of the single-precision vector stacked in the context.

`__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.fpscr`

Offset of `FPSCR` register in the stacked context.

`__ecospro_syminfo.off.HAL_SavedRegisters.u.thread.s`

Offset of the single-precision register vector in the stacked context.

ARM

ARM/Cortex-A Base

For ARM/Cortex-A targets the following symbols describe the main CPU register state. The presence of the symbol `ARMREG_SIZE` can be used as indicator of an eCos `arm` architecture application.

`ARMREG_SIZE`

This symbol, if **non-zero**, provides the total size of the stacked context for inactive threads.

armreg_r0
armreg_r1
armreg_r2
armreg_r3
armreg_r4
armreg_r5
armreg_r6
armreg_r7
armreg_r8
armreg_r9
armreg_r10
armreg_fp
armreg_ip
armreg_sp
armreg_lr
armreg_pc
armreg_cpsr

These symbols provide the offset of the corresponding register within the stacked context referenced from the thread object __ecospro_syminfo.off.cyg_thread.stack_ptr field.

ARM/Cortex-A FPU

Optional ARM FPU symbols.

ARMREG_FPUCONTEXT_SIZE

If non-zero then this symbol indicates that the eCos applicaton has been configured with hardware FPU support. The value is the total size of the stacked inactive thread context.

armreg_fpscr

Offset with the stacked context of the FPSCR register.

ARM/Cortex-A FPU Single-Precision

Symbols present when single-precision ARM FPU is configured.

armreg_s_vec

The offset to the start of the stacked single-precision register vector.

ARMREG_S_COUNT

Number of single-precision registers present from the armreg_s_vec offset.

ARM/Cortex-A FPU Double-Precision

Symbols present when doubled-precision ARM FPU is configured.

armreg_vfp_vec

The offset to the start of the stacked double-precision register vector.

ARMREG_VFP_COUNT

Number of single-precision registers present from the armreg_vfp_vec offset.

ColdFire

Symbols provided by eCos ColdFire targets. The presence of the symbol `hal_context_pcsr_offset` can be used as an identifier for ColdFire targets.

`hal_context_size`

The overall stacked context size.

`hal_context_fpu_size`

If hardware FPU support is configured this symbol provides the size of the stacked FPU context.

`hal_context_pcsr_size`
`hal_context_integer_size`

These symbols provide information on the size (width) of individual registers.

`hal_context_pcsr_offset`
`hal_context_integer_d0_offset`
`hal_context_integer_d2_offset`
`hal_context_integer_a0_offset`
`hal_context_integer_a2_offset`
`hal_context_fpu_offset`
`hal_context_other_offset`

The offsets within the stacked context for the processor state.

`hal_context_rte_adjust`

The value, in bytes, if a `PCSR` RTE adjustment is used.

Other Useful Symbols

Some other standard eCos symbols **may** be present that could also be useful for external debug tools.

`idle_thread`

This symbol can be used to identify the idle (background) thread descriptor object if useful to the thread-aware host debug tool.

`cyg_libc_main_thread`

This symbol will not be present in the application symbol table if the relevant object is not defined. When `CYGSEM_LIBC_STARTUP_MAIN_THREAD` is configured this symbol can be used to reference the thread descriptor object for the `main()` C thread created by the run-time.

GDB

The following documentation uses the GDB command-line interface for its examples, although the thread-aware debug support is applicable to applications that access GDB via its programmatic interface, e.g. Eclipse.

When a GDB debug session halts the CPU, either from the code hitting a previously set breakpoint or via the user requesting a halt, it will display the state of the currently active CPU state and select the currently executing thread. When displaying threads via the `info threads` command the currently selected thread is highlighted by an asterisk (`*`) character. Therefore, immediately after a halt this will indicate the active, running, thread. Examining the CPU register state will report the state of this active thread.

With thread-aware debugging for the target application available, GDB will display a list of all known threads when given the command `info threads`. The command `thread` *`id`* can be used to switch context to other threads, providing the ability to examine their CPU register state, call stack, and local variables.

Notes:

1. The documentation for all GDB features is beyond the scope of this reference. Please refer to the website GDB: The GNU Project Debugger for definitive documentation of the GDB thread debug support.
2. All GDB execution operations such as single stepping and return from function call will always apply to the currently active, executing thread, *NOT* the thread currently selected by the developer or user within the debugger.

Depending on the target system being connected, the act of loading an eCos application into memory will not necessarily initialise all the memory and hardware state. The eCos application run-time startup code will normally initialise memory alongside other I/O requirements. Since it can be possible to execute thread interrogation commands before any target code has been executed, it can be useful having helper macros in your `.gdbinit` script to minimise misinformation being displayed. The following `clear_ecos_thread_pointers` GDB macro is an example which could be executed after loading an application and **before** any system initialisation code in the loaded application has been executed. It ensures that debug commands to interrogate thread state will not parse stale/undefined information from uninitialised memory.

```
define clear_ecos_thread_pointers
  set *((unsigned int *)&Cyg_Thread::thread_list) = 0
  set *((unsigned int *)&Cyg_Scheduler_Base::current_thread) = 0
end

document clear_ecos_thread_pointers
When starting a new debug session from application reset the run-time
code that clears BSS will not have been executed, so stale/unitialised
state may be present in memory. For RTOS aware thread debugging as
provided by external tools the GDB server may be confused and report
invalid state if the thread state is interrogated before the initial
eCos run-time initialisation has cleared the BSS area. This macro just
ensures that the relevant eCos pointers are NULL prior to debugging.
end
```

Of course if a hardware debugger is being used to connect to an existing application session (rather than loading and starting a new application session) then the macro should not be called.

It is useful to wrap the steps needed to connect to a target in a helper macro. e.g.:

```
define connocd
  target extended-remote localhost:3333
  load
  break cyg_test_exit
  break cyg_assert_fail
  display/i $pc
  clear_ecos_thread_pointers
end
```

So that all of the normal steps for loading and setting the debug environment for an application can be performed by a single command:

```
(gdb) connocd
0x080016dc in ?? ()

Loading section .rom_vectors, size 0x8 lma 0x90000000
Loading section .text, size 0x7b34 lma 0x90000008
Loading section .rodata, size 0x678 lma 0x90007b40
Loading section .data, size 0x180 lma 0x900081b8
Start address 0x90000008, load size 33588
Transfer rate: 94 KB/sec, 6717 bytes/write.
Breakpoint 1 at 0x900040f4: file ecospro-path/packages/infra/current/src/tcdiag.cxx, line 391.
```

```
Function "cyg_assert_fail" not defined.
Make breakpoint pending on future shared library load? (y or [n]) [answered N; input not from terminal]
(gdb)
```

The use of such macros from a GDB script file can make the task of debugging less cumbersome.

Ronetix PEEDI

Note

The Ronetix PEEDI firmware must be updated to at least version 21.2.0 to ensure the correct operation of the thread-aware debugging support.

The PEEDI `[TARGET]` section option `COREn_OS` can be used to introduce a thread/context description using the generic PEEDI support.

The example PEEDI configuration files supplied with eCosPro releases 4.5.8 and above should already have suitable RTOS support fragments. For example, the file `packages/hal/arm/arm9/sam9g45ek/<version>/misc/peedi.sam9g45ek.cfg` contains a `[OS_ECOS_ARM]` section, referenced from the head of the file via the `CORE0_OS=OS_ECOS_ARM` setting.

With a suitable `COREn_OS` the PEEDI will parse the eCos thread lists and stacked register contents when interrogating threads other than the current thread of executing on the CPU.

OpenOCD

OpenOCD provides the `-rtos eCos` option that can be used to configure thread-aware debug support in the configuration file used for the OpenOCD session.

Note

eCoscentric contributed the previously eCosPro specific eCos thread-aware debug support to the `OpenOCD` project. As of 2023-01-15 the support was merged into the `OpenOCD` mainline.

At its simplest the OpenOCD configuration file just needs to specify:

```
$_TARGETNAME configure -rtos eCos
```

NOTE: When OpenOCD `-rtos` support for eCos is configured the act of executing `target remote` or `target extended-remote` to connect to an OpenOCD instance will cause the configured OpenOCD RTOS support to perform an **update_threads** operation against the current memory state. This is to allow a debug session to be attached to an active system. However, it does mean that for an undefined memory state (power-on, CPU reset with undefined DRAM state, an application with a different thread context shape to the previous application new different-configuration application to be subsequently loaded after connecting to the OpenOCD GDB server) that the GDB server may report spurious thread information upon request.

The following is example output when the application is halted in a thread named "busy". The name, state and priority of the other available threads is also shown:

```
(gdb) info thr
 Id  Target Id         Frame
* 1  Thread 12 (Name: busy, State: Ready Pri: 20) 0x20009f50 in thread_busy (data=30000) at
     ecospro-path/packages/kernel/current/tests/fpint_thread_switch.cxx:566
  2  Thread 1 (Name: Idle Thread, State: Ready Pri: 31) Cyg_Scheduler::unlock_inner (new_lock=0) at
     ecospro-path/packages/kernel/current/src/sched/sched.cxx:233
  3  Thread 2 (Name: Test, State: Sleeping (WAIT) Pri: 3) Cyg_Scheduler::unlock_inner (new_lock=1) at
     ecospro-path/packages/kernel/current/src/sched/sched.cxx:233
  4  Thread 11 (Name: highpri, State: Sleeping (DELAY) Pri: 10) Cyg_Scheduler::unlock_inner (new_lock=0)
```

```
     at ecospro-path/packages/kernel/current/src/sched/sched.cxx:233
```

The OpenOCD GDB server can be left executing between GDB application debug sessions. It does not need to be re-started for every GDB session.

Segger JLink/JTrace

Segger do not allow source distributions of RTOS aware plugins based on their SDK. This policy unfortunately restricts eCos and eCos eCosPro support to pre-built shared library files only. There does not seem to be any obvious technical reason for this binary-only restriction, considering the simplicity of the exposed SDK API and limited feature set required to support RTOS aware debugging (as can be seen by the functionality required for the open-source OpenOCD "-rtos" support, and the generic config-file description approach built into the PEEDI (closed source) firmware.

Currently only 64-bit Linux `x86_64` is available via the file `libRTOSPlugin_eCosPro.so`. Please contact eCosCentric to discuss the options available if other host platforms are required.

For example, the following is used to start a JLink GDB server session connected to a STM32F429I-DISCO board with the eCosPro RTOS aware plugin selected:

```
$ JLinkGDBServer -device stm32f429zi -if swd -rtos libRTOSPlugin_eCosPro.so
```

The JLinkGDBServer can be left executing between GDB application debug sessions. It does not need to be re-started for every GDB session.

GDB stubs

Unlike the hardware debug approaches described above which benefit from bare-metal hardware support (SWD, JTAG, BDM, etc.), eCos also supports the use of GDBstubs which can be built into the application and accessed via an I/O channel (e.g. serial, Ethernet, etc.), or provided via a boot monitor/loader (e.g. RedBoot covering in Chapter 224, *Getting Started with RedBoot*) that provides an environment for executing applications. Such support has a run-time cost (code+data space as well as CPU cycles), and is only usable after some level of system initialisation has occurred. A hardware debug solution is therefore preferred.

However, if GDBstubs is the only available/possible solution, the eCos GDBstubs implementation supports thread aware debugging.

Name

Kernel Instrumentation — Overview of eCos Kernel and Infrastructure instrumentation

Description

The kernel implements a simple macro based mechanism for tracing the flow of execution. It is designed for embedding many trace points, each with an optional small amount of associated data (e.g. that can be encoded in two 32-bit “argument” fields). The mechanism also allows for extending the instrumentation with further package specific event generation as required.

Instrumentation records will only be generated if the `CYGPKG_KERNEL_INSTRUMENT)` option is enabled, and then only if the relevant individual kernel event code sub-options are also enabled. The default state is for all the kernel instrumentation sub-options to be enabled.

Warning

Some options, when enabled, will generate a **large** quantity of instrumentation records in a heavily loaded system and so care may need to be taken regarding the instrumentation that is enabled vs the instrumentation recording mechanism being used to avoid missing events. Depending on why the kernel instrumentation framework is being enabled (debugging, timing validation, etc.) the user can choose which events they wish to record by enabling only the specific CDL options required.

The tuning of the amount of instrumentation generated, and any buffering required to hold event records, is always a consideration when investigating systems and it may **not** be possible to have every instrumentation option enabled all of the time.

At its simplest, default, the kernel instrumentation stores event records in a memory buffer for subsequent extraction and post-processing.

However the instrumentation code generated can be over-ridden by a configuration providing a suitable `CYGBLD_KERNEL_INSTRUMENT_WRAPPER_H` header to override the default kernel implementation. This allows for other eCos packages, or for application specific support, to provide their own implementation.

The `CYGPKG_INFRA` infrastructure package also provides for other tracing mechanisms to be enabled. The provision of multiple “tracing” solutions reflects the different feature sets they provided. The user has the option for using the mechanism that best suits their needs, e.g. system level events, high-level application logic or performance, etc.

As an adjunct to the main kernel instrumentation support the infrastructure `cyg_systrace.h` header defines some macros used to instrument specific points in the eCos source (INFRA, KERNEL, HAL, etc.). The `CYG_SYSTRACE_*` support has been driven by the support required for specific features of 3rd-party trace tools.

The infrastructure package also provides the `cyg_trac.h` header which implements an alternative approach to tracing the execution path of code. The documentation for that trace mechanism is provided in the actual header file.

Part II. The eCos Hardware Abstraction Layer (HAL)

Table of Contents

Chapter 1. Introduction

This is an initial specification of the *eCos* Hardware Abstraction Layer (HAL). The HAL abstracts the underlying hardware of a processor architecture and/or the platform to a level sufficient for the eCos kernel to be ported onto that platform.

Caveat

This document is an informal description of the HAL capabilities and is not intended to be full documentation, although it may be used as a source for such. It also describes the HAL as it is currently implemented for the architectures targeted in this release. It most closely describes the HALs for the MIPS, I386 and PowerPC HALs. Other architectures are similar but may not be organized precisely as described here.

Chapter 2. Architecture, Variant and Platform

We have identified three levels at which the HAL must operate.

- The *architecture HAL* abstracts the basic CPU architecture and includes things like interrupt delivery, context switching, CPU startup etc.
- The *variant HAL* encapsulates features of the CPU variant such as caches, MMU and FPU features. It also deals with any on-chip peripherals such as memory and interrupt controllers. For architectural variations, the actual implementation of the variation is often in the architectural HAL, and the variant HAL simply provides the correct configuration definitions.
- The *platform HAL* abstracts the properties of the current platform and includes things like platform startup, timer devices, I/O register access and interrupt controllers.

The boundaries between these three HAL levels are necessarily blurred since functionality shifts between levels on a target-by-target basis. For example caches and MMU may be either an architecture feature or a variant feature. Similarly, memory and interrupt controllers may be on-chip and in the variant HAL, or off-chip and in the platform HAL.

Generally there is a separate package for each of the architecture, variant and package HALs for a target. For some of the older targets, or where it would be essentially empty, the variant HAL is omitted.

Chapter 3. General principles

The HAL has been implemented according to the following general principles:

1. The HAL is implemented in C and assembler, although the eCos kernel is largely implemented in C++. This is to permit the HAL the widest possible applicability.

2. All interfaces to the HAL are implemented by CPP macros. This allows them to be implemented as inline C code, inline assembler or function calls to external C or assembler code. This allows the most efficient implementation to be selected without affecting the interface. It also allows them to be redefined if the platform or variant HAL needs to replace or enhance a definition from the architecture HAL.

3. The HAL provides simple, portable mechanisms for dealing with the hardware of a wide range of architectures and platforms. It is always possible to bypass the HAL and program the hardware directly, but this may lead to a loss of portability.

Chapter 4. HAL Interfaces

This section describes the main HAL interfaces.

Base Definitions

These are definitions that characterize the properties of the base architecture that are used to compile the portable parts of the kernel. They are concerned with such things a portable type definitions, endianness, and labeling.

These definitions are supplied by the `cyg/hal/basetype.h` header file which is supplied by the architecture HAL. It is included automatically by `cyg/infra/cyg_type.h`.

Byte order

`CYG_BYTEORDER`

This defines the byte order of the target and must be set to either `CYG_LSBFIRST` or `CYG_MSBFIRST`.

Label Translation

`CYG_LABEL_NAME(name)`

This is a wrapper used in some C and C++ files which use labels defined in assembly code or the linker script. It need only be defined if the default implementation in `cyg/infra/cyg_type.h`, which passes the name argument unaltered, is inadequate. It should be paired with `CYG_LABEL_DEFN()`.

`CYG_LABEL_DEFN(name)`

This is a wrapper used in assembler sources and linker scripts which define labels. It need only be defined if the default implementation in `cyg/infra/cyg_type.h`, which passes the name argument unaltered, is inadequate. The most usual alternative definition of this macro prepends an underscore to the label name.

Base types

```
    cyg_halint8
    cyg_halint16
    cyg_halint32
    cyg_halint64
    cyg_halcount8
    cyg_halcount16
    cyg_halcount32
    cyg_halcount64
    cyg_halbool
```

These macros define the C base types that should be used to define variables of the given size. They only need to be defined if the default types specified in `cyg/infra/cyg_type.h` cannot be used. Note that these are only the base types, they will be composed with `signed` and `unsigned` to form full type specifications.

Atomic types

```
    cyg_halatomic CYG_ATOMIC
```

These types are guaranteed to be read or written in a single uninterruptible operation. It is architecture defined what size this type is, but it will be at least a byte.

Architecture Characterization

These are definition that are related to the basic architecture of the CPU. These include the CPU context save format, context switching, bit twiddling, breakpoints, stack sizes and address translation.

Most of these definition are found in `cyg/hal/hal_arch.h`. This file is supplied by the architecture HAL. If there are variant or platform specific definitions then these will be found in `cyg/hal/var_arch.h` or `cyg/hal/plf_arch.h`. These files are include automatically by this header, so need not be included explicitly.

Register Save Format

```
typedef struct HAL_SavedRegisters
{
    /* architecture-dependent list of registers to be saved */
} HAL_SavedRegisters;
```

This structure describes the layout of a saved machine state on the stack. Such states are saved during thread context switches, interrupts and exceptions. Different quantities of state may be saved during each of these, but usually a thread context state is a subset of the interrupt state which is itself a subset of an exception state. For debugging purposes, the same structure is used for all three purposes, but where these states are significantly different, this structure may contain a union of the three states.

Thread Context Initialization

```
HAL_THREAD_INIT_CONTEXT( sp, arg, entry, id )
```

This macro initializes a thread's context so that it may be switched to by `HAL_THREAD_SWITCH_CONTEXT()`. The arguments are:

sp
: A location containing the current value of the thread's stack pointer. This should be a variable or a structure field. The SP value will be read out of here and an adjusted value written back.

arg
: A value that is passed as the first argument to the entry point function.

entry
: The address of an entry point function. This will be called according the C calling conventions, and the value of *`arg`* will be passed as the first argument. This function should have the following type signature `void entry(CYG_ADDRWORD arg)`.

id
: A thread id value. This is only used for debugging purposes, it is ORed into the initialization pattern for unused registers and may be used to help identify the thread from its register dump. The least significant 16 bits of this value should be zero to allow space for a register identifier.

Thread Context Switching

```
HAL_THREAD_LOAD_CONTEXT( to )
HAL_THREAD_SWITCH_CONTEXT( from, to )
```

These macros implement the thread switch code. The arguments are:

from
: A pointer to a location where the stack pointer of the current thread will be stored.

to
: A pointer to a location from where the stack pointer of the next thread will be read.

For `HAL_THREAD_LOAD_CONTEXT()` the current CPU state is discarded and the state of the destination thread is loaded. This is only used once, to load the first thread when the scheduler is started.

For `HAL_THREAD_SWITCH_CONTEXT()` the state of the current thread is saved onto its stack, using the current value of the stack pointer, and the address of the saved state placed in *`*from`*. The value in *`*to`* is then read and the state of the new thread is loaded from it.

While these two operations may be implemented with inline assembler, they are normally implemented as calls to assembly code functions in the HAL. There are two advantages to doing it this way. First, the return link of the call provides a convenient PC value to be used in the saved context. Second, the calling conventions mean that the compiler will have already saved the caller-saved registers before the call, so the HAL need only save the callee-saved registers.

The implementation of `HAL_THREAD_SWITCH_CONTEXT()` saves the current CPU state on the stack, including the current interrupt state (or at least the register that contains it). For debugging purposes it is useful to save the entire register set, but for performance only the ABI-defined callee-saved registers need be saved. If it is implemented, the option `CYGDBG_HAL_COMMON_CONTEXT_SAVE_MINIMUM` controls how many registers are saved.

The implementation of `HAL_THREAD_LOAD_CONTEXT()` loads a thread context, destroying the current context. With a little care this can be implemented by sharing code with `HAL_THREAD_SWITCH_CONTEXT()`. To load a thread context simply requires the saved registers to be restored from the stack and a jump or return made back to the saved PC.

Note that interrupts are not disabled during this process, any interrupts that occur will be delivered onto the stack to which the current CPU stack pointer points. Hence the stack pointer should never be invalid, or loaded with a value that might cause the saved state to become corrupted by an interrupt. However, the current interrupt state is saved and restored as part of the thread context. If a thread disables interrupts and does something to cause a context switch, interrupts may be re-enabled on switching to another thread. Interrupts will be disabled again when the original thread regains control.

Bit indexing

```
HAL_LSBIT_INDEX( index, mask )
HAL_MSBIT_INDEX( index, mask )
```

These macros place in *`index`* the bit index of the least significant bit in *`mask`*. Some architectures have instruction level support for one or other of these operations. If no architectural support is available, then these macros may call C functions to do the job.

Idle thread activity

```
HAL_IDLE_THREAD_ACTION( count )
```

It may be necessary under some circumstances for the HAL to execute code in the kernel idle thread's loop. An example might be to execute a processor halt instruction. This macro provides a portable way of doing this. The argument is a copy of the idle thread's loop counter, and may be used to trigger actions at longer intervals than every loop.

Reorder barrier

```
HAL_REORDER_BARRIER()
```

When optimizing the compiler can reorder code. In some parts of multi-threaded systems, where the order of actions is vital, this can sometimes cause problems. This macro may be inserted into places where reordering should not happen and prevents code being migrated across it by the compiler optimizer. It should be placed between statements that must be executed in the order written in the code.

Breakpoint support

```
HAL_BREAKPOINT( label )
HAL_BREAKINST
HAL_BREAKINST_SIZE
```

These macros provide support for breakpoints.

HAL_BREAKPOINT() executes a breakpoint instruction. The label is defined at the breakpoint instruction so that exception code can detect which breakpoint was executed.

HAL_BREAKINST contains the breakpoint instruction code as an integer value. HAL_BREAKINST_SIZE is the size of that breakpoint instruction in bytes. Together these may be used to place a breakpoint in any code.

GDB support

```
HAL_THREAD_GET_SAVED_REGISTERS( sp, regs )
HAL_GET_GDB_REGISTERS( regval, regs )
HAL_SET_GDB_REGISTERS( regs, regval )
```

These macros provide support for interfacing GDB to the HAL.

HAL_THREAD_GET_SAVED_REGISTERS() extracts a pointer to a HAL_SavedRegisters structure from a stack pointer value. The stack pointer passed in should be the value saved by the thread context macros. The macro will assign a pointer to the HAL_SavedRegisters structure to the variable passed as the second argument.

HAL_GET_GDB_REGISTERS() translates a register state as saved by the HAL and into a register dump in the format expected by GDB. It takes a pointer to a HAL_SavedRegisters structure in the *regs* argument and a pointer to the memory to contain the GDB register dump in the *regval* argument.

HAL_SET_GDB_REGISTERS() translates a GDB format register dump into a the format expected by the HAL. It takes a pointer to the memory containing the GDB register dump in the *regval* argument and a pointer to a HAL_SavedRegisters structure in the *regs* argument.

Setjmp and longjmp support

```
CYGARC_JMP_BUF_SIZE
hal_jmp_buf[CYGARC_JMP_BUF_SIZE]
hal_setjmp( hal_jmp_buf env )
hal_longjmp( hal_jmp_buf env, int val )
```

These functions provide support for the C setjmp() and longjmp() functions. Refer to the C library for further information.

Stack Sizes

```
CYGNUM_HAL_STACK_SIZE_MINIMUM
CYGNUM_HAL_STACK_SIZE_TYPICAL
```

The values of these macros define the minimum and typical sizes of thread stacks.

CYGNUM_HAL_STACK_SIZE_MINIMUM defines the minimum size of a thread stack. This is enough for the thread to function correctly within eCos and allows it to take interrupts and context switches. There should also be enough space for a simple thread entry function to execute and call basic kernel operations on objects like mutexes and semaphores. However there will not be enough room for much more than this. When creating stacks for their own threads, applications should determine the stack usage needed for application purposes and then add CYGNUM_HAL_STACK_SIZE_MINIMUM.

CYGNUM_HAL_STACK_SIZE_TYPICAL is a reasonable increment over CYGNUM_HAL_STACK_SIZE_MINIMUM, usually about 1kB. This should be adequate for most modest thread needs. Only threads that need to define significant amounts of local data, or have very deep call trees should need to use a larger stack size.

Address Translation

```
CYGARC_CACHED_ADDRESS(addr)
CYGARC_UNCACHED_ADDRESS(addr)
```

```
CYGARC_PHYSICAL_ADDRESS(addr)
```

These macros provide address translation between different views of memory. In many architectures a given memory location may be visible at different addresses in both cached and uncached forms. It is also possible that the MMU or some other address translation unit in the CPU presents memory to the program at a different virtual address to its physical address on the bus.

`CYGARC_CACHED_ADDRESS()` translates the given address to its location in cached memory. This is typically where the application will access the memory.

`CYGARC_UNCACHED_ADDRESS()` translates the given address to its location in uncached memory. This is typically where device drivers will access the memory to avoid cache problems. It may additionally be necessary for the cache to be flushed before the contents of this location is fully valid.

`CYGARC_PHYSICAL_ADDRESS()` translates the given address to its location in the physical address space. This is typically the address that needs to be passed to device hardware such as a DMA engine, Ethernet device or PCI bus bridge. The physical address may not be directly accessible to the program, it may be re-mapped by address translation.

Global Pointer

```
CYGARC_HAL_SAVE_GP()
CYGARC_HAL_RESTORE_GP()
```

These macros insert code to save and restore any global data pointer that the ABI uses. These are necessary when switching context between two eCos instances - for example between an eCos application and RedBoot.

Interrupt Handling

These interfaces contain definitions related to interrupt handling. They include definitions of exception and interrupt numbers, interrupt enabling and masking.

These definitions are normally found in `cyg/hal/hal_intr.h`. This file is supplied by the architecture HAL. Any variant or platform specific definitions will be found in `cyg/hal/var_intr.h`, `cyg/hal/plf_intr.h` or `cyg/hal/hal_platform_ints.h` in the variant or platform HAL, depending on the exact target. These files are include automatically by this header, so need not be included explicitly.

Vector numbers

```
CYGNUM_HAL_VECTOR_XXXX
CYGNUM_HAL_VSR_MIN
CYGNUM_HAL_VSR_MAX
CYGNUM_HAL_VSR_COUNT

CYGNUM_HAL_INTERRUPT_XXXX
CYGNUM_HAL_ISR_MIN
CYGNUM_HAL_ISR_MAX
CYGNUM_HAL_ISR_COUNT

CYGNUM_HAL_EXCEPTION_XXXX
CYGNUM_HAL_EXCEPTION_MIN
CYGNUM_HAL_EXCEPTION_MAX
CYGNUM_HAL_EXCEPTION_COUNT
```

All possible VSR, interrupt and exception vectors are specified here, together with maximum and minimum values for range checking. While the VSR and exception numbers will be defined in this file, the interrupt numbers will normally be defined in the variant or platform HAL file that is included by this header.

There are two ranges of numbers, those for the vector service routines and those for the interrupt service routines. The relationship between these two ranges is undefined, and no equivalence should be assumed if vectors from the two ranges coincide.

The VSR vectors correspond to the set of exception vectors that can be delivered by the CPU architecture, many of these will be internal exception traps. The ISR vectors correspond to the set of external interrupts that can be delivered and are usually determined by extra decoding of the interrupt controller by the interrupt VSR.

Where a CPU supports synchronous exceptions, the range of such exceptions allowed are defined by CYGNUM_HAL_EXCEPTION_MIN and CYGNUM_HAL_EXCEPTION_MAX. The CYGNUM_HAL_EXCEPTION_XXXX definitions are standard names used by target independent code to test for the presence of particular exceptions in the architecture. The actual exception numbers will normally correspond to the VSR exception range. In future other exceptions generated by the system software (such as stack overflow) may be added.

CYGNUM_HAL_ISR_COUNT, CYGNUM_HAL_VSR_COUNT and CYGNUM_HAL_EXCEPTION_COUNT define the number of ISRs, VSRs and EXCEPTIONs respectively for the purposes of defining arrays etc. There might be a translation from the supplied vector numbers into array offsets. Hence CYGNUM_HAL_XXX_COUNT may not simply be CYGNUM_HAL_XXX_MAX - CYGNUM_HAL_XXX_MIN or CYGNUM_HAL_XXX_MAX+1.

Interrupt state control

```
CYG_INTERRUPT_STATE
HAL_DISABLE_INTERRUPTS( old )
HAL_RESTORE_INTERRUPTS( old )
HAL_ENABLE_INTERRUPTS()
HAL_QUERY_INTERRUPTS( state )
```

These macros provide control over the state of the CPUs interrupt mask mechanism. They should normally manipulate a CPU status register to enable and disable interrupt delivery. They should not access an interrupt controller.

CYG_INTERRUPT_STATE is a data type that should be used to store the interrupt state returned by HAL_DISABLE_INTERRUPTS() and HAL_QUERY_INTERRUPTS() and passed to HAL_RESTORE_INTERRUPTS().

HAL_DISABLE_INTERRUPTS() disables the delivery of interrupts and stores the original state of the interrupt mask in the variable passed in the *old* argument.

HAL_RESTORE_INTERRUPTS() restores the state of the interrupt mask to that recorded in *old*.

HAL_ENABLE_INTERRUPTS() simply enables interrupts regardless of the current state of the mask.

HAL_QUERY_INTERRUPTS() stores the state of the interrupt mask in the variable passed in the *state* argument. The state stored here should also be capable of being passed to HAL_RESTORE_INTERRUPTS() at a later point.

It is at the HAL implementer,s discretion exactly which interrupts are masked by this mechanism. Where a CPU has more than one interrupt type that may be masked separately (e.g. the ARM's IRQ and FIQ) only those that can raise DSRs need to be masked here. A separate architecture specific mechanism may then be used to control the other interrupt types.

ISR and VSR management

```
HAL_INTERRUPT_IN_USE( vector, state )
HAL_INTERRUPT_ATTACH( vector, isr, data, object )
HAL_INTERRUPT_DETACH( vector, isr )
HAL_VSR_SET( vector, vsr, poldvsr )
HAL_VSR_GET( vector, pvsr )
HAL_VSR_SET_TO_ECOS_HANDLER( vector, poldvsr )
```

These macros manage the attachment of interrupt and vector service routines to interrupt and exception vectors respectively.

HAL_INTERRUPT_IN_USE() tests the state of the supplied interrupt vector and sets the value of the state parameter to either 1 or 0 depending on whether there is already an ISR attached to the vector. The HAL will only allow one ISR to be attached to each vector, so it is a good idea to use this function before using HAL_INTERRUPT_ATTACH().

`HAL_INTERRUPT_ATTACH()` attaches the ISR, data pointer and object pointer to the given *`vector`*. When an interrupt occurs on this vector the ISR is called using the C calling convention and the vector number and data pointer are passed to it as the first and second arguments respectively.

`HAL_INTERRUPT_DETACH()` detaches the ISR from the vector.

`HAL_VSR_SET()` replaces the VSR attached to the *`vector`* with the replacement supplied in *`vsr`*. The old VSR is returned in the location pointed to by *`pvsr`*. On some platforms, possibly only in certain configurations, the table of VSRs will be in read-only memory. If so then this macro should be left undefined.

`HAL_VSR_GET()` assigns a copy of the VSR to the location pointed to by *`pvsr`*.

`HAL_VSR_SET_TO_ECOS_HANDLER()` ensures that the VSR for a specific exception is pointing at the eCos exception VSR and not one for RedBoot or some other ROM monitor. The default when running under RedBoot is for exceptions to be handled by RedBoot and passed to GDB. This macro diverts the exception to eCos so that it may be handled by application code. The arguments are the VSR vector to be replaces, and a location in which to store the old VSR pointer, so that it may be replaced at a later point. On some platforms, possibly only in certain configurations, the table of VSRs will be in read-only memory. If so then this macro should be left undefined.

Interrupt controller management

```
HAL_INTERRUPT_MASK( vector )
HAL_INTERRUPT_UNMASK( vector )
HAL_INTERRUPT_ACKNOWLEDGE( vector )
HAL_INTERRUPT_CONFIGURE( vector, level, up )
HAL_INTERRUPT_SET_LEVEL( vector, level )
```

These macros exert control over any prioritized interrupt controller that is present. If no priority controller exists, then these macros should be empty.

Note

These macros may not be reentrant, so care should be taken to prevent them being called while interrupts are enabled. This means that they can be safely used in initialization code before interrupts are enabled, and in ISRs. In DSRs, ASRs and thread code, however, interrupts must be disabled before these macros are called. Here is an example for use in a DSR where the interrupt source is unmasked after data processing:

```
…
HAL_DISABLE_INTERRUPTS(old);
HAL_INTERRUPT_UNMASK(CYGNUM_HAL_INTERRUPT_ETH);
HAL_RESTORE_INTERRUPTS(old);
…
```

`HAL_INTERRUPT_MASK()` causes the interrupt associated with the given vector to be blocked.

`HAL_INTERRUPT_UNMASK()` causes the interrupt associated with the given vector to be unblocked.

`HAL_INTERRUPT_ACKNOWLEDGE()` acknowledges the current interrupt from the given vector. This is usually executed from the ISR for this vector when it is prepared to allow further interrupts. Most interrupt controllers need some form of acknowledge action before the next interrupt is allowed through. Executing this macro may cause another interrupt to be delivered. Whether this interrupts the current code depends on the state of the CPU interrupt mask.

`HAL_INTERRUPT_CONFIGURE()` provides control over how an interrupt signal is detected. The arguments are:

vector
: The interrupt vector to be configured.

level
: Set to `true` if the interrupt is detected by level, and `false` if it is edge triggered.

up
: If the interrupt is set to level detect, then if this is `true` it is detected by a high signal level, and if `false` by a low signal level. If the interrupt is set to edge triggered, then if this is `true` it is triggered by a rising edge and if `false` by a falling edge.

`HAL_INTERRUPT_SET_LEVEL()` provides control over the hardware priority of the interrupt. The arguments are:

vector
: The interrupt whose level is to be set.

level
: The priority level to which the interrupt is to set. In some architectures the masking of an interrupt is achieved by changing its priority level. Hence this function, `HAL_INTERRUPT_MASK()` and `HAL_INTERRUPT_UNMASK()` may interfere with each other.

Clocks and Timers

These interfaces contain definitions related to clock and timer handling. They include interfaces to initialize and read a clock for generating regular interrupts, definitions for setting the frequency of the clock, and support for short timed delays.

Clock Control

```
HAL_CLOCK_INITIALIZE( period )
HAL_CLOCK_RESET( vector, period )
HAL_CLOCK_READ( pvalue )
```

These macros provide control over a clock or timer device that may be used by the kernel to provide time-out, delay and scheduling services. The clock is assumed to be implemented by some form of counter that is incremented or decremented by some external source and which raises an interrupt when it reaches a predetermined value.

`HAL_CLOCK_INITIALIZE()` initializes the timer device to interrupt at the given period. The period is essentially the value used to initialize the timer counter and must be calculated from the timer frequency and the desired interrupt rate. The timer device should generate an interrupt every `period` cycles.

`HAL_CLOCK_RESET()` re-initializes the timer to provoke the next interrupt. This macro is only really necessary when the timer device needs to be reset in some way after each interrupt.

`HAL_CLOCK_READ()` reads the current value of the timer counter and puts the value in the location pointed to by *`pvalue`*. The value stored will always be the number of timer cycles since the last interrupt, and hence ranges between zero and the initial period value. If this is a count-down cyclic timer, some arithmetic may be necessary to generate this value.

Microsecond Delay

```
HAL_DELAY_US(us)
```

This macro provides a busy loop delay for the given number of microseconds. It is intended mainly for controlling hardware that needs short delays between operations. Code which needs longer delays, of the order of milliseconds, should instead use higher-level functions such as `cyg_thread_delay`. The macro implementation should be thread-safe. It can also be used in ISRs or DSRs, although such usage is undesirable because of the impact on interrupt and dispatch latency.

The macro should never delay for less than the specified amount of time. It may delay for somewhat longer, although since the macro uses a busy loop this is a waste of CPU cycles. Of course the code invoking `HAL_DELAY_US` may get interrupted or timesliced, in which case the delay may be much longer than intended. If this is unacceptable then the calling code must take preventative action such as disabling interrupts or locking the scheduler.

There are three main ways of implementing the macro:

1. a counting loop, typically written in inline assembler, using an outer loop for the microseconds and an inner loop that consumes approximately 1us. This implementation is automatically thread-safe and does not impose any dependencies on the rest of the

system, for example it does not depend on the system clock having been started. However it assumes that the CPU clock speed is known at compile-time or can be easily determined at run-time.

2. monitor one of the hardware clocks, usually the system clock. Usually this clock ticks at a rate independent of the CPU so calibration is easier. However the implementation relies on the system clock having been started, and assumes that no other code is manipulating the clock hardware. There can also be complications when the system clock wraps around.

3. a combination of the previous two. The system clock is used during system initialization to determine the CPU clock speed, and the result is then used to calibrate a counting loop. This has the disadvantage of significantly increasing the system startup time, which may be unacceptable to some applications. There are also complications if the system startup code normally runs with the cache disabled because the instruction cache will greatly affect any calibration loop.

Clock Frequency Definition

```
CYGNUM_HAL_RTC_NUMERATOR
CYGNUM_HAL_RTC_DENOMINATOR
CYGNUM_HAL_RTC_PERIOD
```

These macros are defined in the CDL for each platform and supply the necessary parameters to specify the frequency at which the clock interrupts. These parameters are usually found in the CDL definitions for the target platform, or in some cases the CPU variant.

`CYGNUM_HAL_RTC_NUMERATOR` and `CYGNUM_HAL_RTC_DENOMINATOR` specify the resolution of the clock interrupt. This resolution involves two separate values, the numerator and the denominator. The result of dividing the numerator by the denominator should correspond to the number of nanoseconds between clock interrupts. For example a numerator of 1000000000 and a denominator of 100 means that there are 10000000 nanoseconds (or 10 milliseconds) between clock interrupts. Expressing the resolution as a fraction minimizes clock drift even for frequencies that cannot be expressed as a simple integer. For example a frequency of 60Hz corresponds to a clock resolution of 16666666.66… nanoseconds. This can be expressed accurately as 1000000000 over 60.

`CYGNUM_HAL_RTC_PERIOD` specifies the exact value used to initialize the clock hardware, it is the value passed as a parameter to `HAL_CLOCK_INITIALIZE()` and `HAL_CLOCK_RESET()`. The exact meaning of the value and the range of legal values therefore depends on the target hardware, and the hardware documentation should be consulted for further details.

The default values for these macros in all HALs are calculated to give a clock interrupt frequency of 100Hz, or 10ms between interrupts. To change the clock frequency, the period needs to be changed, and the resolution needs to be adjusted accordingly. As an example consider the i386 PC target. The default values for these macros are:

```
CYGNUM_HAL_RTC_NUMERATOR     1000000000
CYGNUM_HAL_RTC_DENOMINATOR   100
CYGNUM_HAL_RTC_PERIOD        11932
```

To change to, say, a 200Hz clock the period needs to be halved to 5966, and to compensate the denominator needs to be doubled to 200. To change to a 1KHz interrupt rate change the period to 1193 and the denominator to 1000.

Some HALs make this process a little easier by deriving the period arithmetically from the denominator. This calculation may also involve the CPU clock frequency and possibly other factors. For example in the ARM AT91 variant HAL the period is defined by the following expression:

```
((CYGNUM_HAL_ARM_AT91_CLOCK_SPEED/32) / CYGNUM_HAL_RTC_DENOMINATOR)
```

In this case it is not necessary to change the period at all, just change the denominator to select the desired clock frequency. However, note that for certain choices of frequency, rounding errors in this calculation may result in a small clock drift over time. This is usually negligible, but if perfect accuracy is required, it may be necessary to adjust the frequency or period by hand.

HAL I/O

This section contains definitions for supporting access to device control registers in an architecture neutral fashion.

These definitions are normally found in the header file `cyg/hal/hal_io.h`. This file itself contains macros that are generic to the architecture. If there are variant or platform specific IO access macros then these will be found in `cyg/hal/var_io.h` and `cyg/hal/plf_io.h` in the variant or platform HALs respectively. These files are included automatically by this header, so need not be included explicitly.

This header (or more likely `cyg/hal/plf_io.h`) also defines the PCI access macros. For more information on these see the eCos PCI library reference documentation.

Register address

```
HAL_IO_REGISTER
```

This type is used to store the address of an I/O register. It will normally be a memory address, an integer port address or an offset into an I/O space. More complex architectures may need to code an address space plus offset pair into a single word, or may represent it as a structure.

Values of variables and constants of this type will usually be supplied by configuration mechanisms or in target specific headers.

Register read

```
HAL_READ_XXX( register, value )
HAL_READ_XXX_VECTOR( register, buffer, count, stride )
```

These macros support the reading of I/O registers in various sizes. The *XXX* component of the name may be `UINT8`, `UINT16`, `UINT32`.

`HAL_READ_XXX()` reads the appropriately sized value from the register and stores it in the variable passed as the second argument.

`HAL_READ_XXX_VECTOR()` reads *count* values of the appropriate size into *buffer*. The *stride* controls how the pointer advances through the register space. A stride of zero will read the same register repeatedly, and a stride of one will read adjacent registers of the given size. Greater strides will step by larger amounts, to allow for sparsely mapped registers for example.

Register write

```
HAL_WRITE_XXX( register, value )
HAL_WRITE_XXX_VECTOR( register, buffer,count, stride )
```

These macros support the writing of I/O registers in various sizes. The *XXX* component of the name may be `UINT8`, `UINT16`, `UINT32`.

`HAL_WRITE_XXX()` writes the appropriately sized value from the variable passed as the second argument stored it in the register.

`HAL_WRITE_XXX_VECTOR()` writes *count* values of the appropriate size from *buffer*. The *stride* controls how the pointer advances through the register space. A stride of zero will write the same register repeatedly, and a stride of one will write adjacent registers of the given size. Greater strides will step by larger amounts, to allow for sparsely mapped registers for example.

HAL Unique-ID

This section contains definitions for supporting the optional Unique-ID access in an architecture neutral fashion. Not all variants, or platforms, will provide a mechanism for accessing device-specific Unique-ID data, in which case the macros as documented in this section will not be defined.

The required definitions are normally referenced via the header file `cyg/hal/hal_io.h`. This file itself contains macros that are generic to the configured architecture. If there are variant or platform specific Unique-ID access macros then these will be found in `cyg/hal/var_io.h` and `cyg/hal/plf_io.h` in the variant or platform HALs respectively. These files are included automatically by the architecture header, so need not be included explicitly.

HAL_UNIQUE_ID_LEN

```
HAL_UNIQUE_ID_LEN( CYG_WORD32 maxlen )
```

This macro, when defined, provides a mechanism for ascertaining the maximum number of bytes of Unique-ID data available.

For most implementations this macro will return a build-time constant value in the passed *`maxlen`* parameter, but some systems may have a run-time calculated limit.

HAL_UNIQUE_ID

```
HAL_UNIQUE_ID( CYG_BYTE *buffer, CYG_WORD32 bufflen )
```

T his macro, when defined, provides a mechanism for filling the passed *`buffer`* parameter with upto *`bufflen`* bytes of Unique-ID data. If the implementation provides fewer that *`bufflen`* bytes of unique information then only the available data will be copied to the destination *`buffer`*.

The use of returned Unique-ID data is application specific, but examples may include use for USB device serial# identification, Ethernet MAC addresses, cryptography seeds, etc.

When a valid *`buffer`* parameter is passed then the *`bufflen`* parameter indicates how many bytes are available. This *`bufflen`* size may be less than the total amount of Unique-ID information available, with the variant/platform implementation only copying the requested amount.

Note

This “always-copy” model is used since it allows the same API to be used for systems where the ID information is *not* held in CPU addressable memory, or where multiple sources are concatenated by an implementation to provide a larger Unique-ID value.

Cache Control

This section contains definitions for supporting control of the caches on the CPU.

These definitions are usually found in the header file `cyg/hal/hal_cache.h`. This file may be defined in the architecture, variant or platform HAL, depending on where the caches are implemented for the target. Often there will be a generic implementation of the cache control macros in the architecture HAL with the ability to override or undefine them in the variant or platform HAL. Even when the implementation of the cache macros is in the architecture HAL, the cache dimensions will be defined in the variant or platform HAL. As with other files, the variant or platform specific definitions are usually found in `cyg/hal/var_cache.h` and `cyg/hal/plf_cache.h` respectively. These files are include automatically by this header, so need not be included explicitly.

There are versions of the macros defined here for both the Data and Instruction caches. these are distinguished by the use of either `DCACHE` or `ICACHE` in the macro names. Some architectures have a unified cache, where both data and instruction share the same cache. In these cases the control macros use `UCACHE` and the `DCACHE` and `ICACHE` macros will just be calls to the `UCACHE` version. In the following descriptions, `XCACHE` is used to stand for any of these. Where there are issues specific to a particular cache, this will be explained in the text.

There might be target specific restrictions on the use of some of the macros which it is the user's responsibility to comply with. Such restrictions are documented in the header file with the macro definition.

Note that destructive cache macros should be used with caution. Preceding a cache invalidation with a cache synchronization is not safe in itself since an interrupt may happen after the synchronization but before the invalidation. This might cause the state of dirty data lines created during the interrupt to be lost.

Depending on the architecture's capabilities, it may be possible to temporarily disable the cache while doing the synchronization and invalidation which solves the problem (no new data would be cached during an interrupt). Otherwise it is necessary to disable interrupts while manipulating the cache which may take a long time.

Some platform HALs now support a pair of cache state query macros: `HAL_ICACHE_IS_ENABLED( x )` and `HAL_DCACHE_IS_ENABLED( x )` which set the argument to true if the instruction or data cache is enabled, respectively. Like most cache control macros, these are optional, because the capabilities of different targets and boards can vary considerably. Code which uses them, if it is to be considered portable, should test for their existence first by means of `#ifdef`. Be sure to include `<cyg/hal/hal_cache.h>` in order to do this test and (maybe) use the macros.

Cache Dimensions

```
HAL_XCACHE_SIZE
HAL_XCACHE_LINE_SIZE
HAL_XCACHE_WAYS
HAL_XCACHE_SETS
```

These macros define the size and dimensions of the Instruction and Data caches.

HAL_XCACHE_SIZE

Defines the total size of the cache in bytes.

HAL_XCACHE_LINE_SIZE

Defines the cache line size in bytes.

HAL_XCACHE_WAYS

Defines the number of ways in each set and defines its level of associativity. This would be 1 for a direct mapped cache, 2 for a 2-way cache, 4 for 4-way and so on.

HAL_XCACHE_SETS

Defines the number of sets in the cache, and is calculated from the previous values.

Global Cache Control

```
HAL_XCACHE_ENABLE()
HAL_XCACHE_DISABLE()
HAL_XCACHE_INVALIDATE_ALL()
HAL_XCACHE_SYNC()
HAL_XCACHE_BURST_SIZE( size )
HAL_DCACHE_WRITE_MODE( mode )
HAL_XCACHE_LOCK( base, size )
HAL_XCACHE_UNLOCK( base, size )
HAL_XCACHE_UNLOCK_ALL()
```

These macros affect the state of the entire cache, or a large part of it.

HAL_XCACHE_ENABLE() and HAL_XCACHE_DISABLE()

Enable and disable the cache.

HAL_XCACHE_INVALIDATE_ALL()

Causes the entire contents of the cache to be invalidated. Depending on the hardware, this may require the cache to be disabled during the invalidation process. If so, the implementation must use `HAL_XCACHE_IS_ENABLED()` to save and restore the previous state.

Note

If this macro is called after `HAL_XCACHE_SYNC()` with the intention of clearing the cache (invalidating the cache after writing dirty data back to memory), you must prevent interrupts from happening between the two calls:

```
…
HAL_DISABLE_INTERRUPTS(old);
HAL_XCACHE_SYNC();
HAL_XCACHE_INVALIDATE_ALL();
HAL_RESTORE_INTERRUPTS(old);
…
```

Since the operation may take a very long time, real-time responsiveness could be affected, so only do this when it is absolutely required and you know the delay will not interfere with the operation of drivers or the application.

HAL_XCACHE_SYNC()

Causes the contents of the cache to be brought into synchronization with the contents of memory. In some implementations this may be equivalent to `HAL_XCACHE_INVALIDATE_ALL()`.

HAL_XCACHE_BURST_SIZE()

Allows the size of cache to/from memory bursts to be controlled. This macro will only be defined if this functionality is available.

HAL_DCACHE_WRITE_MODE()

Controls the way in which data cache lines are written back to memory. There will be definitions for the possible modes. Typical definitions are `HAL_DCACHE_WRITEBACK_MODE` and `HAL_DCACHE_WRITETHRU_MODE`. This macro will only be defined if this functionality is available.

HAL_XCACHE_LOCK()

Causes data to be locked into the cache. The base and size arguments define the memory region that will be locked into the cache. It is architecture dependent whether more than one locked region is allowed at any one time, and whether this operation causes the cache to cease acting as a cache for addresses outside the region during the duration of the lock. This macro will only be defined if this functionality is available.

HAL_XCACHE_UNLOCK()

Cancels the locking of the memory region given. This should normally correspond to a region supplied in a matching lock call. This macro will only be defined if this functionality is available.

HAL_XCACHE_UNLOCK_ALL()

Cancels all existing locked memory regions. This may be required as part of the cache initialization on some architectures. This macro will only be defined if this functionality is available.

Cache Line Control

```
HAL_DCACHE_ALLOCATE( base , size )
HAL_DCACHE_FLUSH( base , size )
HAL_XCACHE_INVALIDATE( base , size )
```

```
HAL_DCACHE_STORE( base , size )
HAL_DCACHE_READ_HINT( base , size )
HAL_DCACHE_WRITE_HINT( base , size )
HAL_DCACHE_ZERO( base , size )
```

All of these macros apply a cache operation to all cache lines that match the memory address region defined by the base and size arguments. These macros will only be defined if the described functionality is available. Also, it is not guaranteed that the cache function will only be applied to just the described regions, in some architectures it may be applied to the whole cache.

HAL_DCACHE_ALLOCATE()

Allocates lines in the cache for the given region without reading their contents from memory, hence the contents of the lines is undefined. This is useful for preallocating lines which are to be completely overwritten, for example in a block copy operation.

HAL_DCACHE_FLUSH()

Invalidates all cache lines in the region after writing any dirty lines to memory.

HAL_XCACHE_INVALIDATE()

Invalidates all cache lines in the region. Any dirty lines are invalidated without being written to memory.

HAL_DCACHE_STORE()

Writes all dirty lines in the region to memory, but does not invalidate any lines.

HAL_DCACHE_READ_HINT()

Hints to the cache that the region is going to be read from in the near future. This may cause the region to be speculatively read into the cache.

HAL_DCACHE_WRITE_HINT()

Hints to the cache that the region is going to be written to in the near future. This may have the identical behavior to HAL_DCACHE_READ_HINT().

HAL_DCACHE_ZERO()

Allocates and zeroes lines in the cache for the given region without reading memory. This is useful if a large area of memory is to be cleared.

Linker Scripts

When an eCos application is linked it must be done under the control of a linker script. This script defines the memory areas, addresses and sized, into which the code and data are to be put, and allocates the various sections generated by the compiler to these.

The linker script actually used is in `lib/target.ld` in the install directory. This is actually manufactured out of two other files: a base linker script and an `.ldi` file that was generated by the memory layout tool.

The base linker script is usually supplied either by the architecture HAL or the variant HAL. It consists of a set of linker script fragments, in the form of C preprocessor macros, that define the major output sections to be generated by the link operation. The `.ldi` file, which is `#include'ed` by the base linker script, uses these macro definitions to assign the output sections to the required memory areas and link addresses.

The `.ldi` file is supplied by the platform HAL, and contains knowledge of the memory layout of the target platform. These files generally conform to a standard naming convention, each file being of the form:

```
pkgconf/mlt_<architecture>_<variant>_<platform>_<startup>.ldi
```

where <architecture>, <variant> and <platform> are the respective HAL package names and <startup> is the startup type which is usually one of ROM, RAM or ROMRAM.

In addition to the .ldi file, there is also a congruously name .h file. This may be used by the application to access information defined in the .ldi file. Specifically it contains the memory layout defined there, together with any additional section names defined by the user. Examples of the latter are heap areas or PCI bus memory access windows.

The .ldi is manufactured by the Memory Layout Tool (MLT). The MLT saves the memory configuration into a file named

include/pkgconf/mlt_<architecture>_<variant>_<platform>_<startup>.mlt

in the platform HAL. This file is used by the MLT to manufacture both the .ldi and .h files. Users should beware that direct edits the either of these files may be overwritten if the MLT is run and regenerates them from the .mlt file.

The names of the .ldi and .h files are defined by macro definitions in pkgconf/system.h. These are CYGHWR_MEMORY_LAYOUT_LDI and CYGHWR_MEMORY_LAYOUT_H respectively. While there will be little need for the application to refer to the .ldi file directly, it may include the .h file as follows:

```
#include CYGHWR_MEMORY_LAYOUT_H
```

Diagnostic Support

The HAL provides support for low level diagnostic IO. This is particularly useful during early development as an aid to bringing up a new platform. Usually this diagnostic channel is a UART or some other serial IO device, but it may equally be a a memory buffer, a simulator supported output channel, a ROM emulator virtual UART, and LCD panel, a memory mapped video buffer or any other output device.

HAL_DIAG_INIT() performs any initialization required on the device being used to generate diagnostic output. This may include, for a UART, setting baud rate, and stop, parity and character bits. For other devices it may include initializing a controller or establishing contact with a remote device.

HAL_DIAG_WRITE_CHAR(c) writes the character supplied to the diagnostic output device.

HAL_DIAG_READ_CHAR(c) reads a character from the diagnostic device into the supplied variable. This is not supported for all diagnostic devices.

These macros are defined in the header file cyg/hal/hal_diag.h. This file is usually supplied by the variant or platform HAL, depending on where the IO device being used is located. For example for on-chip UARTs it would be in the variant HAL, but for a board-level LCD panel it would be in the platform HAL.

SMP Support

eCos contains support for limited Symmetric Multi-Processing (SMP). This is only available on selected architectures and platforms.

Target Hardware Limitations

To allow a reasonable implementation of SMP, and to reduce the disruption to the existing source base, a number of assumptions have been made about the features of the target hardware.

- Modest multiprocessing. The typical number of CPUs supported is two to four, with an upper limit around eight. While there are no inherent limits in the code, hardware and algorithmic limitations will probably become significant beyond this point.
- SMP synchronization support. The hardware must supply a mechanism to allow software on two CPUs to synchronize. This is normally provided as part of the instruction set in the form of test-and-set, compare-and-swap or load-link/store-conditional

instructions. An alternative approach is the provision of hardware semaphore registers which can be used to serialize implementations of these operations. Whatever hardware facilities are available, they are used in eCos to implement spinlocks.

- Coherent caches. It is assumed that no extra effort will be required to access shared memory from any processor. This means that either there are no caches, they are shared by all processors, or are maintained in a coherent state by the hardware. It would be too disruptive to the eCos sources if every memory access had to be bracketed by cache load/flush operations. Any hardware that requires this is not supported.

- Uniform addressing. It is assumed that all memory that is shared between CPUs is addressed at the same location from all CPUs. Like non-coherent caches, dealing with CPU-specific address translation is considered too disruptive to the eCos source base. This does not, however, preclude systems with non-uniform access costs for different CPUs.

- Uniform device addressing. As with access to memory, it is assumed that all devices are equally accessible to all CPUs. Since device access is often made from thread contexts, it is not possible to restrict access to device control registers to certain CPUs.

- Interrupt routing. The target hardware must have an interrupt controller that can route interrupts to specific CPUs. It is acceptable for all interrupts to be delivered to just one CPU, or for some interrupts to be bound to specific CPUs, or for some interrupts to be local to each CPU. At present dynamic routing, where a different CPU may be chosen each time an interrupt is delivered, is not supported. ECos cannot support hardware where all interrupts are delivered to all CPUs simultaneously with the expectation that software will resolve any conflicts.

- Inter-CPU interrupts. A mechanism to allow one CPU to interrupt another is needed. This is necessary so that events on one CPU can cause rescheduling on other CPUs.

- CPU Identifiers. Code running on a CPU must be able to determine which CPU it is running on. The CPU Id is usually provided either in a CPU status register, or in a register associated with the inter-CPU interrupt delivery subsystem. ECos expects CPU Ids to be small positive integers, although alternative representations, such as bitmaps, can be converted relatively easily. Complex mechanisms for getting the CPU Id cannot be supported. Getting the CPU Id must be a cheap operation, since it is done often, and in performance critical places such as interrupt handlers and the scheduler.

HAL Support

SMP support in any platform depends on the HAL supplying the appropriate operations. All HAL SMP support is defined in the `cyg/hal/hal_smp.h` header. Variant and platform specific definitions will be in `cyg/hal/var_smp.h` and `cyg/hal/plf_smp.h` respectively. These files are include automatically by this header, so need not be included explicitly.

SMP support falls into a number of functional groups.

CPU Control

This group consists of descriptive and control macros for managing the CPUs in an SMP system.

`HAL_SMP_CPU_TYPE`

A type that can contain a CPU id. A CPU id is usually a small integer that is used to index arrays of variables that are managed on an per-CPU basis.

`HAL_SMP_CPU_MASK`

A type that can contain a bitmask of all CPUs in the system. In this mask, bit n corresponds to CPU n.

`HAL_SMP_CPU_COUNT`

The maximum number of CPUs that can be supported. This is used to provide the size of any arrays that have an element per CPU.

`HAL_SMP_CPU_MAX`

The maximum possible CPU ID. This should normally be one less that `HAL_SMP_CPU_COUNT`.

`HAL_SMP_CPU_THIS()`

Returns the CPU id of the current CPU.

`HAL_SMP_CPU_NONE`

A value that does not match any real CPU id. This is uses where a CPU type variable must be set to a null value.

`HAL_SMP_CPU_MASK_ALL`

A value for the HAL_SMP_CPU_MASK type that has a bit set for each CPU supported. This value can be derived from HAL_SMP_CPU_COUNT.

`HAL_SMP_CPU_START( cpu )`

Starts the given CPU executing at a defined HAL entry point. After performing any HAL level initialization, the CPU calls up into the kernel at `cyg_kernel_cpu_startup()`.

`HAL_SMP_CPU_RESCHEDULE_INTERRUPT( cpu, wait )`

Sends the CPU a reschedule interrupt, and if *`wait`* is non-zero, waits for an acknowledgment. The interrupted CPU should call `cyg_scheduler_set_need_reschedule()` in its DSR to cause the reschedule to occur.

`HAL_SMP_CPU_TIMESLICE_INTERRUPT( cpu, wait )`

Sends the CPU a timeslice interrupt, and if *`wait`* is non-zero, waits for an acknowledgment. The interrupted CPU should call `cyg_scheduler_timeslice_cpu()` to cause the timeslice event to be processed.

Test-and-set Support

Test-and-set is the foundation of the SMP synchronization mechanisms.

`HAL_TAS_TYPE`

The type for all test-and-set variables. The test-and-set macros only support operations on a single bit (usually the least significant bit) of this location. This allows for maximum flexibility in the implementation.

`HAL_TAS_SET( tas, oldb )`

Performs a test and set operation on the location *`tas`*. *`oldb`* will contain `true` if the location was already set, and `false` if it was clear.

`HAL_TAS_CLEAR( tas, oldb )`

Performs a test and clear operation on the location *`tas`*. *`oldb`* will contain `true` if the location was already set, and `false` if it was clear.

Spinlocks

Spinlocks provide inter-CPU locking. Normally they will be implemented on top of the test-and-set mechanism above, but may also be implemented by other means if, for example, the hardware has more direct support for spinlocks.

`HAL_SPINLOCK_TYPE`

The type for all spinlock variables.

`HAL_SPINLOCK_INIT_CLEAR`

A value that may be assigned to a spinlock variable to initialize it to clear.

`HAL_SPINLOCK_INIT_SET`

A value that may be assigned to a spinlock variable to initialize it to set.

`HAL_SPINLOCK_INIT( lock, val )`

A macro to initialize a spinlock at runtime. The current state of the spinlock is set according to `val`: zero for clear, non-zero for set.

`HAL_SPINLOCK_SPIN( lock )`

The caller spins in a busy loop waiting for the lock to become clear. It then sets it and continues. This is all handled atomically, so that there are no race conditions between CPUs.

`HAL_SPINLOCK_CLEAR( lock )`

The caller clears the lock. One of any waiting spinners will then be able to proceed.

`HAL_SPINLOCK_TRY( lock, val )`

Attempts to set the lock. The value put in *`val`* will be `true` if the lock was claimed successfully, and `false` if it was not.

`HAL_SPINLOCK_TEST( lock, val )`

Tests the current value of the lock. The value put in *`val`* will be `true` if the lock is claimed and `false` of it is clear.

Scheduler Lock

The scheduler lock is the main protection for all kernel data structures. By default the kernel implements the scheduler lock itself using a spinlock. However, if spinlocks cannot be supported by the hardware, or there is a more efficient implementation available, the HAL may provide macros to implement the scheduler lock.

`HAL_SMP_SCHEDLOCK_DATA_TYPE`

A data type, possibly a structure, that contains any data items needed by the scheduler lock implementation. A variable of this type will be instantiated as a static member of the Cyg_Scheduler_SchedLock class and passed to all the following macros.

`HAL_SMP_SCHEDLOCK_INIT( lock, data )`

Initialize the scheduler lock. The *`lock`* argument is the scheduler lock counter and the *`data`* argument is a variable of HAL_SMP_SCHEDLOCK_DATA_TYPE type.

`HAL_SMP_SCHEDLOCK_INC( lock, data )`

Increment the scheduler lock. The first increment of the lock from zero to one for any CPU may cause it to wait until the lock is zeroed by another CPU. Subsequent increments should be less expensive since this CPU already holds the lock.

`HAL_SMP_SCHEDLOCK_ZERO( lock, data )`

Zero the scheduler lock. This operation will also clear the lock so that other CPUs may claim it.

`HAL_SMP_SCHEDLOCK_SET( lock, data, new )`

Set the lock to a different value, in *`new`*. This is only called when the lock is already known to be owned by the current CPU. It is never called to zero the lock, or to increment it from zero.

Interrupt Routing

The routing of interrupts to different CPUs is supported by two new interfaces in hal_intr.h.

Once an interrupt has been routed to a new CPU, the existing vector masking and configuration operations should take account of the CPU routing. For example, if the operation is not invoked on the destination CPU itself, then the HAL may need to arrange to transfer the operation to the destination CPU for correct application.

`HAL_INTERRUPT_SET_CPU( vector, mask )`

Route the interrupt for the given *`vector`* to any of the CPUs whose bit is set in *`mask`*.

`HAL_INTERRUPT_GET_CPU( vector, mask )`

Set *`mask`* to the set of CPUs to which this vector is routed.

Chapter 5. Exception Handling

Most of the HAL consists of simple macros or functions that are called via the interfaces described in the previous section. These just perform whatever operation is required by accessing the hardware and then return. The exception to this is the handling of exceptions: either synchronous hardware traps or asynchronous device interrupts. Here control is passed first to the HAL, which then passed it on to eCos or the application. After eCos has finished with it, control is then passed back to the HAL for it to tidy up the CPU state and resume processing from the point at which the exception occurred.

The HAL exceptions handling code is usually found in the file `vectors.S` in the architecture HAL. Since the reset entry point is usually implemented as one of these it also deals with system startup.

The exact implementation of this code is under the control of the HAL implementer. So long as it interacts correctly with the interfaces defined previously it may take any form. However, all current implementation follow the same pattern, and there should be a very good reason to break with this. The rest of this section describes these operate.

Exception handling normally deals with the following broad areas of functionality:

- Startup and initialization.
- Hardware exception delivery.
- Default handling of synchronous exceptions.
- Default handling of asynchronous interrupts.

HAL Startup

Execution normally begins at the reset vector with the machine in a minimal startup state. From here the HAL needs to get the machine running, set up the execution environment for the application, and finally invoke its entry point.

The following is a list of the jobs that need to be done in approximately the order in which they should be accomplished. Many of these will not be needed in some configurations.

- Initialize the hardware. This may involve initializing several subsystems in both the architecture, variant and platform HALs. These include:
  - Initialize various CPU status registers. Most importantly, the CPU interrupt mask should be set to disable interrupts.
  - Initialize the MMU, if it is used. On many platforms it is only possible to control the cacheability of address ranges via the MMU. Also, it may be necessary to remap RAM and device registers to locations other than their defaults. However, for simplicity, the mapping should be kept as close to one-to-one physical-to-virtual as possible.
  - Set up the memory controller to access RAM, ROM and I/O devices correctly. Until this is done it may not be possible to access RAM. If this is a ROMRAM startup then the program code can now be copied to its RAM address and control transferred to it.
  - Set up any bus bridges and support chips. Often access to device registers needs to go through various bus bridges and other intermediary devices. In many systems these are combined with the memory controller, so it makes sense to set these up together. This is particularly important if early diagnostic output needs to go through one of these devices.
  - Set up diagnostic mechanisms. If the platform includes an LED or LCD output device, it often makes sense to output progress indications on this during startup. This helps with diagnosing hardware and software errors.
  - Initialize floating point and other extensions such as SIMD and multimedia engines. It is usually necessary to enable these and maybe initialize control and exception registers for these extensions.

  - Initialize interrupt controller. At the very least, it should be configured to mask all interrupts. It may also be necessary to set up the mapping from the interrupt controller's vector number space to the CPU's exception number space. Similar mappings may need to be set up between primary and secondary interrupt controllers.
  - Disable and initialize the caches. The caches should not normally be enabled at this point, but it may be necessary to clear or initialize them so that they can be enabled later. Some architectures require that the caches be explicitly reinitialized after a power-on reset.
  - Initialize the timer, clock etc. While the timer used for RTC interrupts will be initialized later, it may be necessary to set up the clocks that drive it here.

  The exact order in which these initializations is done is architecture or variant specific. It is also often not necessary to do anything at all for some of these options. These fragments of code should concentrate on getting the target up and running so that C function calls can be made and code can be run. More complex initializations that cannot be done in assembly code may be postponed until calls to `hal_variant_init()` or `hal_platform_init()` are made.

  Not all of these initializations need to be done for all startup types. In particular, RAM startups can reasonably assume that the ROM monitor or loader has already done most of this work.

- Set up the stack pointer, this allows subsequent initialization code to make proper procedure calls. Usually the interrupt stack is used for this purpose since it is available, large enough, and will be reused for other purposes later.
- Initialize any global pointer register needed for access to globally defined variables. This allows subsequent initialization code to access global variables.
- If the system is starting from ROM, copy the ROM template of the `.data` section out to its correct position in RAM. (the section called “Linker Scripts”).
- Zero the `.bss` section.
- Create a suitable C call stack frame. This may involve making stack space for call frames, and arguments, and initializing the back pointers to halt a GDB backtrace operation.
- Call `hal_variant_init()` and `hal_platform_init()`. These will perform any additional initialization needed by the variant and platform. This typically includes further initialization of the interrupt controller, PCI bus bridges, basic IO devices and enabling the caches.
- Call `cyg_hal_invoke_constructors()` to run any static constructors.
- Call `cyg_start()`. If `cyg_start()` returns, drop into an infinite loop.

Vectors and VSRs

The CPU delivers all exceptions, whether synchronous faults or asynchronous interrupts, to a set of hardware defined vectors. Depending on the architecture, these may be implemented in a number of different ways. Examples of existing mechanisms are:

PowerPC

Exceptions are vectored to locations 256 bytes apart starting at either zero or `0xFFF00000`. There are 16 such vectors defined by the basic architecture and extra vectors may be defined by specific variants. One of the base vectors is for all external interrupts, and another is for the architecture defined timer.

MIPS

Most exceptions and all interrupts are vectored to a single address at either `0x80000000` or `0xBFC00180`. Software is responsible for reading the exception code from the CPU `cause` register to discover its true source. Some TLB and debug exceptions are delivered to different vector addresses, but these are not used currently by eCos. One of the exception codes in the `cause` register indicates an external interrupt. Additional bits in the `cause` register provide a first-level decode for the interrupt source, one of which represents an architecture defined timer.

IA32 Exceptions are delivered via an Interrupt Descriptor Table (IDT) which is essentially an indirection table indexed by exception number. The IDT may be placed anywhere in memory. In PC hardware the standard interrupt controller can be programmed to deliver the external interrupts to a block of 16 vectors at any offset in the IDT. There is no hardware supplied mechanism for determining the vector taken, other than from the address jumped to.

ARM All exceptions, including the FIQ and IRQ interrupts, are vectored to locations four bytes apart starting at zero. There is only room for one instruction here, which must immediately jump out to handling code higher in memory. Interrupt sources have to be decoded entirely from the interrupt controller.

With such a wide variety of hardware approaches, it is not possible to provide a generic mechanism for the substitution of exception vectors directly. Therefore, eCos translates all of these mechanisms in to a common approach that can be used by portable code on all platforms.

The mechanism implemented is to attach to each hardware vector a short piece of trampoline code that makes an indirect jump via a table to the actual handler for the exception. This handler is called the Vector Service Routine (VSR) and the table is called the VSR table.

The trampoline code performs the absolute minimum processing necessary to identify the exception source, and jump to the VSR. The VSR is then responsible for saving the CPU state and taking the necessary actions to handle the exception or interrupt. The entry conditions for the VSR are as close to the raw hardware exception entry state as possible - although on some platforms the trampoline will have had to move or reorganize some registers to do its job.

To make this more concrete, consider how the trampoline code operates in each of the architectures described above:

PowerPC A separate trampoline is contained in each of the vector locations. This code saves a few work registers away to the special purposes registers available, loads the exception number into a register and then uses that to index the VSR table and jump to the VSR. The VSR is entered with some registers move to the SPRs, and one of the data register containing the number of the vector taken.

MIPS A single trampoline routine attached to the common vector reads the exception code out of the `cause` register and uses that value to index the VSR table and jump to the VSR. The trampoline uses the two registers defined in the ABI for kernel use to do this, one of these will contain the exception vector number for the VSR.

IA32 There is a separate 3 or 4 instruction trampoline pointed to by each active IDT table entry. The trampoline for exceptions that also have an error code pop it from the stack and put it into a memory location. Trampolines for non-error-code exceptions just zero the memory location. Then all trampolines push an interrupt/exception number onto the stack, and take an indirect jump through a precalculated offset in the VSR table. This is all done without saving any registers, using memory-only operations. The VSR is entered with the vector number pushed onto the stack on top of the standard hardware saved state.

ARM The trampoline consists solely of the single instruction at the exception entry point. This is an indirect jump via a location 32 bytes higher in memory. These locations, from `0x20` up, form the VSR table. Since each VSR is entered in a different CPU mode (`SVC,UNDEF,ABORT,IRQ or FIQ`) there has to be a different VSR for each exception that knows how to save the CPU state correctly.

Default Synchronous Exception Handling

Most synchronous exception VSR table entries will point to a default exception VSR which is responsible for handling all exceptions in a generic manner. The default VSR simply saves the CPU state, makes any adjustments to the CPU state that is necessary, and calls `cyg_hal_exception_handler()`.

`cyg_hal_exception_handler()` needs to pass the exception on to some handling code. There are two basic destinations: enter GDB or pass the exception up to eCos. Exactly which destination is taken depends on the configuration. When the GDB stubs are included then the exception is passed to them, otherwise it is passed to eCos.

If an eCos application has been loaded by RedBoot then the VSR table entries will all point into RedBoot's exception VSR, and will therefore enter GDB if an exception occurs. If the eCos application wants to handle an exception itself, it needs to replace the the VSR table entry with one pointing to its own VSR. It can do this with the `HAL_VSR_SET_TO_ECOS_HANDLER()` macro.

Default Interrupt Handling

Most asynchronous external interrupt vectors will point to a default interrupt VSR which decodes the actual interrupt being delivered from the interrupt controller and invokes the appropriate ISR.

The default interrupt VSR has a number of responsibilities if it is going to interact with the Kernel cleanly and allow interrupts to cause thread preemption.

To support this VSR an ISR vector table is needed. For each valid vector three pointers need to be stored: the ISR, its data pointer and an opaque (to the HAL) interrupt object pointer needed by the kernel. It is implementation defined whether these are stored in a single table of triples, or in three separate tables.

The VSR follows the following approximate plan:

1. Save the CPU state. In non-debug configurations, it may be possible to get away with saving less than the entire machine state. The option `CYGDBG_HAL_COMMON_INTERRUPTS_SAVE_MINIMUM_CONTEXT` is supported in some targets to do this.

2. Increment the kernel scheduler lock. This is a static member of the Cyg_Scheduler class, however it has also been aliased to `cyg_scheduler_sched_lock` so that it can be accessed from assembly code.

3. (Optional) Switch to an interrupt stack if not already running on it. This allows nested interrupts to be delivered without needing every thread to have a stack large enough to take the maximum possible nesting. It is implementation defined how to detect whether this is a nested interrupt but there are two basic techniques. The first is to inspect the stack pointer and switch only if it is not currently within the interrupt stack range; the second is to maintain a counter of the interrupt nesting level and switch only if it is zero. The option `CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK` controls whether this happens.

4. Decode the actual external interrupt being delivered from the interrupt controller. This will yield the ISR vector number. The code to do this usually needs to come from the variant or platform HAL, so is usually present in the form of a macro or procedure callout.

5. (Optional) Re-enable interrupts to permit nesting. At this point we can potentially allow higher priority interrupts to occur. It depends on the interrupt architecture of the CPU and platform whether more interrupts will occur at this point, or whether they will only be delivered after the current interrupt has been acknowledged (by a call to `HAL_INTERRUPT_ACKNOWLEDGE()` in the ISR).

6. Using the ISR vector number as an index, retrieve the ISR pointer and its data pointer from the ISR vector table.

7. Construct a C call stack frame. This may involve making stack space for call frames, and arguments, and initializing the back pointers to halt a GDB backtrace operation.

8. Call the ISR, passing the vector number and data pointer. The vector number and a pointer to the saved state should be preserved across this call, preferably by storing them in registers that are defined to be callee-saved by the calling conventions.

9. If this is an un-nested interrupt and a separate interrupt stack is being used, switch back to the interrupted thread's own stack.

10. Use the saved ISR vector number to get the interrupt object pointer from the ISR vector table.

11. Call `interrupt_end()` passing it the return value from the ISR, the interrupt object pointer and a pointer to the saved CPU state. This function is implemented by the Kernel and is responsible for finishing off the interrupt handling. Specifically, it may post a DSR depending on the ISR return value, and will decrement the scheduler lock. If the lock is zeroed by this operation then any posted DSRs may be called and may in turn result in a thread context switch.

12. The return from `interrupt_end()` may occur some time after the call. Many other threads may have executed in the meantime. So here all we may do is restore the machine state and resume execution of the interrupted thread. Depending on the architecture, it may be necessary to disable interrupts again for part of this.

The detailed order of these steps may vary slightly depending on the architecture, in particular where interrupts are enabled and disabled.

Chapter 6. HAL GDB File I/O Routines

Name

`hal_gdb_fileio` — access host file system

Synopsis

#include <cyg/hal/hal_gdb_fileio.h>

int **hal_gdb_fileio_open** (*path*, *flags*, *mode*);

int **hal_gdb_fileio_close** (*fd*);

int **hal_gdb_fileio_read** (*fd*, *buffer*, *count*);

int **hal_gdb_fileio_write** (*fd*, *buffer*, *count*);

cyg_int32 **hal_gdb_fileio_lseek** (*fd*, *offset*, *whence*);

int **hal_gdb_fileio_rename** (*oldpath*, *newpath*);

int **hal_gdb_fileio_unlink** (*path*);

int **hal_gdb_fileio_stat** (*path*, *stat*);

int **hal_gdb_fileio_fstat** (*fd*, *stat*);

int **hal_gdb_fileio_gettimeofday** (*tv*, *tz*);

int **hal_gdb_fileio_isatty** (*fd*);

int **hal_gdb_fileio_system** (*command*);

Description

In some configurations an eCos application can perform a number of file I/O and other operations on the host by interacting with gdb. For example the application can open a log file to the host and write very large amounts of debug data to that file over a period of time while consuming minimal target-side resources. However, the application will be completely blocked for the duration of the I/O operation with interrupts globally disabled. The functionality uses the gdb File I/O Remote Protocol Extension, described in the Remote Protocol appendix of the gdb documentation.

The gdb file I/O support is only available when the configuration option `CYGFUN_HAL_GDB_FILEIO` is enabled. In turn that option will have dependencies on other parts of the HAL, and the required functionality will not be available for all targets.

When debugging involves a hardware debug solution such as jtag or BDM, typically gdb will interact with a remote protocol server running inside or controlling the hardware debug unit. That server will implement the core parts of the remote protocol such as accessing memory, but typically there will be no way for the eCos application to get the server to send specific requests such as for file I/O. Instead a different approach is used. From inside the gdb session the command **set hwdebug on** should be used after attaching to the target. The next time the eCos application attempts a file I/O operation it will cause execution to halt at `_gdb_hwdebug_breakpoint`. Code inside gdb recognises that address, retrieves details of the I/O request from the target's memory, and then acts as if the request had come in a remote protocol message. The target resumes execution automatically once the I/O operation has been performed. If the `hwdebug` flag has not been set or if the application is running outside a gdb debug session, the behaviour of eCos is dependant on the `CYGFUN_HAL_DIAG_VIA_GDB_FILEIO` and `CYGSEM_HAL_DIAG_VIA_GDB_FILEIO_IMMEDIATE` configuration options. If both options are set, the target will halt at `_gdb_hwdebug_breakpoint` until a gdb session is established and the command **set hwdebug on** issued. Otherwise the file I/O operations will fail with error code `HAL_GDB_FILEIO_ENOSYS`.

This behaviour is useful during initial debugging using Eclipse as it allows diagnostic messages that would otherwise be discarded to be captured by a gdb session. A typical example is where an application is located in flash and diagnostic messages are issued by eCos before the application's main entry point is reached. During this initial stage of target bring-up eCos's internal data structures may not be adequately initialized so as to allow eCos to determine whether file I/O operations should either: (1) fail with diagnostic messages to `gdb_hwdebug_fileio` discarded (See HAL GDB File I/O Diagnostics Support); or (2) be passed to an underlying gdb session. See Use with the Eclipse CDT extensions for eCosPro application development for additional information regarding the use of Eclipse for debugging.

The Functions

Full details of the functions, parameters, data structures and error codes can be found in the header file `cyg/hal/hal_gdb_fileio.h`. The I/O calls are loosely modelled after the equivalent POSIX calls. They return 0 or a positive number for success, a negative number to indicate an error. The specific error code is the absolute value of the return value, so for example `hal_gdb_fileio_open` will return `-HAL_GDB_FILEIO_ENOENT` when attempting to open a file that does not exist. Some example code can be found in the testcase `gdb_fileio.c`.

`hal_gdb_fileio_open` is used to open a file on the host file system. It should only be used on files, not on special devices such as serial port or Unix-domain sockets: the gdb file I/O functionality is limited and has no support for `select`, non-blocking I/O, `ioctl`-style control, and so on. Hence if the eCos application does attempt to open and read from a serial port that will cause gdb to block and both the application and the debug session will freeze. Valid flags include `HAL_GDB_FILEIO_O_RDONLY`, `HAL_GDB_FILEIO_O_WRONLY`, and `HAL_GDB_FILEIO_O_CREAT`. The *`mode`* argument is used only when creating a new file and is used to set the access rights, for example `HAL_GDB_FILEIO_S_IURSR+HAL_GDB_FILEIO_S_IWUSR`.

The return value of `hal_gdb_fileio_open` is an integer file descriptor. Note that this is distinct from the file descriptor returned by the eCos `open` call. The two types of file descriptor are not interchangeable. For example `hal_gdb_fileio_read` should only be used with a file descriptor returned from `hal_gdb_fileio_open`, not with the return value of `open`.

`hal_gdb_fileio_read`, `hal_gdb_fileio_write`, `hal_gdb_fileio_lseek`, `hal_gdb_fileio_fstat` and `hal_gdb_fileio_isatty` perform operations on a file opened with `hal_gdb_fileio_open`. `hal_gdb_fileio_write` can also be used with the predefined file descriptor `HAL_GDB_FILEIO_STDOUT`, corresponding to gdb's standard output. For `hal_gdb_fileio_lseek` valid *`whence`* parameters are `HAL_GDB_FILEIO_SEEK_SET`, `HAL_GDB_FILEIO_SEEK_CUR` and `HAL_GDB_FILEIO_SEEK_END`. Due to limitations within the protocol and the implementation `hal_gdb_fileio_lseek` cannot fully support files of 2GB or larger. In other words offsets are limited to 31 bits.

The `hal_gdb_fileio_stat` and `hal_gdb_fileio_fstat` functions should be called with a struct hal_gdb-fileio_stat buffer:

```
struct hal_gdb_fileio_stat
{
    cyg_uint32 st_dev;
    cyg_uint32 st_ino;
    cyg_uint32 st_mode;
    cyg_uint32 st_nlink;
    cyg_uint32 st_uid;
    cyg_uint32 st_gid;
    cyg_uint32 st_rdev;
    cyg_uint64 st_size;
    cyg_uint64 st_blksize;
    cyg_uint64 st_blocks;
    cyg_uint32 st_atime;
    cyg_uint32 st_mtime;
    cyg_uint32 st_ctime;
};
```

Warning

The time values obtained are not year 2038 safe, as only space for a 32-bit `time_t` has been allocated. It is hoped that newlib and GDB will update the protocol in order to support 64-bit `time_t`, at which point eCos will be able to conform to whatever mechanism they use to supply the updated time, but this has not yet happened. It is therefore recommended that the time values are not used if this function is intended to be used after year 2038.

The first argument to `hal_gdb_fileio_gettimeofday` should be hal_gdb_fileio_timeval structure:

```
struct hal_gdb_fileio_timeval
{
    cyg_uint32 tv_sec;
    cyg_uint32 tv_usec;
};
```

The second argument to `hal_gdb_fileio_gettimeofday` is not currently used and application code should use a NULL pointer for this.

Warning

Again, the time values obtained are not year 2038 safe, as only space for a 32-bit `time_t` has been allocated. eCos will be updated when the GDB maintainers update the protocol to exchange a 64-bit time value. It is therefore strongly recommended that this function is not used if it may still be in use after year 2038.

`hal_gdb_fileio_system` can be used to invoke an arbitrary command on the host. For obvious security reasons this functionality is disabled within gdb by default. It must be explicitly enabled within gdb using a **set remote system-call-allowed** command.

Diagnostics Support

When the eCos application is built stand-alone and will be debugged via a hardware debug solution such as jtag or BDM, some platforms will allow HAL diagnostics to be sent a destination `gdb_hwdebug_fileio`. This output will end up being written to the gdb console via `hal_gdb_fileio_write` if the application is running inside a gdb session and the **set hwdebug on** command has been used after connecting to the target. Otherwise, if both `CYGFUN_HAL_DIAG_VIA_GDB_FILEIO` and `CYGSEM_HAL_DIAG_VIA_GDB_FILEIO_IMMEDIATE` configuration options are set, the eCos application will halt at a simulated breakpoint at `_gdb_hwdebug_breakpoint` until a gdb session is established. If `CYGSEM_HAL_DIAG_VIA_GDB_FILEIO_IMMEDIATE` is not set, the eCos application will not halt and HAL diagnostics will be discarded. Upon establishing a gdb session, the GDB console command **set hwdebug on** command must be used. On resuming the target and eCos application with the GDB command **continue**, the original HAL diagnostics message will appear within the gdb console and execution of the eCos application continue. Subsequent HAL diagnostics messages will appear without further interaction as GDB automatically resumes the application once `hwdebug` has been set. (See HAL GDB File I/O Description)

If the eCos application is resumed by a gdb session without the **set hwdebug on** command being issued, this output will be discarded and execution resumed until the next time the application performs a GDB file I/O operation and halts at the simulated breakpoint at `_gdb_hwdebug_breakpoint`. This behaviour will continue until **set hwdebug on** is issued as automatic resumption of execution is only performed by GDB once it has been issued. If subsequent HAL diagnostics are to be discarded, the **set hwdebug off** can be issued although this will also disable any further GDB file I/O operations as well.

Use with the Eclipse CDT extensions for eCosPro application development

The eCosCentric CDT extensions for eCosPro application development for the Eclipse Kepler release and above always effectively test if an eCos application is configured with option `CYGFUN_HAL_GDB_FILEIO` enabled and automatically issues the command **set hwdebug on** when enabled. This ensures that all HAL diagnostics messages will be visible within the GDB console window prior to and after the initial application entry point is reached (normally either `main` or `cyg_user_start`). The eCos application developer therefore does not need to be concerned with issuing these GDB commands when using eCosCentric's Eclipse CDT extensions for the Kepler release and above. They only need to configure eCos appropriately when they wish to make use of GDB file I/O operations or capture HAL diagnostics messages when debugging through either jtag or BDM when no alternative stream is available for HAL diagnostics messages (e.g. serial). (See HAL GDB File I/O Diagnostics Support and HAL GDB File I/O Description)

Chapter 7. Porting Guide

Introduction

eCos has been designed to be fairly easy to port to new targets. A target is a specific platform (board) using a given architecture (CPU type). The porting is facilitated by the hierarchical layering of the eCos sources - all architecture and platform specific code is implemented in a HAL (hardware abstraction layer).

By porting the eCos HAL to a new target the core functionality of eCos (infra, kernel, uITRON, etc) will be able to run on the target. It may be necessary to add further platform specific code such as serial drivers, display drivers, ethernet drivers, etc. to get a fully capable system.

This document is intended as a help to the HAL porting process. Due to the nature of a porting job, it is impossible to give a complete description of what has to be done for each and every potential target. This should not be considered a clear-cut recipe - you will probably need to make some implementation decisions, tweak a few things, and just plain have to rely on common sense.

However, what is covered here should be a large part of the process. If you get stuck, you are advised to read the ecos-discuss archive where you may find discussions which apply to the problem at hand. You are also invited to ask questions on the ecos-discuss mailing list to help you resolve problems - but as is always the case with community lists, do not consider it an oracle for any and all questions. Use common sense - if you ask too many questions which could have been answered by reading the documentation, FAQ or source code, you are likely to be ignored.

This document will be continually improved by Red Hat engineers as time allows. Feedback and help with improving the document is sought, so if you have any comments at all, please do not hesitate to post them on ecos-discuss (please prefix the subject with [porting]).

At the moment this document is mostly an outline. There are many details to fill in before it becomes complete. Many places you'll just find a list of keywords / concepts that should be described (please post on ecos-discuss if there are areas you think are not covered).

All pages or sections where the caption ends in [TBD] contain little more than key words and/or random thoughts - there has been no work done as such on the content. The word FIXME may appear in the text to highlight places where information is missing.

HAL Structure

In order to write an eCos HAL it's a good idea to have at least a passing understanding of how the HAL interacts with the rest of the system.

HAL Classes

The eCos HAL consists of four HAL sub-classes. This table gives a brief description of each class and partly reiterates the description in Chapter 2, *Architecture, Variant and Platform*. The links refer to the on-line CVS tree (specifically to the sub-HALs used by the PowerPC MBX target).

HAL type	**Description**	**Functionality Overview**
Common HAL (hal/common)	Configuration options and functionality shared by all HALs.	Generic debugging functionality, driver API, eCos/ROM monitor calling interface, and tests.
Architecture HAL (hal/<architecture>/arch)	Functionality specific to the given architecture. Also default implementations of some functionality which can be overridden by variant or platform HALs.	Architecture specific debugger functionality (handles single stepping, exception-to-signal conversion, etc.), exception/interrupt vector definitions and

HAL type	Description	Functionality Overview
		handlers, cache definition and control macros, context switching code, assembler functions for early system initialization, configuration options, and possibly tests.
Variant HAL (hal/<architecture>/<variant>)	Some CPU architectures consist of a number variants, for example MIPS CPUs come in both 32 and 64 bit versions, and some variants have embedded features additional to the CPU core.	Variant extensions to the architecture code (cache, exception/interrupt), configuration options, possibly drivers for variant on-core devices, and possibly tests.
Platform HAL (hal/<architecture>/<platform>)	Contains functionality and configuration options specific to the platform.	Early platform initialization code, platform memory layout specification, configuration options (processor speed, compiler options), diagnostic IO functions, debugger IO functions, platform specific extensions to architecture or variant code (off-core interrupt controller), and possibly tests.
Auxiliary HAL (hal/<architecture>/<module>)	Some variants share common modules on the core. Motorola's PowerPC QUICC is an example of such a module.	Module specific functionality (interrupt controller, simple device drivers), possibly tests.

File Descriptions

Listed below are the files found in various HALs, with a short description of what each file contains. When looking in existing HALs beware that they do not necessarily follow this naming scheme. If you are writing a new HAL, please try to follow it as closely as possible. Still, no two targets are the same, so sometimes it makes sense to use additional files.

Common HAL

File	Description
`include/dbg-thread-syscall.h`	Defines the thread debugging syscall function. This is used by the ROM monitor to access the thread debugging API in the RAM application. .
`include/dbg-threads-api.h`	Defines the thread debugging API. .
`include/drv_api.h`	Defines the driver API.
`include/generic-stub.h`	Defines the generic stub features.
`include/hal_if.h`	Defines the ROM/RAM calling interface API.
`include/hal_misc.h`	Defines miscellaneous helper functions shared by all HALs.
`include/hal_stub.h`	Defines eCos mappings of GDB stub features.
`src/dbg-threads-syscall.c`	Thread debugging implementation.
`src/drv_api.c`	Driver API implementation. Depending on configuration this provides either wrappers for the kernel API, or a minimal implementation of these features. This allows drivers to be written relying only on HAL features.
`src/dummy.c`	Empty dummy file ensuring creation of libtarget.a.
`src/generic-stub.c`	Generic GDB stub implementation. This provides the communication protocol used to communicate with GDB over a serial device or via the network.

File	Description
`src/hal_if.c`	ROM/RAM calling interface implementation. Provides wrappers from the calling interface API to the eCos features used for the implementation.
`src/hal_misc.c`	Various helper functions shared by all platforms and architectures.
`src/hal_stub.c`	Wrappers from eCos HAL features to the features required by the generic GDB stub.
`src/stubrom/stubrom.c`	The file used to build eCos GDB stub images. Basically a cyg_start function with a hard coded breakpoint.
`src/thread-packets.c`	More thread debugging related functions.
`src/thread-pkts.h`	Defines more thread debugging related function.

Architecture HAL

Some architecture HALs may add extra files for architecture specific serial drivers, or for handling interrupts and exceptions if it makes sense.

Note that many of the definitions in these files are only conditionally defined - if the equivalent variant or platform headers provide the definitions, those override the generic architecture definitions.

File	Description
`include/arch.inc`	Various assembly macros used during system initialization.
`include/basetype.h`	Endian, label, alignment, and type size definitions. These override common defaults in CYGPKG_INFRA.
`include/hal_arch.h`	Saved register frame format, various thread, register and stack related macros.
`include/hal_cache.h`	Cache definitions and cache control macros.
`include/hal_intr.h`	Exception and interrupt definitions. Macros for configuring and controlling interrupts. eCos real-time clock control macros.
`include/hal_io.h`	Macros for accessing IO devices.
`include/<arch>_regs.h`	Architecture register definitions.
`include/<arch>_stub.h`	Architecture stub definitions. In particular the register frame layout used by GDB. This may differ from the one used by eCos.
`include/<arch>.inc`	Architecture convenience assembly macros.
`src/<arch>.ld`	Linker macros.
`src/context.S`	Functions handling context switching and setjmp/longjmp.
`src/hal_misc.c`	Exception and interrupt handlers in C. Various other utility functions.
`src/hal_mk_defs.c`	Used to export definitions from C header files to assembler header files.
`src/hal_intr.c`	Any necessary interrupt handling functions.
`src/<arch>stub.c`	Architecture stub code. Contains functions for translating eCos exceptions to UNIX signals and functions for single-stepping.
`src/vectors.S`	Exception, interrupt and early initialization code.

Variant HAL

Some variant HALs may add extra files for variant specific serial drivers, or for handling interrupts/exceptions if it makes sense.

Note that these files may be mostly empty if the CPU variant can be controlled by the generic architecture macros. The definitions present are only conditionally defined - if the equivalent platform headers provide the definitions, those override the variant definitions.

File	Description
`include/var_arch.h`	Saved register frame format, various thread, register and stack related macros.
`include/var_cache.h`	Cache related macros.
`include/var_intr.h`	Interrupt related macros.
`include/var_regs.h`	Extra register definitions for the CPU variant.
`include/variant.inc`	Various assembly macros used during system initialization.
`src/var_intr.c`	Interrupt functions if necessary.
`src/var_misc.c`	hal_variant_init function and any necessary extra functions.
`src/variant.S`	Interrupt handler table definition.
`src/<arch>_<variant>.ld`	Linker macros.

Platform HAL

Extras files may be added for platform specific serial drivers. Extra files for handling interrupts and exceptions will be present if it makes sense.

File	Description
`include/hal_diag.h`	Defines functions used for HAL diagnostics output. This would normally be the ROM calling interface wrappers, but may also be the low-level IO functions themselves, saving a little overhead.
`include/platform.inc`	Platform initialization code. This includes memory controller, vectors, and monitor initialization. Depending on the architecture, other things may need defining here as well: interrupt decoding, status register initialization value, etc.
`include/plf_cache.h`	Platform specific cache handling.
`include/plf_intr.h`	Platform specific interrupt handling.
`include/plf_io.h`	PCI IO definitions and macros. May also be used to override generic HAL IO macros if the platform endianness differs from that of the CPU.
`include/plf_stub.h`	Defines stub initializer and board reset details.
`src/hal_diag.c`	May contain the low-level device drivers. But these may also reside in plf_stub.c
`src/platform.S`	Memory controller setup macro, and if necessary interrupt springboard code.
`src/plf_misc.c`	Platform initialization code.
`src/plf_mk_defs.c`	Used to export definitions from C header files to assembler header files.
`src/plf_stub.c`	Platform specific stub initialization and possibly the low-level device driver.

The platform HAL also contains files specifying the platform's memory layout. These files are located in `include/pkgconf`.

Auxiliary HAL

Auxiliary HALs contain whatever files are necessary to provide the required functionality. There are no predefined set of files required in an auxiliary HAL.

Virtual Vectors (eCos/ROM Monitor Calling Interface)

Virtually all eCos platforms provide full debugging capabilities via RedBoot. This environment contains not only debug stubs based on GDB, but also rich I/O support which can be exported to loaded programs. Such programs can take advantage of the I/O capabilities using a special ROM/RAM calling interface (also referred to as virtual vector table). eCos programs make use of the virtual vector mechanism implicitly. Non-eCos programs can access these functions using the support from the *newlib* library.

Virtual Vectors

What are virtual vectors, what do they do, and why are they needed?

"Virtual vectors" is the name of a table located at a static location in the target address space. This table contains 64 vectors that point to *service* functions or data.

The fact that the vectors are always placed at the same location in the address space means that both ROM and RAM startup configurations can access these and thus the services pointed to.

The primary goal is to allow services to be provided by ROM configurations (ROM monitors such as RedBoot in particular) with *clients* in RAM configurations being able to use these services.

Without the table of pointers this would be impossible since the ROM and RAM applications would be linked separately - in effect having separate name spaces - preventing direct references from one to the other.

This decoupling of service from client is needed by RedBoot, allowing among other things debugging of applications which do not contain debugging client code (stubs).

Initialization (or Mechanism vs. Policy)

Virtual vectors are a *mechanism* for decoupling services from clients in the address space.

The mechanism allows services to be implemented by a ROM monitor, a RAM application, to be switched out at run-time, to be disabled by installing pointers to dummy functions, etc.

The appropriate use of the mechanism is specified loosely by a *policy*. The general policy dictates that the vectors are initialized in whole by ROM monitors (built for ROM or RAM), or by stand-alone applications.

For configurations relying on a ROM monitor environment, the policy is to allow initialization on a service by service basis. The default is to initialize all services, except COMMS services since these are presumed to already be carrying a communication session to the debugger / console which was used for launching the application. This means that the bulk of the code gets tested in normal builds, and not just once in a blue moon when building new stubs or a ROM configuration.

The configuration options are written to comply with this policy by default, but can be overridden by the user if desired. Defaults are:

- For application development: the ROM monitor provides debugging and diagnostic IO services, the RAM application relies on these by default.
- For production systems: the application contains all the necessary services.

Pros and Cons of Virtual Vectors

There are pros and cons associated with the use of virtual vectors. We do believe that the pros generally outweigh the cons by a great margin, but there may be situations where the opposite is true.

The use of the services are implemented by way of macros, meaning that it is possible to circumvent the virtual vectors if desired. There is (as yet) no implementation for doing this, but it is possible.

Here is a list of pros and cons:

Pro: Allows debugging without including stubs

> This is the primary reason for using virtual vectors. It allows the ROM monitor to provide most of the debugging infrastructure, requiring only the application to provide hooks for asynchronous debugger interrupts and for accessing kernel thread information.

Pro: Allows debugging to be initiated from arbitrary channel

> While this is only true where the application does not actively override the debugging channel setup, it is a very nice feature during development. In particular it makes it possible to launch (and/or debug) applications via Ethernet even though the application configuration does not contain networking support.

Pro: Image smaller due to services being provided by ROM monitor

> All service functions except HAL IO are included in the default configuration. But if these are all disabled the image for download will be a little smaller. Probably doesn't matter much for regular development, but it is a worthwhile saving for the 20000 daily tests run in the Red Hat eCos test farm.

Con: The vectors add a layer of indirection, increasing application size and reducing performance.

> The size increase is a fraction of what is required to implement the services. So for RAM configurations there is a net saving, while for ROM configurations there is a small overhead.
>
> The performance loss means little for most of the services (of which the most commonly used is diagnostic IO which happens via polled routines anyway).

Con: The layer of indirection is another point of failure.

> The concern primarily being that of vectors being trashed by rogue writes from bad code, causing a complete loss of the service and possibly a crash. But this does not differ much from a rogue write to anywhere else in the address space which could cause the same amount of mayhem. But it is arguably an additional point of failure for the service in question.

Con: All the indirection stuff makes it harder to bring a HAL up

> This is a valid concern. However, seeing as most of the code in question is shared between all HALs and should remain unchanged over time, the risk of it being broken when a new HAL is being worked on should be minimal.
>
> When starting a new port, be sure to implement the HAL IO drivers according to the scheme used in other drivers, and there should be no problem.
>
> However, it is still possible to circumvent the vectors if they are suspect of causing problems: simply change the HAL_DIAG_INIT and HAL_DIAG_WRITE_CHAR macros to use the raw IO functions.

Available services

The `hal_if.h` file in the common HAL defines the complete list of available services. A few worth mentioning in particular:

- COMMS services. All HAL IO happens via the communication channels.

- uS delay. Fine granularity (busy wait) delay function.
- Reset. Allows a software initiated reset of the board.

The COMMS channels

As all HAL IO happens via the COMMS channels these deserve to be described in a little more detail. In particular the controls of where diagnostic output is routed and how it is treated to allow for display in debuggers.

Console and Debugging Channels

There are two COMMS channels - one for console IO and one for debugging IO. They can be individually configured to use any of the actual IO ports (serial or Ethernet) available on the platform.

The console channel is used for any IO initiated by calling the `diag_*()` functions. Note that these should only be used during development for debugging, assertion and possibly tracing messages. All proper IO should happen via proper devices. This means it should be possible to remove the HAL device drivers from production configurations where assertions are disabled.

The debugging channel is used for communication between the debugger and the stub which remotely controls the target for the debugger (the stub runs on the target). This usually happens via some protocol, encoding commands and replies in some suitable form.

Having two separate channels allows, e.g., for simple logging without conflicts with the debugger or interactive IO which some debuggers do not allow.

Mangling

As debuggers usually have a protocol using specialized commands when communicating with the stub on the target, sending out text as raw ASCII from the target on the same channel will either result in protocol errors (with loss of control over the target) or the text may just be ignored as junk by the debugger.

To get around this, some debuggers have a special command for text output. Mangling is the process of encoding diagnostic ASCII text output in the form specified by the debugger protocol.

When it is necessary to use mangling, i.e. when writing console output to the same port used for debugging, a mangler function is installed on the console channel which mangles the text and passes it on to the debugger channel.

Controlling the Console Channel

Console output configuration is either inherited from the ROM monitor launching the application, or it is specified by the application. This is controlled by the new option `CYGSEM_HAL_VIRTUAL_VECTOR_INHERIT_CONSOLE` which defaults to enabled when the configuration is set to use a ROM monitor.

If the user wants to specify the console configuration in the application image, there are two new options that are used for this.

Defaults are to direct diagnostic output via a mangler to the debugging channel (`CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` enabled). The mangler type is controlled by the option `CYGSEM_HAL_DIAG_MANGLER`. At present there are only two mangler types:

GDB
: This causes a mangler appropriate for debugging with GDB to be installed on the console channel.

None
: This causes a NULL mangler to be installed on the console channel. It will redirect the IO to/from the debug channel without mangling of the data. This option differs from setting the console channel to the same IO port as the debugging channel in that it will keep redirecting data to the debugging channel even if that is changed to some other port.

Finally, by disabling `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN`, the diagnostic output is directed in raw form to the specified console IO port.

In summary this results in the following common configuration scenarios for RAM startup configurations:

- For regular debugging with diagnostic output appearing in the debugger, mangling is enabled and stubs disabled.

  Diagnostic output appears via the debugging channel as initiated by the ROM monitor, allowing for correct behavior whether the application was launched via serial or Ethernet, from the RedBoot command line or from a debugger.

- For debugging with raw diagnostic output, mangling is disabled.

  Debugging session continues as initiated by the ROM monitor, whether the application was launched via serial or Ethernet. Diagnostic output is directed at the IO port configured in the application configuration.

Note:

There is one caveat to be aware of. If the application uses proper devices (be it serial or Ethernet) on the same ports as those used by the ROM monitor, the connections initiated by the ROM monitor will be terminated.

And for ROM startup configurations:

- Production configuration with raw output and no debugging features (configured for RAM or ROM), mangling is disabled, no stubs are included.

  Diagnostic output appears (in unmangled form) on the specified IO port.

- RedBoot configuration, includes debugging features and necessary mangling.

  Diagnostic and debugging output port is auto-selected by the first connection to any of the supported IO ports. Can change from interactive mode to debugging mode when a debugger is detected - when this happens a mangler will be installed as required.

- GDB stubs configuration (obsoleted by RedBoot configuration), includes debugging features, mangling is hardwired to GDB protocol.

  Diagnostic and debugging output is hardwired to configured IO ports, mangling is hardwired.

Footnote: Design Reasoning for Control of Console Channel

The current code for controlling the console channel is a replacement for an older implementation which had some shortcomings which addressed by the new implementation.

This is what the old implementation did: on initialization it would check if the CDL configured console channel differed from the active debug channel - and if so, set the console channel, thereby disabling mangling.

The idea was that whatever channel was configured to be used for console (i.e., diagnostic output) in the application was what should be used. Also, it meant that if debug and console channels were normally the same, a changed console channel would imply a request for unmangled output.

But this prevented at least two things:

- It was impossible to inherit the existing connection by which the application was launched (either by RedBoot commands via telnet, or by via a debugger).

  This was mostly a problem on targets supporting Ethernet access since the diagnostic output would not be returned via the Ethernet connection, but on the configured serial port.

The problem also occurred on any targets with multiple serial ports where the ROM monitor was configured to use a different port than the CDL defaults.

- Proper control of when to mangle or just write out raw ASCII text.

  Sometimes it's desirable to disable mangling, even if the channel specified is the same as that used for debugging. This usually happens if GDB is used to download the application, but direct interaction with the application on the same channel is desired (GDB protocol only allows output from the target, no input).

The calling Interface API

The calling interface API is defined by hal_if.h and hal_if.c in hal/common.

The API provides a set of services. Different platforms, or different versions of the ROM monitor for a single platform, may implement fewer or extra service. The table has room for growth, and any entries which are not supported map to a NOP-service (when called it returns 0 (`false`)).

A client of a service should either be selected by configuration, or have suitable fall back alternatives in case the feature is not implemented by the ROM monitor.

Note:

Checking for unimplemented service when this may be a data field/pointer instead of a function: suggest reserving the last entry in the table as the NOP-service pointer. Then clients can compare a service entry with this pointer to determine whether it's initialized or not.

The header file `cyg/hal/hal_if.h` defines the table layout and accessor macros (allowing primitive type checking and alternative implementations should it become necessary).

The source file `hal_if.c` defines the table initialization function. All HALs should call this during platform initialization - the table will get initialized according to configuration. Also defined here are wrapper functions which map between the calling interface API and the API of the used eCos functions.

Implemented Services

This is a brief description of the services, some of which are described in further detail below.

`VERSION`
Version of table. Serves as a way to check for how many features are available in the table. This is the index of the last service in the table.

`KILL_VECTOR`
[Presently unused by the stub code, but initialized] This vector defines a function to execute when the system receives a kill signal from the debugger. It is initialized with the reset function (see below), but the application (or eCos) can override it if necessary.

`CONSOLE_PROCS`
The communication procedure table used for console IO (see the section called “IO channels”.

`DEBUG_PROCS`
The communication procedure table used for debugger IO (see the section called “IO channels”).

`FLUSH_DCACHE`
Flushes the data cache for the specified region. Some implementations may flush the entire data cache.

`FLUSH_ICACHE`
Flushes (invalidates) the instruction cache for the specified region. Some implementations may flush the entire instruction cache.

`SET_DEBUG_COMM` Change debugging communication channel.

`SET_CONSOLE_COMM` Change console communication channel.

`DBG_SYSCALL` Vector used to communication between debugger functions in ROM and in RAM. RAM eCos configurations may install a function pointer here which the ROM monitor uses to get thread information from the kernel running in RAM.

`RESET` Resets the board on call. If it is not possible to reset the board from software, it will jump to the ROM entry point which will perform a "software" reset of the board.

`CONSOLE_INTERRUPT_FLAG` Set if a debugger interrupt request was detected while processing console IO. Allows the actual breakpoint action to be handled after return to RAM, ensuring proper backtraces etc.

`DELAY_US` Will delay the specified number of microseconds. The precision is platform dependent to some extend - a small value (<100us) is likely to cause bigger delays than requested.

`FLASH_CFG_OP` For accessing configuration settings kept in flash memory.

`INSTALL_BPT_FN` Installs a breakpoint at the specified address. This is used by the asynchronous breakpoint support (see).

Compatibility

When a platform is changed to support the calling interface, applications will use it if so configured. That means that if an application is run on a platform with an older ROM monitor, the service is almost guaranteed to fail.

For this reason, applications should only use Console Comm for HAL diagnostics output if explicitly configured to do so (`CYGSEM_HAL_VIRTUAL_VECTOR_DIAG`).

As for asynchronous GDB interrupts, the service will always be used. This is likely to cause a crash under older ROM monitors, but this crash may be caught by the debugger. The old workaround still applies: if you need asynchronous breakpoints or thread debugging under older ROM monitors, you may have to include the debugging support when configuring eCos.

Implementation details

During the startup of a ROM monitor, the calling table will be initialized. This also happens if eCos is configured *not* to rely on a ROM monitor.

Note:

There is reserved space (256 bytes) for the vector table whether it gets used or not. This may be something that we want to change if we ever have to shave off every last byte for a given target.

If thread debugging features are enabled, the function for accessing the thread information gets registered in the table during startup of a RAM startup configuration.

Further implementation details are described where the service itself is described.

New Platform Ports

The `hal_platform_init()` function must call `hal_if_init()`.

The HAL serial driver must, when called via `cyg_hal_plf_comms_init()` must initialize the communication channels.

The `reset()` function defined in `hal_if.c` will attempt to do a hardware reset, but if this fails it will fall back to simply jumping to the reset entry-point. On most platforms the startup initialization will go a long way to reset the target to a sane state (there will be exceptions, of course). For this reason, make sure to define `HAL_STUB_PLATFORM_RESET_ENTRY` in plf_stub.h.

All debugging features must be in place in order for the debugging services to be functional. See general platform porting notes.

New architecture ports

There are no specific requirements for a new architecture port in order to support the calling interface, but the basic debugging features must be in place. See general architecture porting notes.

IO channels

The calling interface provides procedure tables for all IO channels on the platform. These are used for console (diagnostic) and debugger IO, allowing a ROM monitor to provided all the needed IO routines. At the same time, this makes it easy to switch console/debugger channels at run-time (the old implementation had hardwired drivers for console and debugger IO, preventing these to change at run-time).

The hal_if provides wrappers which interface these services to the eCos infrastructure diagnostics routines. This is done in a way which ensures proper string mangling of the diagnostics output when required (e.g. O-packetization when using a GDB compatible ROM monitor).

Available Procedures

This is a brief description of the procedures

`CH_DATA`

Pointer to the controller IO base (or a pointer to a per-device structure if more data than the IO base is required). All the procedures below are called with this data item as the first argument.

`WRITE`

Writes the buffer to the device.

`READ`

Fills a buffer from the device.

`PUTC`

Write a character to the device.

`GETC`

Read a character from the device.

`CONTROL`

Device feature control. Second argument specifies function:

`SETBAUD`	Changes baud rate.
`GETBAUD`	Returns the current baud rate.
`INSTALL_DBG_ISR`	[Unused]
`REMOVE_DBG_ISR`	[Unused]
`IRQ_DISABLE`	Disable debugging receive interrupts on the device.
`IRQ_ENABLE`	Enable debugging receive interrupts on the device.

`DBG_ISR_VECTOR` Returns the ISR vector used by the device for debugging receive interrupts.

`SET_TIMEOUT` Set GETC timeout in milliseconds.

`FLUSH_OUTPUT` Forces driver to flush data in its buffers. Note that this may not affect hardware buffers (e.g. FIFOs).

`DBG_ISR`

ISR used to handle receive interrupts from the device (see).

`GETC_TIMEOUT`

Read a character from the device with timeout.

Usage

The standard eCos diagnostics IO functions use the channel procedure table when `CYGSEM_HAL_VIRTUAL_VECTOR_DIAG` is enabled. That means that when you use diag_printf (or the libc printf function) the stream goes through the selected console procedure table. If you use the virtual vector function SET_CONSOLE_COMM you can change the device which the diagnostics output goes to at run-time.

You can also use the table functions directly if desired (regardless of the `CYGSEM_HAL_VIRTUAL_VECTOR_DIAG` setting - assuming the ROM monitor provides the services). Here is a small example which changes the console to use channel 2, fetches the comm procs pointer and calls the write function from that table, then restores the console to the original channel:

```
#define T "Hello World!\n"

int
main(void)
{
    hal_virtual_comm_table_t* comm;
    int cur = CYGACC_CALL_IF_SET_CONSOLE_COMM(CYGNUM_CALL_IF_SET_COMM_ID_QUERY_CURRENT);

    CYGACC_CALL_IF_SET_CONSOLE_COMM(2);

    comm = CYGACC_CALL_IF_CONSOLE_PROCS();
    CYGACC_COMM_IF_WRITE(*comm, T, strlen(T));

    CYGACC_CALL_IF_SET_CONSOLE_COMM(cur);
}
```

Beware that if doing something like the above, you should only do it to a channel which does not have GDB at the other end: GDB ignores raw data, so you would not see the output.

Compatibility

The use of this service is controlled by the option `CYGSEM_HAL_VIRTUAL_VECTOR_DIAG` which is disabled per default on most older platforms (thus preserving backwards compatibility with older stubs). On newer ports, this option should always be set.

Implementation Details

There is an array of procedure tables (raw comm channels) for each IO device of the platform which get initialized by the ROM monitor, or optionally by a RAM startup configuration (allowing the RAM configuration to take full control of the target). In addition to this, there's a special table which is used to hold mangler procedures.

The vector table defines which of these channels are selected for console and debugging IO respectively: console entry can be empty, point to mangler channel, or point to a raw channel. The debugger entry should always point to a raw channel.

During normal console output (i.e., diagnostic output) the console table will be used to handle IO if defined. If not defined, the debug table will be used.

This means that debuggers (such as GDB) which require text streams to be mangled (O-packetized in the case of GDB), can rely on the ROM monitor install mangling IO routines in the special mangler table and select this for console output. The mangler will pass the mangled data on to the selected debugging channel.

If the eCos configuration specifies a different console channel from that used by the debugger, the console entry will point to the selected raw channel, thus overriding any mangler provided by the ROM monitor.

See hal_if_diag_* routines in hal_if.c for more details of the stream path of diagnostic output. See `cyg_hal_gdb_diag_*()` routines in `hal_stub.c` for the mangler used for GDB communication.

New Platform Ports

Define CDL options `CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS`, `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL`, and `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL`.

If `CYGSEM_HAL_VIRTUAL_VECTOR_DIAG` is set, make sure the infra diag code uses the hal_if diag functions:

```
#define HAL_DIAG_INIT() hal_if_diag_init()
#define HAL_DIAG_WRITE_CHAR(_c_) hal_if_diag_write_char(_c_)
#define HAL_DIAG_READ_CHAR(_c_) hal_if_diag_read_char(&_c_)
```

In addition to the above functions, the platform HAL must also provide a function cyg_hal_plf_comms_init which initializes the drivers and the channel procedure tables.

Most of the other functionality in the table is more or less possible to copy unchanged from existing ports. Some care is necessary though to ensure the proper handling of interrupt vectors and timeouts for various devices handled by the same driver. See PowerPC/Cogent platform HAL for an example implementation.

Note:

When vector table console code is *not* used, the platform HAL must map the HAL_DIAG_INIT, HAL_DIAG_WRITE_CHAR and HAL_DIAG_READ_CHAR macros directly to the low-level IO functions, hardwired to use a compile-time configured channel.

Note:

On old ports the hardwired `HAL_DIAG_INIT`, `HAL_DIAG_WRITE_CHAR` and `HAL_DIAG_READ_CHAR` implementations will also contain code to O-packetize the output for GDB. This should *not* be adopted for new ports! On new ports the ROM monitor is guaranteed to provide the necessary mangling via the vector table. The hardwired configuration should be reserved for ROM startups where achieving minimal image size is crucial.

HAL Coding Conventions

To get changes and larger submissions included into the eCos source repository, we ask that you adhere to a set of coding conventions. The conventions are defined as an attempt to make a consistent tree. Consistency makes it easier for people to read, understand and maintain the code, which is important when many people work on the same project.

The below is only a brief, and probably incomplete, summary of the rules. Please look through files in the area where you are making changes to get a feel for any additional conventions. Also feel free to ask on the list if you have specific questions.

Implementation issues

There are a few implementation issues that should be kept in mind:

HALs

HALs must be written in C and assembly only. C++ must not be used. This is in part to keep the HALs simple since this is usually the first part of eCos a newcomer will see, and in part to maintain the existing de facto standard.

IO access

Use HAL IO access macros for code that might be reused on different platforms than the one you are writing it for.

MMU

If it is necessary to use the MMU (e.g., to prevent caching of IO areas), use a simple 1-1 mapping of memory if possible. On most platforms where using the MMU is necessary, it will be possible to achieve the 1-1 mapping using the MMU's provision for mapping large continuous areas (hardwired TLBs or BATs). This reduces the footprint (no MMU table) and avoids execution overhead (no MMU-related exceptions).

Assertions

The code should contain assertions to validate argument values, state information and any assumptions the code may be making. Assertions are not enabled in production builds, so liberally sprinkling assertions throughout the code is good.

Testing

The ability to test your code is very important. In general, do not add new code to the eCos runtime unless you also add a new test to exercise that code. The test also serves as an example of how to use the new code.

Source code details

Line length

Keep line length below 78 columns whenever possible.

Comments

Whenever possible, use // comments instead of /**/.

Indentation

Use spaces instead of TABs. Indentation level is 4. Braces start on the same line as the expression. See below for emacs mode details.

```
;;=================================================================
;; eCos C/C++ mode Setup.
;;
;; bsd mode: indent = 4
;; tail comments are at col 40.
;; uses spaces not tabs in C;

(defun ecos-c-mode ()
  "C mode with adjusted defaults for use with the eCos sources."
  (interactive)
  (c++-mode)
  (c-set-style "bsd")
  (setq comment-column 40)
  (setq indent-tabs-mode nil)
  (show-paren-mode 1)
  (setq c-basic-offset 4)

  (set-variable 'add-log-full-name "Your Name")
  (set-variable 'add-log-mailing-address "Your email address"))

(defun ecos-asm-mode ()
  "ASM mode with adjusted defaults for use with the eCos sources."
  (interactive)
  (setq comment-column 40)
  (setq indent-tabs-mode nil)
  (asm-mode)
  (setq c-basic-offset 4)

  (set-variable 'add-log-full-name "Your Name")
  (set-variable 'add-log-mailing-address "Your email address"))

(setq auto-mode-alist
  (append '(("/local/ecc/.*\\.C$"   . ecos-c-mode)
  ("/local/ecc/.*\\.cc$"  . ecos-c-mode)
  ("/local/ecc/.*\\.cpp$" . ecos-c-mode)
  ("/local/ecc/.*\\.inl$" . ecos-c-mode)
  ("/local/ecc/.*\\.c$"   . ecos-c-mode)
  ("/local/ecc/.*\\.h$"   . ecos-c-mode)
  ("/local/ecc/.*\\.S$"   . ecos-asm-mode)
  ("/local/ecc/.*\\.inc$" . ecos-asm-mode)
  ("/local/ecc/.*\\.cdl$" . tcl-mode)
) auto-mode-alist))
```

Nested Headers

In order to allow platforms to define all necessary details, while still maintaining the ability to share code between common platforms, all HAL headers are included in a nested fashion.

The architecture header (usually `hal_XXX.h`) includes the variant equivalent of the header (`var_XXX.h`) which in turn includes the platform equivalent of the header (`plf_XXX.h`).

All definitions that may need to be overridden by a platform are then only conditionally defined, depending on whether a lower layer has already made the definition:

```
hal_intr.h:     #include <var_intr.h>

                #ifndef MACRO_DEFINED
                # define MACRO ...
                # define MACRO_DEFINED
                #endif

var_intr.h:     #include <plf_intr.h>

                #ifndef MACRO_DEFINED
                # define MACRO ...
                # define MACRO_DEFINED
                #endif

plf_intr.h:

                # define MACRO ...
                # define MACRO_DEFINED
```

This means a platform can opt to rely on the variant or architecture implementation of a feature, or implement it itself.

Platform HAL Porting

This is the type of port that takes the least effort. It basically consists of describing the platform (board) for the HAL: memory layout, early platform initialization, interrupt controllers, and a simple serial device driver.

Doing a platform port requires a preexisting architecture and possibly a variant HAL port.

HAL Platform Porting Process

Brief overview

The easiest way to make a new platform HAL is simply to copy an existing platform HAL of the same architecture/variant and change all the files to match the new one. In case this is the first platform for the architecture/variant, a platform HAL from another architecture should be used as a template.

The best way to start a platform port is to concentrate on getting RedBoot to run. RedBoot is a simpler environment than full eCos, it does not use interrupts or threads, but covers most of the basic startup requirements.

RedBoot normally runs out of FLASH or ROM and provides program loading and debugging facilities. This allows further HAL development to happen using RAM startup configurations, which is desirable for the simple reason that downloading an image which you need to test is often many times faster than either updating a flash part, or indeed, erasing and reprogramming an EPROM.

There are two approaches to getting to this first goal:

1. The board is equipped with a ROM monitor which allows "load and go" of ELF, binary, S-record or some other image type which can be created using objcopy. This allows you to develop RedBoot by downloading and running the code (saving time).

   When the stub is running it is a good idea to examine the various hardware registers to help you write the platform initialization code.

   Then you may have to fiddle a bit going through step two (getting it to run from ROM startup). If at all possible, preserve the original ROM monitor so you can revert to it if necessary.

2. The board has no ROM monitor. You need to get the platform initialization and stub working by repeatedly making changes, updating flash or EPROM and testing the changes. If you are lucky, you have a JTAG or similar CPU debugger to help you. If not, you will probably learn to appreciate LEDs. This approach may also be needed during the initial phase of moving RedBoot from RAM startup to ROM, since it is very unlikely to work first time.

Step-by-step

Given that no two platforms are exactly the same, you may have to deviate from the below. Also, you should expect a fair amount of fiddling - things almost never go right the first time. See the hints section below for some suggestions that might help debugging.

The description below is based on the HAL layout used in the MIPS, PC and MN10300 HALs. Eventually all HALs should be converted to look like these - but in a transition period there will be other HALs which look substantially different. Please try to adhere to the following as much is possible without causing yourself too much grief integrating with a HAL which does not follow this layout.

Minimal requirements

These are the changes you must make before you attempt to build RedBoot. You are advised to read all the sources though.

1. Copy an existing platform HAL from the same or another architecture. Rename the files as necessary to follow the standard: CDL and MLT related files should contain the <arch>_<variant>_<platform> triplet.

2. Adjust CDL options. Primarily option naming, real-time clock/counter, and CYGHWR_MEMORY_LAYOUT variables, but also other options may need editing. Look through the architecture/variant CDL files to see if there are any requirements/features which where not used on the platform you copied. If so, add appropriate ones. See the section called “HAL Platform CDL” for more details.

3. Add the necessary packages and target descriptions to the top-level `ecos.db` file. See the section called “eCos Database”. Initially, the target entry should only contain the HAL packages. Other hardware support packages will be added later.

4. Adjust the MLT files in `include/pkgconf` to match the memory layout on the platform. For initial testing it should be enough to just hand edit .h and .ldi files, but eventually you should generate all files using the memory layout editor in the configuration tool. See the section called “Platform Memory Layout” for more details.

5. Edit the `misc/redboot_<STARTUP>.ecm` for the startup type you have chosen to begin with. Rename any platform specific options and remove any that do not apply. In the `cdl_configuration` section, comment out any extra packages that are added, particularly packages such as `CYGPKG_IO_FLASH` and `CYGPKG_IO_ETH_DRIVERS`. These are not needed for initial porting and will be added back later.

6. If the default IO macros are not correct, override them in plf_io.h. This may be necessary if the platform uses a different endianness from the default for the CPU.

7. Leave out/comment out code that enables caches and/or MMU if possible. Execution speed will not be a concern until the port is feature complete.

8. Implement a simple serial driver (polled mode only). Make sure the initialization function properly hooks the procedures up in the virtual vector IO channel tables. RedBoot will call the serial driver via these tables.

   By copying an existing platform HAL most of this code will be already done, and will only need the platform specific hardware access code to be written.

9. Adjust/implement necessary platform initialization. This can be found in `platform.inc` and `platform.S` files (ARM: `hal_platform_setup.h` and `<platform>_misc.c`, PowerPC: `<platform>.S`). This step can be postponed if you are doing a RAM startup RedBoot first and the existing ROM monitor handles board initialization.

10. Define `HAL_STUB_PLATFORM_RESET` (optionally empty) and `HAL_STUB_PLATFORM_RESET_ENTRY` so that RedBoot can reset-on-detach - this is very handy, often removing the need for physically resetting the board between downloads.

You should now be able to build RedBoot. For ROM startup:

```
% ecosconfig new <target_name> redboot
% ecosconfig import $(ECOS_REPOSITORY)/hal/<architecture>/<platform>/<version>/misc/redboot_ROM.ecm
% ecosconfig tree
% make
```

You may have to make further changes than suggested above to get the make command to succeed. But when it does, you should find a RedBoot image in install/bin. To program this image into flash or EPROM, you may need to convert to some other file type, and possibly adjust the start address. When you have the correct objcopy command to do this, add it to the `CYGBLD_BUILD_GDB_STUBS` custom build rule in the platform CDL file.

Having updated the flash/EPROM on the board, you should see output on the serial port looking like this when powering on the board:

```
RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 15:42:24, Mar 14 2002

Platform: <PLATFORM> (<ARCHITECTURE> <VARIANT>)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x01000000, 0x000293e8-0x00ed1000 available
FLASH: 0x24000000 - 0x26000000, 256 blocks of 0x00020000 bytes each.
RedBoot>
```

If you do not see this output, you need to go through all your changes and figure out what's wrong. If there's a user programmable LED or LCD on the board it may help you figure out how far RedBoot gets before it hangs. Unfortunately there's no good way to describe what to do in this situation - other than that you have to play with the code and the board.

Adding features

Now you should have a basic RedBoot running on the board. This means you have a the correct board initialization and a working serial driver. It's time to flesh out the remaining HAL features.

1. Reset. As mentioned above it is desirable to get the board to reset when GDB disconnects. When GDB disconnects it sends RedBoot a kill-packet, and RedBoot first calls `HAL_STUB_PLATFORM_RESET()`, attempting to perform a software-invoked reset. Most embedded CPUs/boards have a watchdog which is capable of triggering a reset. If your target does not have a watchdog, leave `HAL_STUB_PLATFORM_RESET()` empty and rely on the fallback approach.

   If `HAL_STUB_PLATFORM_RESET()` did not cause a reset, RedBoot will jump to `HAL_STUB_PLATFORM_RESET_ENTRY` - this should be the address where the CPU will start execution after a reset. Re-initializing the board and drivers will *usually* be good enough to make a hardware reset unnecessary.

After the reset caused by the kill-packet, the target will be ready for GDB to connect again. During a days work, this will save you from pressing the reset button many times.

Note that it is possible to disconnect from the board without causing it to reset by using the GDB command "detach".

2. Single-stepping is necessary for both instruction-level debugging and for breakpoint support. Single-stepping support should already be in place as part of the architecture/variant HAL, but you want to give it a quick test since you will come to rely on it.
3. Real-time clock interrupts drive the eCos scheduler clock. Many embedded CPUs have an on-core timer (e.g. SH) or decrementer (e.g. MIPS, PPC) that can be used, and in this case it will already be supported by the architecture/variant HAL. You only have to calculate and enter the proper `CYGNUM_HAL_RTC_CONSTANTS` definitions in the platform CDL file.

   On some targets it may be necessary to use a platform-specific timer source for driving the real-time clock. In this case you also have to enter the proper CDL definitions, but must also define suitable versions of the `HAL_CLOCK_XXXX` macros.
4. Interrupt decoding usually differs between platforms because the number and type of devices on the board differ. In `plf_intr.h` (ARM: `hal_platform_ints.h`) you must either extend or replace the default vector definitions provided by the architecture or variant interrupt headers. You may also have to define `HAL_INTERRUPT_XXXX` control macros.
5. Caching may also differ from architecture/variant definitions. This maybe just the cache sizes, but there can also be bigger differences for example if the platform supports 2nd level caches.

   When cache definitions are in place, enable the caches on startup. First verify that the system is stable for RAM startups, then build a new RedBoot and install it. This will test if caching, and in particular the cache sync/flush operations, also work for ROM startup.
6. Asynchronous breakpoints allow you to stop application execution and enter the debugger. Asynchronous breakpoint details are described in .

You should now have a completed platform HAL port. Verify its stability and completeness by running all the eCos tests and fix any problems that show up (you have a working RedBoot now, remember! That means you can debug the code to see why it fails).

Given the many configuration options in eCos, there may be hidden bugs or missing features that do not show up even if you run all the tests successfully with a default configuration. A comprehensive test of the entire system will take many configuration permutations and many many thousands of tests executed.

Hints

- JTAG or similar CPU debugging hardware can greatly reduce the time it takes to write a HAL port since you always have full visibility of what the CPU is doing.
- LEDs can be your friends if you don't have a JTAG device. Especially in the start of the porting effort if you don't already have a working ROM monitor on the target. Then you have to get a basic RedBoot working while basically being blindfolded. The LED can make it little easier, as you'll be able to do limited tracking of program flow and behavior by switching the LED on and off. If the board has multiple LEDs you can show a number (using binary notation with the LEDs) and sprinkle code which sets different numbers throughout the code.
- Debugging the interrupt processing is possible if you are careful with the way you program the very early interrupt entry handling. Write it so that as soon as possible in the interrupt path, taking a trap (exception) does not harm execution. See the SH vectors.S code for an example. Look for `cyg_hal_default_interrupt_vsr` and the label `cyg_hal_default_interrupt_vsr_bp_safe`, which marks the point after which traps/single-stepping is safe.

  Being able to display memory content, CPU registers, interrupt controller details at the time of an interrupt can save a lot of time.
- Using assertions is a good idea. They can sometimes reveal subtle bugs or missing features long before you would otherwise have found them, let alone notice them.

The default eCos configuration does not use assertions, so you have to enable them by switching on the option `CYGPKG_INFRA_DEBUG` in the infra package.

- The idle loop can be used to help debug the system.

  Triggering clock from the idle loop is a neat trick for examining system behavior either before interrupts are fully working, or to speed up "the clock".

  Use the idle loop to monitor and/or print out variables or hardware registers.

- hal_mk_defs is used in some of the HALs (ARM, SH) as a way to generate assembler symbol definitions from C header files without imposing an assembler/C syntax separation in the C++ header files.

HAL Platform CDL

The platform CDL both contains details necessary for the building of eCos, and platform-specific configuration options. For this reason the options differ between platforms, and the below is just a brief description of the most common options.

See Components Writers Guide for more details on CDL. Also have a quick look around in existing platform CDL files to get an idea of what is possible and how various configuration issues can be represented with CDL.

eCos Database

The eCos configuration system is made aware of a package by adding a package description in `ecos.db`. As an example we use the `TX39/JMR3904` platform:

```
package CYGPKG_HAL_MIPS_TX39_JMR3904 {
    alias     { "Toshiba JMR-TX3904 board" hal_tx39_jmr3904 tx39_jmr3904_hal }
    directory hal/mips/jmr3904
    script    hal_mips_tx39_jmr3904.cdl
    hardware
    description "
        The JMR3904 HAL package should be used when targeting the
        actual hardware. The same package can also be used when
        running on the full simulator, since this provides an
        accurate simulation of the hardware including I/O devices.
        To use the simulator in this mode the command
        `target sim --board=jmr3904' should be used from inside gdb."
}
```

This contains the title and description presented in the Configuration Tool when the package is selected. It also specifies where in the tree the package files can be found (`directory`) and the name of the CDL file which contains the package details (`script`).

To be able to build and test a configuration for the new target, there also needs to be a `target` entry in the `ecos.db` file.

```
target jmr3904 {
    alias       { "Toshiba JMR-TX3904 board" jmr tx39 }
    packages    { CYGPKG_HAL_MIPS
                  CYGPKG_HAL_MIPS_TX39
                  CYGPKG_HAL_MIPS_TX39_JMR3904
    }
    description "
        The jmr3904 target provides the packages needed to run
        eCos on a Toshiba JMR-TX3904 board. This target can also
        be used when running in the full simulator, since the simulator provides an
        accurate simulation of the hardware including I/O devices.
        To use the simulator in this mode the command
        `target sim --board=jmr3904' should be used from inside gdb."
}
```

The important part here is the packages section which defines the various hardware specific packages that contribute to support for this target. In this case the MIPS architecture package, the TX39 variant package, and the JMR-TX3904 platform packages are selected. Other packages, for serial drivers, ethernet drivers and FLASH memory drivers may also appear here.

CDL File Layout

All the platform options are contained in a CDL package named CYGPKG_HAL_<architecture>_<variant>_<platform>. They all share more or less the same cdl_package details:

```
cdl_package CYGPKG_HAL_MIPS_TX39_JMR3904 {
    display       "JMR3904 evaluation board"
    parent        CYGPKG_HAL_MIPS
    requires      CYGPKG_HAL_MIPS_TX39
    define_header hal_mips_tx39_jmr3904.h
    include_dir   cyg/hal
    description   "
        The JMR3904 HAL package should be used when targeting the
        actual hardware. The same package can also be used when
        running on the full simulator, since this provides an
        accurate simulation of the hardware including I/O devices.
        To use the simulator in this mode the command
        `target sim --board=jmr3904' should be used from inside gdb."

    compile       platform.S plf_misc.c plf_stub.c

    define_proc {
        puts $::cdl_system_header "#define CYGBLD_HAL_TARGET_H   <pkgconf/hal_mips_tx39.h>"
        puts $::cdl_system_header "#define CYGBLD_HAL_PLATFORM_H <pkgconf/hal_mips_tx39_jmr3904.h>"
    }

    …
}
```

This specifies that the platform package should be parented under the MIPS packages, requires the TX39 variant HAL and all configuration settings should be saved in cyg/hal/hal_mips_tx39_jmt3904.h.

The compile line specifies which files should be built when this package is enabled, and the define_proc defines some macros that are used to access the variant or architecture (the _TARGET_ name is a bit of a misnomer) and platform configuration options.

Startup Type

eCos uses an option to select between a set of valid startup configurations. These are normally RAM, ROM and possibly ROMRAM. This setting is used to select which linker map to use (i.e., where to link eCos and the application in the memory space), and how the startup code should behave.

```
cdl_component CYG_HAL_STARTUP {
    display       "Startup type"
    flavor        data
    legal_values  {"RAM" "ROM"}
    default_value {"RAM"}
    no_define
    define -file system.h CYG_HAL_STARTUP
    description   "
        When targeting the JMR3904 board it is possible to build
        the system for either RAM bootstrap, ROM bootstrap, or STUB
        bootstrap. RAM bootstrap generally requires that the board
        is equipped with ROMs containing a suitable ROM monitor or
        equivalent software that allows GDB to download the eCos
        application on to the board. The ROM bootstrap typically
        requires that the eCos application be blown into EPROMs or
        equivalent technology."
}
```

The no_define and define pair is used to make the setting of this option appear in the file system.h instead of the default specified in the header.

Build options

A set of options under the components CYGBLD_GLOBAL_OPTIONS and CYGHWR_MEMORY_LAYOUT specify how eCos should be built: what tools and compiler options should be used, and which linker fragments should be used.

```
cdl_component CYGBLD_GLOBAL_OPTIONS {
    display "Global build options"
    flavor  none
    parent  CYGPKG_NONE
    description   "
        Global build options including control over
        compiler flags, linker flags and choice of toolchain."

    cdl_option CYGBLD_GLOBAL_COMMAND_PREFIX {
        display "Global command prefix"
        flavor  data
        no_define
        default_value { "mips-tx39-elf" }
        description "
            This option specifies the command prefix used when
            invoking the build tools."
    }

    cdl_option CYGBLD_GLOBAL_CFLAGS {
        display "Global compiler flags"
        flavor  data
        no_define
        default_value { "-Wall -Wpointer-arith -Wstrict-prototypes -Winline -Wundef -Woverloaded-virtual " .
            "-g -O2 -ffunction-sections -fdata-sections -fno-rtti -fno-exceptions" }
        description   "
            This option controls the global compiler flags which
            are used to compile all packages by
            default. Individual packages may define
            options which override these global flags."
    }

    cdl_option CYGBLD_GLOBAL_LDFLAGS {
        display "Global linker flags"
        flavor  data
        no_define
        default_value { "-g -nostdlib -Wl,--gc-sections -Wl,-static" }
        description   "
            This option controls the global linker flags. Individual
            packages may define options which override these global flags."
        }
    }

    cdl_component CYGHWR_MEMORY_LAYOUT {
        display "Memory layout"
        flavor data
        no_define
        calculated { CYG_HAL_STARTUP == "RAM" ? "mips_tx39_jmr3904_ram" : \
                                                "mips_tx39_jmr3904_rom" }

        cdl_option CYGHWR_MEMORY_LAYOUT_LDI {
        display "Memory layout linker script fragment"
        flavor data
        no_define
        define -file system.h CYGHWR_MEMORY_LAYOUT_LDI
        calculated { CYG_HAL_STARTUP == "RAM" ? "<pkgconf/mlt_mips_tx39_jmr3904_ram.ldi>" : \
                                                "<pkgconf/mlt_mips_tx39_jmr3904_rom.ldi>" }
    }
    cdl_option CYGHWR_MEMORY_LAYOUT_H {
        display "Memory layout header file"
        flavor data
        no_define
        define -file system.h CYGHWR_MEMORY_LAYOUT_H
        calculated { CYG_HAL_STARTUP == "RAM" ? "<pkgconf/mlt_mips_tx39_jmr3904_ram.h>" : \
                                                "<pkgconf/mlt_mips_tx39_jmr3904_rom.h>" }
    }
}
```

Common Target Options

All platforms also specify real-time clock details:

```
# Real-time clock/counter specifics
cdl_component CYGNUM_HAL_RTC_CONSTANTS {
    display       "Real-time clock constants."
    flavor        none

    cdl_option CYGNUM_HAL_RTC_NUMERATOR {
        display       "Real-time clock numerator"
        flavor        data
        calculated    1000000000
    }
    cdl_option CYGNUM_HAL_RTC_DENOMINATOR {
        display       "Real-time clock denominator"
        flavor        data
        calculated    100
    }
    # Isn't a nice way to handle freq requirement!
    cdl_option CYGNUM_HAL_RTC_PERIOD {
        display       "Real-time clock period"
        flavor        data
        legal_values  { 15360 20736 }
        calculated     { CYGHWR_HAL_MIPS_CPU_FREQ == 50 ? 15360 : \
        CYGHWR_HAL_MIPS_CPU_FREQ == 66 ? 20736 : 0 }
    }
}
```

The `NUMERATOR` divided by the `DENOMINATOR` gives the number of nanoseconds per tick. The `PERIOD` is the divider to be programmed into a hardware timer that is driven from an appropriate hardware clock, such that the timer overflows once per tick (normally generating a CPU interrupt to mark the end of a tick). The tick default rate is typically 100Hz.

Platforms that make use of the virtual vector ROM calling interface (see the section called “Virtual Vectors (eCos/ROM Monitor Calling Interface)”) will also specify details necessary to define configuration channels (these options are from the SH/EDK7707 HAL) :

```
cdl_option CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS {
    display      "Number of communication channels on the board"
    flavor       data
    calculated   1
}

cdl_option CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL {
    display          "Debug serial port"
    flavor data
    legal_values     0 to CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS-1
    default_value    0
    description      "
        The EDK/7708 board has only one serial port. This option
        chooses which port will be used to connect to a host
        running GDB."
}
```

```
cdl_option CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL {
    display          "Diagnostic serial port"
    flavor data
    legal_values     0 to CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS-1
    default_value    0
    description      "
        The EDK/7708 board has only one serial port.  This option
        chooses which port will be used for diagnostic output."
}
```

The platform usually also specify an option controlling the ability to co-exist with a ROM monitor:

```
cdl_option CYGSEM_HAL_USE_ROM_MONITOR {
    display       "Work with a ROM monitor"
    flavor        booldata
    legal_values  { "Generic" "CygMon" "GDB_stubs" }
    default_value { CYG_HAL_STARTUP == "RAM" ? "CygMon" : 0 }
    parent        CYGPKG_HAL_ROM_MONITOR
    requires      { CYG_HAL_STARTUP == "RAM" }
    description   "
        Support can be enabled for three different varieties of ROM monitor.
        This support changes various eCos semantics such as the encoding
        of diagnostic output, or the overriding of hardware interrupt
        vectors.
        Firstly there is \"Generic\" support which prevents the HAL
        from overriding the hardware vectors that it does not use, to
        instead allow an installed ROM monitor to handle them. This is
        the most basic support which is likely to be common to most
        implementations of ROM monitor.
        \"CygMon\" provides support for the Cygnus ROM Monitor.
        And finally, \"GDB_stubs\" provides support when GDB stubs are
        included in the ROM monitor or boot ROM."
}
```

Or the ability to be configured as a ROM monitor:

```
cdl_option CYGSEM_HAL_ROM_MONITOR {
    display       "Behave as a ROM monitor"
    flavor        bool
    default_value 0
    parent        CYGPKG_HAL_ROM_MONITOR
    requires      { CYG_HAL_STARTUP == "ROM" }
    description   "
        Enable this option if this program is to be used as a ROM monitor,
        i.e. applications will be loaded into RAM on the board, and this
        ROM monitor may process exceptions or interrupts generated from the
        application. This enables features such as utilizing a separate
        interrupt stack when exceptions are generated."
}
```

The latter option is accompanied by a special build rule that extends the generic ROM monitor build rule in the common HAL:

```
cdl_option CYGBLD_BUILD_GDB_STUBS {
    display "Build GDB stub ROM image"
    default_value 0
    requires { CYG_HAL_STARTUP == "ROM" }
    requires CYGSEM_HAL_ROM_MONITOR
    requires CYGBLD_BUILD_COMMON_GDB_STUBS
    requires CYGDBG_HAL_DEBUG_GDB_INCLUDE_STUBS
    requires ! CYGDBG_HAL_DEBUG_GDB_BREAK_SUPPORT
    requires ! CYGDBG_HAL_DEBUG_GDB_THREAD_SUPPORT
    requires ! CYGDBG_HAL_COMMON_INTERRUPTS_SAVE_MINIMUM_CONTEXT
    requires ! CYGDBG_HAL_COMMON_CONTEXT_SAVE_MINIMUM
    no_define
    description "
        This option enables the building of the GDB stubs for the
        board. The common HAL controls takes care of most of the
        build process, but the final conversion from ELF image to
        binary data is handled by the platform CDL, allowing
        relocation of the data if necessary."

    make -priority 320 {
        <PREFIX>/bin/gdb_module.bin : <PREFIX>/bin/gdb_module.img
        $(OBJCOPY) -O binary $< $@
    }
}
```

Most platforms support RedBoot, and some options are needed to configure for RedBoot.

```
    cdl_component CYGPKG_REDBOOT_HAL_OPTIONS {
    display       "Redboot HAL options"
    flavor        none
    no_define
    parent        CYGPKG_REDBOOT
    active_if     CYGPKG_REDBOOT
    description   "
        This option lists the target's requirements for a valid Redboot
        configuration."

    cdl_option CYGBLD_BUILD_REDBOOT_BIN {
        display       "Build Redboot ROM binary image"
        active_if     CYGBLD_BUILD_REDBOOT
        default_value 1
        no_define
        description "This option enables the conversion of the Redboot ELF
            image to a binary image suitable for ROM programming."

        make -priority 325 {
            <PREFIX>/bin/redboot.bin : <PREFIX>/bin/redboot.elf
            $(OBJCOPY) --strip-debug $< $(@:.bin=.img)
            $(OBJCOPY) -O srec $< $(@:.bin=.srec)
            $(OBJCOPY) -O binary $< $@
        }
    }
}
```

The important part here is the `make` command in the `CYGBLD_BUILD_REDBOOT_BIN` option which emits makefile commands to translate the `.elf` file generated by the link phase into both a binary file and an S-Record file. If a different format is required by a PROM programmer or ROM monitor, then different output formats would need to be generated here.

Platform Memory Layout

The platform memory layout is defined using the Memory Configuration Window in the Configuration Tool.

Note

If you do not have access to a Windows machine, you can hand edit the `.h` and `.ldi` files to match the properties of your platform. If you want to contribute your port back to the eCos community, ask someone on the list to make proper memory map files for you.

Layout Files

The memory configuration details are saved in three files:

`.mlt` This is the Configuration Tool save-file. It is only used by the Configuration Tool.

`.ldi` This is the linker script fragment. It defines the memory and location of sections by way of macros defined in the architecture or variant linker script.

`.h` This file describes some of the memory region details as C macros, allowing eCos or the application adapt the memory layout of a specific configuration.

These three files are generated for each startup-type, since the memory details usually differ.

Reserved Regions

Some areas of the memory space are reserved for specific purposes, making room for exception vectors and various tables. RAM startup configurations also need to reserve some space at the bottom of the memory map for the ROM monitor.

These reserved areas are named with the prefix "reserved_" which is handled specially by the Configuration Tool: instead of referring to a linker macro, the start of the area is labeled and a gap left in the memory map.

Platform Serial Device Support

The first step is to set up the CDL definitions. The configuration options that need to be set are the following:

`CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS`

The number of channels, usually 0, 1 or 2.

`CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL`

The channel to use for GDB.

`CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD`

Initial baud rate for debug channel.

`CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL`

The channel to use for the console.

`CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD`

The initial baud rate for the console channel.

`CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_DEFAULT`

The default console channel.

The code in `hal_diag.c` need to be converted to support the new serial device. If this the same as a device already supported, copy that.

The following functions and types need to be rewritten to support a new serial device.

`struct channel_data_t;`

Structure containing base address, timeout and ISR vector number for each serial device supported. Extra fields my be added if necessary for the device. For example some devices have write-only control registers, so keeping a shadow of the last value written here can be useful.

`xxxx_ser_channels[];`

Array of `channel_data_t`, initialized with parameters of each channel. The index into this array is the channel number used in the CDL options above and is used by the virtual vector mechanism to refer to each channel.

`void cyg_hal_plf_serial_init_channel(void *__ch_data)`

Initialize the serial device. The parameter is actually a pointer to a `channel_data_t` and should be cast back to this type before use. This function should use the CDL definition for the baud rate for the channel it is initializing.

`void cyg_hal_plf_serial_putc(void * __ch_data, char *c)`

Send a character to the serial device. This function should poll for the device being ready to send and then write the character. Since this is intended to be a diagnostic/debug channel, it is often also a good idea to poll for end of transmission too. This ensures that as much data gets out of the system as possible.

`bool cyg_hal_plf_serial_getc_nonblock(void* __ch_data, cyg_uint8* ch)`

This function tests the device and if a character is available, places it in *`*ch`* and returns `TRUE`. If no character is available, then the function returns `FALSE` immediately.

`int cyg_hal_plf_serial_control(void *__ch_data, __comm_control_cmd_t __func, ...)`

This is an IOCTL-like function for controlling various aspects of the serial device. The only part in which you may need to do some work initially is in the `__COMMCTL_IRQ_ENABLE` and `__COMMCTL_IRQ_DISABLE` cases to enable/disable interrupts.

`int cyg_hal_plf_serial_isr(void *__ch_data, int* __ctrlc, CYG_ADDRWORD __vector, CYG_ADDRWORD __data)`

This interrupt handler, called from the spurious interrupt vector, is specifically for dealing with `Ctrl-C` interrupts from GDB. When called this function should do the following:

1. Check for an incoming character. The code here is very similar to that in `cyg_hal_plf_serial_getc_nonblock()`.
2. Read the character and call `cyg_hal_is_break()`.
3. If result is true, set *`*__ctrlc`* to `1`.
4. Return `CYG_ISR_HANDLED`.

`void cyg_hal_plf_serial_init()`

Initialize each of the serial channels. First call `cyg_hal_plf_serial_init_channel()` for each channel. Then call the `CYGACC_COMM_IF_*` macros for each channel. This latter set of calls are identical for all channels, so the best way to do this is to copy and edit an existing example.

Variant HAL Porting

A variant port can be a fairly limited job, but can also require quite a lot of work. A variant HAL describes how a specific CPU variant differs from the generic CPU architecture. The variant HAL can re-define cache, MMU, interrupt, and other features which override the default implementation provided by the architecture HAL.

Doing a variant port requires a preexisting architecture HAL port. It is also likely that a platform port will have to be done at the same time if it is to be tested.

HAL Variant Porting Process

The easiest way to make a new variant HAL is simply to copy an existing variant HAL and change all the files to match the new variant. If this is the first variant for an architecture, it may be hard to decide which parts should be put in the variant - knowledge of other variants of the architecture is required.

Looking at existing variant HALs (e.g., MIPS tx39, tx49) may be a help - usually things such as caching, interrupt and exception handling differ between variants. Initialization code, and code for handling various core components (FPU, DSP, MMU, etc.) may also differ or be missing altogether on some variants. Linker scripts may also require specific variant versions.

Note

Some CPU variants may require specific compiler support. That support must be in place before you can undertake the eCos variant port.

HAL Variant CDL

The CDL in a variant HAL tends to depend on the exact functionality supported by the variant. If it implements some of the devices described in the platform HAL, then the CDL for those will be here rather than there (for example the real-time clock).

There may also be CDL to select options in the architecture HAL to configure it to a particular architectural variant.

Each variant needs an entry in the `ecos.db` file. This is the one for the SH3:

```
package CYGPKG_HAL_SH_SH3 {
    alias         { "SH3 architecture" hal_sh_sh3 }
    directory     hal/sh/sh3
    script        hal_sh_sh3.cdl
    hardware
    description   "
    The SH3 (SuperH 3) variant HAL package provides generic
    support for SH3 variant CPUs."
}
```

As you can see, it is very similar to the platform entry.

The variant CDL file will contain a package entry named for the architecture and variant, matching the package name in the `ecos.db` file. Here is the initial part of the MIPS VR4300 CDL file:

```
cdl_package CYGPKG_HAL_MIPS_VR4300 {
    display       "VR4300 variant"
    parent        CYGPKG_HAL_MIPS
    implements    CYGINT_HAL_MIPS_VARIANT
    hardware
    include_dir   cyg/hal
    define_header hal_mips_vr4300.h
    description   "
        The VR4300 variant HAL package provides generic support
        for this processor architecture. It is also necessary to
        select a specific target platform HAL package."
}
```

This defines the package, placing it under the MIPS architecture package in the hierarchy. The `implements` line indicates that this is a MIPS variant. The architecture package uses this to check that exactly one variant is configured in.

The variant defines some options that cause the architecture HAL to configure itself to support this variant.

```
    cdl_option CYGHWR_HAL_MIPS_64BIT {
    display    "Variant 64 bit architecture support"
    calculated 1
}

cdl_option CYGHWR_HAL_MIPS_FPU {
    display    "Variant FPU support"
    calculated 1
}

cdl_option CYGHWR_HAL_MIPS_FPU_64BIT {
    display    "Variant 64 bit FPU support"
    calculated 1
}
```

These tell the architecture that this is a 64 bit MIPS architecture, that it has a floating point unit, and that we are going to use it in 64 bit mode rather than 32 bit mode.

The CDL file finishes off with some build options.

```
    define_proc {
        puts $::cdl_header "#include <pkgconf/hal_mips.h>"
    }

    compile       var_misc.c

    make {
        <PREFIX>/lib/target.ld: <PACKAGE>/src/mips_vr4300.ld
        $(CC) -E -P -Wp,-MD,target.tmp -DEXTRAS=1 -xc $(INCLUDE_PATH) $(CFLAGS) -o $@ $<
        @echo $@ ": \\" > $(notdir $@).deps
        @tail +2 target.tmp >> $(notdir $@).deps
        @echo >> $(notdir $@).deps
        @rm target.tmp
    }

    cdl_option CYGBLD_LINKER_SCRIPT {
        display "Linker script"
        flavor data
        no_define
        calculated  { "src/mips_vr4300.ld" }
    }

}
```

The `define_proc` causes the architecture configuration file to be included into the configuration file for the variant. The `compile` causes the single source file for this variant, `var_misc.c` to be compiled. The `make` command emits makefile rules to combine the linker script with the `.ldi` file to generate `target.ld`. Finally, in the MIPS HALs, the main linker script is defined in the variant, rather than the architecture, so `CYGBLD_LINKER_SCRIPT` is defined here.

Cache Support

The main area where the variant is likely to be involved is in cache support. Often the only thing that distinguishes one CPU variant from another is the size of its caches.

In architectures such as the MIPS and PowerPC where cache instructions are part of the ISA, most of the actual cache operations are implemented in the architecture HAL. In this case the variant HAL only needs to define the cache dimensions. The following are the cache dimensions defined in the MIPS VR4300 variant `var_cache.h`.

```
// Data cache
#define HAL_DCACHE_SIZE                 (8*1024)        // Size of data cache in bytes
#define HAL_DCACHE_LINE_SIZE            16              // Size of a data cache line
#define HAL_DCACHE_WAYS                 1               // Associativity of the cache

// Instruction cache
#define HAL_ICACHE_SIZE                 (16*1024)       // Size of cache in bytes
#define HAL_ICACHE_LINE_SIZE            32              // Size of a cache line
#define HAL_ICACHE_WAYS                 1               // Associativity of the cache

#define HAL_DCACHE_SETS (HAL_DCACHE_SIZE/(HAL_DCACHE_LINE_SIZE*HAL_DCACHE_WAYS))
#define HAL_ICACHE_SETS (HAL_ICACHE_SIZE/(HAL_ICACHE_LINE_SIZE*HAL_ICACHE_WAYS))
```

Additional cache macros, or overrides for the defaults, may also appear in here. While some architectures have instructions for managing cache lines, overall enable/disable operations may be handled via variant specific registers. If so then `var_cache.h` should also define the `HAL_XCACHE_ENABLE()` and `HAL_XCACHE_DISABLE()` macros.

If there are any generic features that the variant does not support (cache locking is a typical example) then `var_cache.h` may need to disable definitions of certain operations. It is architecture dependent exactly how this is done.

Architecture HAL Porting

A new architecture HAL is the most complex HAL to write, and it the least easily described. Hence this section is presently nothing more than a place holder for the future.

HAL Architecture Porting Process

The easiest way to make a new architecture HAL is simply to copy an existing architecture HAL of an, if possible, closely matching architecture and change all the files to match the new architecture. The MIPS architecture HAL should be used if possible, as it has the appropriate layout and coding conventions. Other HALs may deviate from that norm in various ways.

Note

eCos is written for GCC. It requires C and C++ compiler support as well as a few compiler features introduced during eCos development - so compilers older than eCos may not provide these features. Note that there is no C++ support for any 8 or 16 bit CPUs. Before you can undertake an eCos port, you need the required compiler support.

The following gives a rough outline of the steps needed to create a new architecture HAL. The exact order and set of steps needed will vary greatly from architecture to architecture, so a lot of flexibility is required. And of course, if the architecture HAL is to be tested, it is necessary to do variant and platform ports for the initial target simultaneously.

1. Make a new directory for the new architecture under the `hal` directory in the source repository. Make an `arch` directory under this and populate this with the standard set of package directories.

2. Copy the CDL file from an example HAL changing its name to match the new HAL. Edit the file, changing option names as appropriate. Delete any options that are specific to the original HAL, and and any new options that are necessary for the new architecture. This is likely to be a continuing process during the development of the HAL. See the section called “CDL Requirements” for more details.

3. Copy the `hal_arch.h` file from an example HAL. Within this file you need to change or define the following:

   - Define the HAL_SavedRegisters structure. This may need to reflect the save order of any group register save/restore instructions, the interrupt and exception save and restore formats, and the procedure calling conventions. It may also need to cater for optional FPUs and other functional units. It can be quite difficult to develop a layout that copes with all requirements.

   - Define the bit manipulation routines, `HAL_LSBIT_INDEX()` and `HAL_MSBIT_INDEX()`. If the architecture contains instructions to perform these, or related, operations, then these should be defined as inline assembler fragments. Otherwise make them calls to functions.

   - Define `HAL_THREAD_INIT_CONTEXT()`. This initializes a restorable CPU context onto a stack pointer so that a later call to `HAL_THREAD_LOAD_CONTEXT()` or `HAL_THREAD_SWITCH_CONTEXT()` will execute it correctly. This macro needs to take account of the same optional features of the architecture as the definition of HAL_SavedRegisters.

   - Define `HAL_THREAD_LOAD_CONTEXT()` and `HAL_THREAD_SWITCH_CONTEXT()`. These should just be calls to functions in `context.S`.

   - Define `HAL_REORDER_BARRIER()`. This prevents code being moved by the compiler and is necessary in some order-sensitive code. This macro is actually defined identically in all architecture, so it can just be copied.

   - Define breakpoint support. The macro `HAL_BREAKPOINT(label)` needs to be an inline assembly fragment that invokes a breakpoint. The breakpoint instruction should be labeled with the *`label`* argument. `HAL_BREAKINST` and `HAL_BREAKINST_SIZE` define the breakpoint instruction for debugging purposes.

- Optionally provide a macro HAL_HWDEBUG_BREAKPOINT. This is used by the common HAL's gdb file I/O support to get the attention of gdb when using hardware debug technology such as jtag or BDM. The macro may involve a dedicated breakpoint instruction or a processor exception or trap of some sort. Only one instance of this macro will ever be invoked. It should define either one or two labels. _gdb_hwdebug_break should correspond to the address that will be reported to gdb. If that address is the same as the breakpoint instruction or trap, or if the instruction has side effects like pushing exception data onto the stack, then the macro should also define a label _gdb_hwdebug_continue. When the application is resumed gdb will transfer control to that label if defined, allowing any necessary clean-up operations to be performed.

- Define GDB support. GDB views the registers of the target as a linear array, with each register having a well defined offset. This array may differ from the ordering defined in HAL_SavedRegisters. The macros HAL_GET_GDB_REGISTERS() and HAL_SET_GDB_REGISTERS() translate between the GDB array and the HAL_SavedRegisters structure. The HAL_THREAD_GET_SAVED_REGISTERS() translates a stack pointer saved by the context switch macros into a pointer to a HAL_SavedRegisters structure. Usually this is a one-to-one translation, but this macro allows it to differ if necessary.

- Define long jump support. The type hal_jmp_buf and the functions hal_setjmp() and hal_longjmp() provide the underlying implementation of the C library setjmp() and longjmp().

- Define idle thread action. Generally the macro HAL_IDLE_THREAD_ACTION() is defined to call a function in hal_misc.c.

- Define stack sizes. The macros CYGNUM_HAL_STACK_SIZE_MINIMUM and CYGNUM_HAL_STACK_SIZE_TYPICAL should be defined to the minimum size for any thread stack and a reasonable default for most threads respectively. It is usually best to construct these out of component sizes for the CPU save state and procedure call stack usage. These definitions should not use anything other than numerical values since they can be used from assembly code in some HALs.

- Define memory access macros. These macros provide translation between cached and uncached and physical memory spaces. They usually consist of masking out bits of the supplied address and ORing in alternative address bits.

- Define global pointer save/restore macros. These really only need defining if the calling conventions of the architecture require a global pointer (as does the MIPS architecture), they may be empty otherwise. If it is necessary to define these, then take a look at the MIPS implementation for an example.

4. Copy hal_intr.h from an example HAL. Within this file you should change or define the following:

   - Define the exception vectors. These should be detailed in the architecture specification. Essentially for each exception entry point defined by the architecture there should be an entry in the VSR table. The offsets of these VSR table entries should be defined here by CYGNUM_HAL_VECTOR_* definitions. The size of the VSR table also needs to be defined here.

   - Map any hardware exceptions to standard names. There is a group of exception vector name of the form CYGNUM_HAL_EXCEPTION_* that define a wide variety of possible exceptions that many architectures raise. Generic code detects whether the architecture can raise a given exception by testing whether a given CYGNUM_HAL_EXCEPTION_* definition is present. If it is present then its value is the vector that raises that exception. This does not need to be a one-to-one correspondence, and several CYGNUM_HAL_EXCEPTION_* definitions may have the same value.

     Interrupt vectors are usually defined in the variant or platform HALs. The interrupt number space may either be continuous with the VSR number space, where they share a vector table (as in the i386) or may be a separate space where a separate decode stage is used (as in MIPS or PowerPC).

   - Declare any static data used by the HAL to handle interrupts and exceptions. This is usually three vectors for interrupts: hal_interrupt_handlers[], hal_interrupt_data[] and hal_interrupt_objects[], which are sized according to the interrupt vector definitions. In addition a definition for the VSR table, hal_vsr_table[] should be made. These vectors are normally defined in either vectors.S or hal_misc.c.

   - Define interrupt enable/disable macros. These are normally inline assembly fragments to execute the instructions, or manipulate the CPU register, that contains the CPU interrupt enable bit.

- A feature that many HALs support is the ability to execute DSRs on the interrupt stack. This is not an essential feature, and is better left unimplemented in the initial porting effort. If this is required, then the macro `HAL_INTERRUPT_STACK_CALL_PENDING_DSRS()` should be defined to call a function in `vectors.S`.
- Define the interrupt and VSR attachment macros. If the same arrays as for other HALs have been used for VSR and interrupt vectors, then these macro can be copied across unchanged.

5. A number of other header files also need to be filled in:

   - `basetype.h`. This file defines the basic types used by eCos, together with the endianness and some other characteristics. This file only really needs to contain definitions if the architecture differs significantly from the defaults defined in `cyg_type.h`
   - `hal_io.h`. This file contains macros for accessing device IO registers. If the architecture uses memory mapped IO, then these can be copied unchanged from an existing HAL such as MIPS. If the architecture uses special IO instructions, then these macros must be defined as inline assembler fragments. See the I386 HAL for an example. PCI bus access macros are usually defined in the variant or platform HALs.

     This file may also provide further macro definitions, if relevant for the underlying hardware:

     `HAL_MEMORY_BARRIER()`

     This causes any memory writes pending within the CPU to be flushed to memory before continuing. Frequently there is a specific instruction, such as **sync** on MIPS, to cause write buffers to be flushed. This macro is generally not relevant to be called if you also have a writeback data cache, as that needs separate treatment. However this macro is relevant for systems with no data cache, a writethrough data cache, or in code running with the data cache disabled. For the latter reason this macro should be implemented if the facility exists, irrespective of the cache properties.

     `HAL_IO_BARRIER()`

     This causes any I/O writes pending within the CPU to be flushed to the I/O space before continuing. Frequently there is a specific instruction, such as **eieio** on PowerPC, to cause such pending writes to be guaranteed to be committed. On systems with no separate I/O space, such that all device access is instead memory-mapped, then this function may be defined to be the same as `HAL_MEMORY_BARRIER()`.
   - `hal_cache.h`. This file contains cache access macros. If the architecture defines cache instructions, or control registers, then the access macros should be defined here. Otherwise they must be defined in the variant or platform HAL. Usually the cache dimensions (total size, line size, ways etc.) are defined in the variant HAL.
   - `arch.inc` and `<architecture>.inc`. These files are assembler headers used by `vectors.S` and `context.S`. `<architecture>.inc` is a general purpose header that should contain things like register aliases, ABI definitions and macros useful to general assembly code. If there are no such definitions, then this file need not be provided. `arch.inc` contains macros for performing various eCos related operations such as initializing the CPU, caches, FPU etc. The definitions here may often be configured or overridden by definitions in the variant or platform HALs. See the MIPS HAL for an example of this.

6. Write `vectors.S`. This is the most important file in the HAL. It contains the CPU initialization code, exception and interrupt handlers. While other HALs should be consulted for structures and techniques, there is very little here that can be copied over without major edits.

   The main pieces of code that need to be defined here are:

   - Reset vector. This usually need to be positioned at the start of the ROM or FLASH, so should be in a linker section of its own. It can then be placed correctly by the linker script. Normally this code is little more than a jump to the label `_start`.
   - Exception vectors. These are the trampoline routines connected to the hardware exception entry points that vector through the VSR table. In many architectures these are adjacent to the reset vector, and should occupy the same linker section. If

the architecture allow the vectors to be moved then it may be necessary for these trampolines to be position independent so they can be relocated at runtime.

The trampolines should do the minimum necessary to transfer control from the hardware vector to the VSR pointed to by the matching table entry. Exactly how this is done depends on the architecture. Usually the trampoline needs to get some working registers by either saving them to CPU special registers (e.g. PowerPC SPRs), using reserved general registers (MIPS K0 and K1), using only memory based operations (IA32), or just jumping directly (ARM). The VSR table index to be used is either implicit in the entry point taken (PowerPC, IA32, ARM), or must be determined from a CPU register (MIPS).

- Write kernel startup code. This is the location the reset vector jumps to, and can be in the main text section of the executable, rather than a special section. The code here should first initialize the CPU and other hardware subsystems. The best approach is to use a set of macro calls that are defined either in `arch.inc` or overridden in the variant or platform HALs. Other jobs that this code should do are: initialize stack pointer; copy the data section from ROM to RAM if necessary; zero the BSS; call variant and platform initializers; call `cyg_hal_invoke_constructors()`; call `initialize_stub()` if necessary. Finally it should call `cyg_start()`. See the section called “HAL Startup” for details.
- Write the default exception VSR. This VSR is installed in the VSR table for all synchronous exception vectors. See the section called “Default Synchronous Exception Handling” for details of what this VSR does.
- Write the default interrupt VSR. This is installed in all VSR table entries that correspond to external interrupts. See the section called “Default Synchronous Exception Handling” for details of what this VSR does.
- Write `hal_interrupt_stack_call_pending_dsrs()`. If this function is defined in `hal_arch.h` then it should appear here. The purpose of this function is to call DSRs on the interrupt stack rather than the current thread's stack. This is not an essential feature, and may be left until later. However it interacts with the stack switching that goes on in the interrupt VSR, so it may make sense to write these pieces of code at the same time to ensure consistency.

  When this function is implemented it should do the following:

  - Take a copy of the current SP and then switch to the interrupt stack.
  - Save the old SP, together with the CPU status register (or whatever register contains the interrupt enable status) and any other registers that may be corrupted by a function call (such as any link register) to locations in the interrupt stack.
  - Enable interrupts.
  - Call `cyg_interrupt_call_pending_DSRs()`. This is a kernel functions that actually calls any pending DSRs.
  - Retrieve saved registers from the interrupt stack and switch back to the current thread stack.
  - Merge the interrupt enable state recorded in the save CPU status register with the current value of the status register to restore the previous enable state. If the status register does not contain any other persistent state then this can be a simple restore of the register. However if the register contains other state bits that might have been changed by a DSR, then care must be taken not to disturb these.
- Define any data items needed. Typically `vectors.S` may contain definitions for the VSR table, the interrupt tables and the interrupt stack. Sometimes these are only default definitions that may be overridden by the variant or platform HALs.

7. Write `context.S`. This file contains the context switch code. See the section called “Thread Context Switching” for details of how these functions operate. This file may also contain the implementation of `hal_setjmp()` and `hal_longjmp()`.
8. Write `hal_misc.c`. This file contains any C data and functions needed by the HAL. These might include:

   - `hal_interrupt_*[]`. In some HALs, if these arrays are not defined in `vectors.S` then they must be defined here.
   - `cyg_hal_exception_handler()`. This function is called from the exception VSR. It usually does extra decoding of the exception and invokes any special handlers for things like FPU traps, bus errors or memory exceptions. If there is nothing

special to be done for an exception, then it either calls into the GDB stubs, by calling `__handle_exception()`, or invokes the kernel by calling `cyg_hal_deliver_exception()`.

- `hal_arch_default_isr()`. The `hal_interrupt_handlers[]` array is usually initialized with pointers to `hal_default_isr()`, which is defined in the common HAL. This function handles things like Ctrl-C processing, but if that is not relevant, then it will call `hal_arch_default_isr()`. Normally this function should just return zero.

- `cyg_hal_invoke_constructors()`. This calls the constructors for all static objects before the program starts. eCos relies on these being called in the correct order for it to function correctly. The exact way in which constructors are handled may differ between architectures, although most use a simple table of function pointers between labels `__CTOR_LIST__` and `__CTOR_END__` which must called in order from the top down. Generally, this function can be copied directly from an existing architecture HAL.

- Bit indexing functions. If the macros `HAL_LSBIT_INDEX()` and `HAL_MSBIT_INDEX()` are defined as function calls, then the functions should appear here. The main reason for doing this is that the architecture does not have support for bit indexing and these functions must provide the functionality by conventional means. While the trivial implementation is a simple for loop, it is expensive and non-deterministic. Better, constant time, implementations can be found in several HALs (MIPS for example).

- `hal_delay_us()`. If the macro `HAL_DELAY_US()` is defined in `hal_intr.h` then it should be defined to call this function. While most of the time this function is called with very small values, occasionally (particularly in some ethernet drivers) it is called with values of several seconds. Hence the function should take care to avoid overflow in any calculations.

- `hal_idle_thread_action()`. This function is called from the idle thread via the `HAL_IDLE_THREAD_ACTION()` macro, if so defined. While normally this function does nothing, during development this is often a good place to report various important system parameters on LCDs, LED or other displays. This function can also monitor system state and report any anomalies. If the architecture supports a `halt` instruction then this is a good place to put an inline assembly fragment to execute it. It is also a good place to handle any power saving activity.

9. Create the `<architecture>.ld` file. While this file may need to be moved to the variant HAL in the future, it should initially be defined here, and only moved if necessary.

   This file defines a set of macros that are used by the platform `.ldi` files to generate linker scripts. Most GCC toolchains are very similar so the correct approach is to copy the file from an existing architecture and edit it. The main things that will need editing are the `OUTPUT_FORMAT()` directive and maybe the creation or allocation of extra sections to various macros. Running the target linker with just the `--verbose` argument will cause it to output its default linker script. This can be compared with the `.ld` file and appropriate edits made.

10. If GDB stubs are to be supported in RedBoot or eCos, then support must be included for these. The most important of these are `include/<architecture>-stub.h` and `src/<architecture>-stub.c`. In all existing architecture HALs these files, and any support files they need, have been derived from files supplied in `libgloss`, as part of the GDB toolchain package. If this is a totally new architecture, this may not have been done, and they must be created from scratch.

    `include/<architecture>-stub.h` contains definitions that are used by the GDB stubs to describe the size, type, number and names of CPU registers. This information is usually found in the GDB support files for the architecture. It also contains prototypes for the functions exported by `src/<architecture>-stub.c`; however, since this is common to all architectures, it can be copied from some other HAL.

    `src/<architecture>-stub.c` implements the functions exported by the header. Most of this is fairly straight forward: the implementation in existing HALs should show exactly what needs to be done. The only complex part is the support for single-stepping. This is used a lot by GDB, so it cannot be avoided. If the architecture has support for a trace or single-step trap then that can be used for this purpose. If it does not then this must be simulated by planting a breakpoint in the next instruction. This can be quite involved since it requires some analysis of the current instruction plus the state of the CPU to determine where execution is going to go next.

CDL Requirements

The CDL needed for any particular architecture HAL depends to a large extent on the needs of that architecture. This includes issues such as support for different variants, use of FPUs, MMUs and caches. The exact split between the architecture, variant and platform HALs for various features is also somewhat fluid.

To give a rough idea about how the CDL for an architecture is structured, we will take as an example the I386 CDL.

This first section introduces the CDL package and placed it under the main HAL package. Include files from this package will be put in the `include/cyg/hal` directory, and definitions from this file will be placed in `include/pkgconf/hal_i386.h`. The `compile` line specifies the files in the `src` directory that are to be compiled as part of this package.

```
cdl_package CYGPKG_HAL_I386 {
    display       "i386 architecture"
    parent        CYGPKG_HAL
    hardware
    include_dir   cyg/hal
    define_header hal_i386.h
    description   "
        The i386 architecture HAL package provides generic
        support for this processor architecture. It is also
        necessary to select a specific target platform HAL
        package."

    compile       hal_misc.c context.S i386_stub.c hal_syscall.c
```

Next we need to generate some files using non-standard make rules. The first is `vectors.S`, which is not put into the library, but linked explicitly with all applications. The second is the generation of the `target.ld` file from `i386.ld` and the startup-selected `.ldi` file. Both of these are essentially boilerplate code that can be copied and edited.

```
make {
    <PREFIX>/lib/vectors.o : <PACKAGE>/src/vectors.S
    $(CC) -Wp,-MD,vectors.tmp $(INCLUDE_PATH) $(CFLAGS) -c -o $@ $<
    @echo $@ ": \\" > $(notdir $@).deps
    @tail +2 vectors.tmp >> $(notdir $@).deps
    @echo >> $(notdir $@).deps
    @rm vectors.tmp
}

make {
    <PREFIX>/lib/target.ld: <PACKAGE>/src/i386.ld
    $(CC) -E -P -Wp,-MD,target.tmp -DEXTRAS=1 -xc $(INCLUDE_PATH) $(CFLAGS) -o $@ $<
    @echo $@ ": \\" > $(notdir $@).deps
    @tail +2 target.tmp >> $(notdir $@).deps
    @echo >> $(notdir $@).deps
    @rm target.tmp
}
```

The i386 is currently the only architecture that supports SMP. The following CDL simply enabled the HAL SMP support if required. Generally this will get enabled as a result of a `requires` statement in the kernel. The `requires` statement here turns off lazy FPU switching in the FPU support code, since it is inconsistent with SMP operation.

```
cdl_component CYGPKG_HAL_SMP_SUPPORT {
    display       "SMP support"
    default_value 0
    requires { CYGHWR_HAL_I386_FPU_SWITCH_LAZY == 0 }

    cdl_option CYGPKG_HAL_SMP_CPU_MAX {
        display       "Max number of CPUs supported"
        flavor        data
        default_value 2
    }
}
```

The i386 HAL has optional FPU support, which is enabled by default. It can be disabled to improve system performance. There are two FPU support options: either to save and restore the FPU state on every context switch, or to only switch the FPU state when necessary.

```
cdl_component CYGHWR_HAL_I386_FPU {
    display       "Enable I386 FPU support"
    default_value 1
    description   "This component enables support for the
        I386 floating point unit."

    cdl_option CYGHWR_HAL_I386_FPU_SWITCH_LAZY {
        display       "Use lazy FPU state switching"
        flavor        bool
        default_value 1

        description "
            This option enables lazy FPU state switching.
            The default behaviour for eCos is to save and
            restore FPU state on every thread switch, interrupt
            and exception. While simple and deterministic, this
            approach can be expensive if the FPU is not used by
            all threads. The alternative, enabled by this option,
            is to use hardware features that allow the FPU state
            of a thread to be left in the FPU after it has been
            descheduled, and to allow the state to be switched to
            a new thread only if it actually uses the FPU. Where
            only one or two threads use the FPU this can avoid a
            lot of unnecessary state switching."
    }
}
```

The i386 HAL also has support for different classes of CPU. In particular, Pentium class CPUs have extra functional units, and some variants of GDB expect more registers to be reported. These options enable these features. Generally these are enabled by `requires` statements in variant or platform packages, or in `.ecm` files.

```
cdl_component CYGHWR_HAL_I386_PENTIUM {
    display       "Enable Pentium class CPU features"
    default_value 0
    description   "This component enables support for various
        features of Pentium class CPUs."

    cdl_option CYGHWR_HAL_I386_PENTIUM_SSE {
        display       "Save/Restore SSE registers on context switch"
        flavor        bool
        default_value 0

        description "
            This option enables SSE state switching. The default
            behaviour for eCos is to ignore the SSE registers.
            Enabling this option adds SSE state information to
            every thread context."
    }

    cdl_option CYGHWR_HAL_I386_PENTIUM_GDB_REGS {
        display       "Support extra Pentium registers in GDB stub"
        flavor        bool
        default_value 0

        description "
        This option enables support for extra Pentium registers
        in the GDB stub. These are registers such as CR0-CR4, and
        all MSRs. Not all GDBs support these registers, so the
        default behaviour for eCos is to not include them in the
        GDB stub support code."
    }
}
```

In the i386 HALs, the linker script is provided by the architecture HAL. In other HALs, for example MIPS, it is provided in the variant HAL. The following option provides the name of the linker script to other elements in the configuration system.

```
    cdl_option CYGBLD_LINKER_SCRIPT {
        display "Linker script"
        flavor data
        no_define
        calculated  { "src/i386.ld" }
    }
```

Finally, this interface indicates whether the platform supplied an implementation of the `hal_i386_mem_real_region_top()` function. If it does then it will contain a line of the form: `implements CYGINT_HAL_I386_MEM_REAL_REGION_TOP`. This allows packages such as RedBoot to detect the presence of this function so that they may call it.

```
    cdl_interface CYGINT_HAL_I386_MEM_REAL_REGION_TOP {
        display  "Implementations of hal_i386_mem_real_region_top()"
    }

}
```

Chapter 8. Future developments

The HAL is not complete, and will evolve and increase over time. Among the intended developments are:

- Common macros for interpreting the contents of a saved machine context. These would allow portable code, such as debug stubs, to extract such values as the program counter and stack pointer from a state without having to interpret a HAL_SavedRegisters structure directly.

- Debugging support. Macros to set and clear hardware and software breakpoints. Access to other areas of machine state may also be supported.

- Static initialization support. The current HAL provides a dynamic interface to things like thread context initialization and ISR attachment. We also need to be able to define the system entirely statically so that it is ready to go on restart, without needing to run code. This will require extra macros to define these initializations. Such support may have a consequential effect on the current HAL specification.

- CPU state control. Many CPUs have both kernel and user states. Although it is not intended to run any code in user state for the foreseeable future, it is possible that this may happen eventually. If this is the case, then some minor changes may be needed to the current HAL API to accommodate this. These should mostly be extensions, but minor changes in semantics may also be required.

- Physical memory management. Many embedded systems have multiple memory areas with varying properties such as base address, size, speed, bus width, cacheability and persistence. An API is needed to support the discovery of this information about the machine's physical memory map.

- Memory management control. Some embedded processors have a memory management unit. In some cases this must be enabled to allow the cache to be controlled, particularly if different regions of memory must have different caching properties. For some purposes, in some systems, it will be useful to manipulate the MMU settings dynamically.

- Power management. Macros to access and control any power management mechanisms available on the CPU implementation. These would provide a substrate for a more general power management system that also involved device drivers and other hardware components.

- Generic serial line macros. Most serial line devices operate in the same way, the only real differences being exactly which bits in which registers perform the standard functions. It should be possible to develop a set of HAL macros that provide basic serial line services such as baud rate setting, enabling interrupts, polling for transmit or receive ready, transmitting and receiving data etc. Given these it should be possible to create a generic serial line device driver that will allow rapid bootstrapping on any new platform. It may be possible to extend this mechanism to other device types.

Part III. The ISO Standard C and Math Libraries

Table of Contents

Chapter 9. C and math library overview

eCos provides compatibility with the ISO 9899:1990 specification for the standard C library, which is essentially the same as the better-known ANSI C3.159-1989 specification (C-89).

There are three aspects of this compatibility supplied by *eCos*. First there is a *C library* which implements the functions defined by the ISO standard, except for the mathematical functions. This is provided by the eCos C library packages.

Then *eCos* provides a math library, which implements the mathematical functions from the ISO C library. This distinction between C and math libraries is frequently drawn — most standard C library implementations provide separate linkable files for the two, and the math library contains all the functions from the `math.h` header file.

There is a third element to the ISO C library, which is the environment in which applications run when they use the standard C library. This environment is set up by the C library startup procedure (the section called “C library startup”>) and it provides (among other things) a `main()` entry point function, an `exit()` function that does the cleanup required by the standard (including handlers registered using the `atexit()` function), and an environment that can be read with `getenv()`.

The description in this manual focuses on the *eCos*-specific aspects of the C library (mostly related to *eCos*'s configurability) as well as mentioning the omissions from the standard in this release. We do not attempt to define the semantics of each function, since that information can be found in the ISO, ANSI, POSIX and IEEE standards, and the many good books that have been written about the standard C library, that cover usage of these functions in a more general and useful way.

Included non-ISO functions

The following functions from the POSIX specification are included for convenience:

`extern char **`*environ* variable (for setting up the environment for use with `getenv()`)
`_exit()`
`strtok_r()`
`rand_r()`
`asctime_r()`
`ctime_r()`
`localtime_r()`
`gmtime_r()`

eCos provides the following additional implementation-specific functions within the standard C library to adjust the date and time settings:

```
void cyg_libc_time_setdst(
    cyg_libc_time_dst state
);
```

This function sets the state of Daylight Savings Time. The values for state are:

```
CYG_LIBC_TIME_DSTNA   unknown
CYG_LIBC_TIME_DSTOFF  off
CYG_LIBC_TIME_DSTON   on
```

These values will be reflected in the `tm_isdst` member of a struct tm. No other meaning is given to `CYG_LIBC_TIME_DSTNA`, and in particular it is not interpreted as any sort of "auto-detect" value, as eCos does not have the extensive timezone information that would be required in order to provide this. A call to `mktime()` with `tm_isdst` set to `-1` (which corresponds to `CYG_LIBC_TIME_DSTNA`) will be treated as if the supplied time is in UTC, i.e. with neither standard time nor Daylight Savings Time offsets applied.

```
void cyg_libc_time_setzoneoffsets(
    time_t stdoffset, time_t dstoffset
);
```

This function sets the offsets from UTC used when Daylight Savings Time is enabled or disabled. The offsets are in time_t,s, which are seconds in the current inplementation.

```
Cyg_libc_time_dst cyg_libc_time_getzoneoffsets(
    time_t *stdoffset, time_t *dstoffset
);
```

This function retrieves the current setting for Daylight Savings Time along with the offsets used for both STD and DST. The offsets are both in time_t,s, which are seconds in the current implementation.

```
cyg_bool cyg_libc_time_settime(
      time_t utctime
);
```

This function sets the current time for the system The time is specified as a time_t in UTC. It returns non-zero on error.

Math library compatibility modes

This math library is capable of being operated in several different compatibility modes. These options deal solely with how errors are handled.

There are 4 compatibility modes: ANSI/POSIX 1003.1; IEEE-754; X/Open Portability Guide issue 3 (XPG3); and System V Interface Definition Edition 3.

In IEEE mode, the `matherr()` function (see below) is never called, no warning messages are printed on the stderr output stream, and errno is never set.

In ANSI/POSIX mode, errno is set correctly, but `matherr()` is never called and no warning messages are printed on the stderr output stream.

In X/Open mode, errno is set correctly, `matherr()` is called, but no warning messages are printed on the stderr output stream.

In SVID mode, functions which overflow return a value HUGE (defined in `math.h`), which is the maximum single precision floating point value (as opposed to HUGE_VAL which is meant to stand for infinity). errno is set correctly and `matherr()` is called. If `matherr()` returns 0, warning messages are printed on the stderr output stream for some errors.

The mode can be compiled-in as IEEE-only, or any one of the above methods settable at run-time.

Note

This math library assumes that the hardware (or software floating point emulation) supports IEEE-754 style arithmetic, 32-bit 2's complement integer arithmetic, doubles are in 64-bit IEEE-754 format.

matherr()

As mentioned above, in X/Open or SVID modes, the user can supply a function `matherr()` of the form:

```
int matherr( struct exception *e )
```

where struct exception is defined as:

```
struct exception {
  int type;
  char *name;
  double arg1, arg2, retval;
};
```

type is the exception type and is one of:

DOMAIN

argument domain exception

SING

argument singularity

OVERFLOW

overflow range exception

UNDERFLOW

underflow range exception

TLOSS

total loss of significance

PLOSS

partial loss of significance

`name` is a string containing the name of the function

`arg1` and `arg2` are the arguments passed to the function

`retval` is the default value that will be returned by the function, and can be changed by `matherr()`

Note

matherr must have “C” linkage, not “C++” linkage.

If matherr returns zero, or the user doesn't supply their own matherr, then the following *usually* happens in SVID mode:

Table 9.1. Behavior of math exception handling

Type	Behavior
DOMAIN	0.0 returned, errno=EDOM, and a message printed on stderr
SING	HUGE of appropriate sign is returned, errno=EDOM, and a message is printed on stderr
OVERFLOW	HUGE of appropriate sign is returned, and errno=ERANGE
UNDERFLOW	0.0 is returned and errno=ERANGE
TLOSS	0.0 is returned, errno=ERANGE, and a message is printed on stderr
PLOSS	The current implementation doesn't return this type

X/Open mode is similar except that the message is not printed on stderr and HUGE_VAL is used in place of HUGE

Thread-safety and re-entrancy

With the appropriate configuration options set below, the math library is fully thread-safe if:

- Depending on the compatibility mode, the setting of the errno variable from the C library is thread-safe

- Depending on the compatibility mode, sending error messages to the stderr output stream using the C library `fputs()` function is thread-safe
- Depending on the compatibility mode, the user-supplied `matherr()` function and anything it depends on are thread-safe

In addition, with the exception of the `gamma*()` and `lgamma*()` functions, the math library is reentrant (and thus safe to use from interrupt handlers) if the Math library is always in IEEE mode.

Some implementation details

Here are some details about the implementation which might be interesting, although they do not affect the ISO-defined semantics of the library.

- It is possible to configure *eCos* to have the standard C library without the kernel. You might want to do this to use less memory.
- The opaque type returned by `clock()` is called clock_t, and is implemented as a 64 bit integer. The value returned by `clock()` is only correct if the kernel is configured with real-time clock support, as determined by the CYGVAR_KERNEL_COUNTERS_CLOCK configuration option in `kernel.h` .
- The FILE type is not implemented as a structure, but rather as a CYG_ADDRESS.
- The GNU C compiler will replace its own *built-in* implementations instead of calls to some C library functions. This can be turned off with the *-fno-builtin* option. But it is recommended for normal use to leave compiler builtins enabled. The functions affected by this are described in the documentation associated with the particular GNU compiler version you are using, but include at least:

  ```
  abs()
  cos()
  fabs()
  labs()
  memcmp()
  memcpy()
  sin()
  sqrt()
  strcmp()
  strcpy()
  strlen()
  ```

- `memcpy()` and `memset()` are located in the infrastructure package, not in the C library package. This is because the compiler calls these functions, and the kernel needs to resolve them even if the C library is not configured.
- Error codes such as EDOM and ERANGE, as well as `strerror()` , are implemented in the *error* package. The error package is separate from the rest of the C and math libraries so that the rest of *eCos* can use these error handling facilities even if the C library is not configured.
- The memory allocation package `CYGPKG_MEMALLOC` is responsible for providing the various heap management functions such as `malloc()`, `free()`, etc.
- Signals, as implemented by `<signal.h>`, are guaranteed to work correctly if raised using the `raise()` function from a normal working program context. Using signals from within an ISR or DSR context is not expected to work. Also, it is not guaranteed that if CYGSEM_LIBC_SIGNALS_HWEXCEPTIONS is set, that handling a signal using `signal()` will necessarily catch that form of exception. For example, it may be expected that a divide-by-zero error would be caught by handling `SIGFPE`. However it depends on the underlying HAL implementation to implement the required hardware exception. And indeed the hardware itself may not be capable of detecting these exceptions so it may not be possible for the HAL implementer to do this in any case. Despite this lack of guarantees in this respect, the signals implementation is still ISO C compliant since ISO C does not offer any such guarantees either.
- If you include the POSIX compatibility layer in your configuration, by default it will present a conflict if the C library signals implementation is also present. Only one signals implementation may be present.
- The `getenv()` function is implemented (as long as the CYGPKG_LIBC_STDLIB package is present in your configuration), but there is no shell or `putenv()` function to set the environment dynamically. The environment is set in a global variable environ, declared as:

```
extern char **environ; // Standard environment definition
```

If the "ISO environment startup/termination" (CYGPKG_LIBC_STARTUP) package is included in your configuration, the environment can be statically initialized at startup time using the CYGDAT_LIBC_DEFAULT_ENVIRONMENT option. If so, remember that the final entry of the array initializer must be NULL.

Here is a minimal *eCos* program which demonstrates the use of environments (see also the test case in `language/c/libc/`*`VERSION`*`/tests/stdlib/getenv.c`):

```
#include <stdio.h>
#include <stdlib.h> // Main header for stdlib functions

extern char **environ; // Standard environment definition

int
main( int argc, char *argv[] )
{
    char *str;
    char *env[] = { "PATH=/usr/local/bin:/usr/bin",
    "HOME=/home/fred",
    "TEST=1234=5678",
    "home=hatstand",
    NULL };

    printf("Display the current PATH environment variable\n");

    environ = (char **)&env;

    str = getenv("PATH");

    if (str==NULL) {
        printf("The current PATH is unset\n");
    } else {
        printf("The current PATH is \"%s\"\n", str);
    }
    return 0;
}
```

Thread safety

The ISO C library has configuration options that control thread safety, i.e. working behavior if multiple threads call the same function at the same time.

The following functionality has to be configured correctly, or used carefully in a multi-threaded environment:

- **`mblen`** `();`
- **`mbtowc`** `();`
- **`wctomb`** `();`
- **`printf`** `();`

  and all standard I/O functions except for

  `sprintf()` `();`
  `sscanf` `();`
- **`strtok`** `();`
- **`rand`** `();`

  srand ();

- **signal** ();
  raise ();

- **asctime** ();
  ctime ();
  gmtime ();
  localtime ();

- the `errno` variable

- the `environ` variable

- date and time settings

In some cases, to make *eCos* development easier, functions are provided (as specified by POSIX 1003.1) that define re-entrant alternatives, i.e. `rand_r()`, `strtok_r()`, `asctime_r()`, `ctime_r()`, `gmtime_r()`, and `localtime_r()`. In other cases, configuration options are provided that control either locking of functions or their shared data, such as with standard I/O streams, or by using per-thread data, such as with the `errno` variable.

In some other cases, like the setting of date and time, no re-entrant or thread-safe alternative or configuration is provided as it is simply not a worthwhile addition (date and time should rarely need to be set.)

C library startup

The C library includes a function declared as:

```
void cyg_iso_c_start( void )
```

This function is used to start an environment in which an ISO C style program can run in the most compatible way.

What this function does is to create a thread which will invoke `main()` — normally considered a program's entry point. In particular, it can supply arguments to `main()` using the CYGDAT_LIBC_ARGUMENTS configuration option, and when returning from `main()`, or calling `exit()`, pending stdio file output is flushed and any functions registered with `atexit()` are invoked. This is all compliant with the ISO C standard in this respect.

This thread starts execution when the *eCos* scheduler is started. If the *eCos* kernel package is not available (and hence there is no scheduler), then `cyg_iso_c_start()` will invoke the `main()` function directly, i.e. it will not return until the `main()` function returns.

The `main()` function should be defined as the following, and if defined in a C++ file, should have “C” linkage:

```
extern int main(
    int argc,
    char *argv[] )
```

The thread that is started by `cyg_iso_c_start()` can be manipulated directly, if you wish. For example you can suspend it. The kernel C API needs a handle to do this, which is available by including the following in your source code.

```
extern cyg_handle_t cyg_libc_main_thread;
```

Then for example, you can suspend the thread with the line:

```
cyg_thread_suspend( cyg_libc_main_thread );
```

If you call `cyg_iso_c_start()` and do not provide your own `main()` function, the system will provide a `main()` for you which will simply return immediately.

In the default configuration, `cyg_iso_c_start()` is invoked automatically by the `cyg_package_start()` function in the infrastructure configuration. This means that in the simplest case, your program can indeed consist of simply:

```
int main( int argc, char *argv[] )
{
    printf("Hello eCos\n");
}
```

If you override `cyg_package_start()` or `cyg_start()`, or disable the infrastructure configuration option CYGSEM_START_ISO_C_COMPATIBILITY then you must ensure that you call `cyg_iso_c_start()` yourself if you want to be able to have your program start at the entry point of `main()` automatically.

Chapter 10. Overview of ISO Standards Compliance

This chapter has been prepared in order to provide an overview of the compliance of the eCos Standard C and Math libraries against ISO C and C++ Standards, as implemented in eCosPro.

It is intended to describe functionality required by the ISO/IEC 9899:2011 C and ISO/IEC 14882:2011 C++ standards which is missing, as well as behaviour which differs from the standards, or only meets the specification of the standards in part. This documentation is focused on these 2011 revisions of the standards, and earlier and later revisions of these standards are not covered.

Further details on compliance with the ISO C++ standard can be found in the documentation on eCosPro's Standard C++ support.

The general approach which will be taken is to describe standards compliance with regard to the APIs defined by each standard header file, in turn. By examining compliance on a header by header basis, rather than looking at each standard in turn, it is hoped to avoid confusing duplication due to the considerable overlap in headers between the C and C++ standards.

Definitions

Some terms are frequently used in this document, or only used in shorthand form, and are defined here to allow us to reference them later more conveniently.

C90
: The ISO/IEC 9899:1990 C standard, occasionally also known as C89, or informally as “ANSI C” (which differ only in formatting with the ISO standard).

C99
: The ISO/IEC 9899:1999 C standard

C11
: The ISO/IEC 9899:2011 C standard

C++11
: The ISO/IEC 14882:2011 C++ standard. Note that this standard does not implicitly require the C11 standard, but the C99 standard.

GCC
: The GNU Compiler Collection, including C and C++ compilers. Unless otherwise described, this should be taken as to refer to GCC 7 including patches supplied by eCosCentric in order to support use with eCosPro. Vanilla GCC sources from the main GCC download sites are not suitable for use without the eCosPro-specific patches.

libstdc++
: The Standard C++ Library provided by GCC. It provides much of the library functionality defined by the C++ standard.

Scope

Broadly, this documentation is only intended as an overview. Although it is intended to cover as much as possible, it is not guaranteed to be fully complete. While broad areas of non-compliance should be identified here, some elements of finer detail not in compliance with the standards may not have been addressed. As a result, this documentation does not warrant that, just because non-compliance has not been identified here, that that means that eCosPro and GCC are fully compliant in all remaining areas.

At time of writing, eCosPro is currently supplied with GCC 7, which is a version of the compiler intended to be compliant with the C11 and C++11 standards.

Although there are exceptions, in general, GCC provides language parts of standard, eCos provides runtime library parts of standard, but GCC must interact with eCos for various abstractions. GCC also provides the Standard C++ Library (libstdc++). In this document, we do not cover conformance of portions provided by GCC, including the majority of the very large Standard C++ library.

For more information on GCC's standards compliance, the webpage at https://gcc.gnu.org/onlinedocs/gcc-7.3.0/gcc/Standards.html may be informative (also note that the similarly named webpage https://gcc.gnu.org/onlinedocs/gcc/Standards.html refers to GCC standards compliance information for the very latest version of GCC, and not necessarily the version supplied by eCosCentric for use with eCosPro).

There is also detailed information on GCC's ongoing compliance efforts with the various C++ standards, described at https://www.gnu.org/software/gcc/projects/cxx-status.html.

This documentation only covers compliance against the C11 and C++11 standards. It does not cover the specifics of more recent revisions of the standards such as C18, C++14 or C++17, even though it is understood some of the differences are well understood, and for example in the case of C++11 versus C++14, the differences are relatively small.

General Overview

Much of the support for the runtime library portions of the standards comes from the C library suite of packages, with certain elements also coming from the Infrastructure package. In general, the eCos C library was written to be compliant with the C90 standard, with some elements of C99 compliance added subsequently.

Particularly notable and wide-ranging omissions are in the areas of internationalization and localization, such as wide character and multibyte character variations of functions, many of which are absent. This also affects the level of internationalization/localization functionality that libstdc++ is able to provide as well.

Standard eCos headers occasionally make use of identifiers which are not reserved by the standard, which means that these identifiers may not be able to be used by programs which would otherwise be C11/C++11 standards-compliant. This is typically known as "namespace pollution", and fortunately is usually easy to work around.

Building with the GCC compiler flag `-std=`... may not work as intended as eCos headers do not always adapt to different language standard requirements.

Function prototypes that are expected to use the "`restrict`" keyword for arguments widely do not do so.

Annex K of C11 describes bounds-checking variants of many standard functions. This is an optional part of the standard and eCos does not implement it.

Feature-test macros such as those defined in C11 sections 6.10.8.2 and 6.10.8.3 (all of which begin with the prefix "`__STDC_`") are not defined.

Common C/C++ headers

These headers are required by both the C11 and C++11 standards, although note that strictly C++11 itself only requires C99 compliance.

In all cases, where the C++11 standard describes a C++ wrapper for the listed header files, such as `<cassert>` for `<assert.h>` or `<cstdlib>` for `<stdlib.h>`, these comments apply equally to headers included via these wrappers.

`<assert.h>`

static_assert is not defined.

`<complex.h>`

This header is not provided if compiling for C11. Unusually, a compatibility header is provided by GCC if compiling for C++11 to provide an implementation of specific elements from the C++ standard.

<ctype.h>

No compliance issues noticed.

<errno.h>

No compliance issues noticed.

<fenv.h>

This header is not supported by eCos.

<float.h>

No compliance issues noticed.

<inttypes.h>

This header is provided by eCos. It includes integer type format string definitions to be used with the `printf()` and `scanf()` families of functions. It also includes the `imaxabs()`, `imaxdiv()`, `strtoimax()` and `strtoumax()` functions. However the wide character related functions `wcstoimax()` and `wcstoumax()` are not implemented.

<iso646.h>

No compliance issues noticed.

<limits.h>

No compliance issues noticed.

<locale.h>

“struct lconv” does not contain members: *`int_p_cs_precedes`*, *`int_n_cs_precedes`*, *`int_p_sep_by_space`*, *`int_n_sep_by_space`*, *`int_p_sign_posn`*, *`int_n_sign_posn`*.

<math.h>

The following identifiers are not defined: `HUGE_VALL`, `INFINITY`, `NAN`, `FP_FASTFMA*`, `FP_ILOG*`.

Error handling does not use `math_errhandling` to generate floating point exceptions. `MATH_ERRNO`, `MATH_ERREXCEPT`, `math_errhandling` are not defined.

No “long double” variants of any maths functions are provided. For example, `sin()` and `sinf()` are provided, but not `sinl()`.

None of `llround()`, `llroundf()` or `llroundl()` are provided. None of the `nexttoward()`, `nexttowardf()`, `nexttowardl()` functions are provided.

<setjmp.h>

While in general the `<setjmp.h>` functionality operates as defined, it is worth noting that in line with the comments about `<signal.h>`, in eCos configurations where the POSIX package is not used and where a hardware exception context is used to handle hardware exception related signals (SIGSEGV, SIGILL, etc.) the fact that the signal handler is being called in a non-standard CPU context means that the practice of longjmp()ing out of a signal handler must be avoided.

<signal.h>

The signal subsystem is broadly compliant. But it is worth noting that if the eCos configuration is set to use the C library signals package (CYGPKG_LIBC_SIGNALS), then while signals generated (with raise()) by software behave normally, hardware-related signals such as SIGILL, SIGFPE or SIGSEGV may result in the signal handler being invoked in an unusual CPU context such as an exception context, and the effect of returning from the signal handler or attempting to longjmp() out of it is undefined. In an exception context, calling certain functions such as those which may interact with synchronisation objects (mutexes etc.) or cause pre-emption are likely to misbehave.

For compliant behaviour, instead it is recommended to use the signals facility provide by the eCos POSIX compatibility package (CYGPKG_POSIX) in place of CYGPKG_LIBC_SIGNALS.

<stdarg.h>

No compliance issues noticed.

<stdbool.h>

No compliance issues noticed.

<stddef.h>

No compliance issues noticed.

<stdint.h>

No compliance issues noticed.

<stdio.h>

None of the wide character input or output functions, nor any other definitions and functionality related to wide character support, are provided. These include at least the functions: fgetwc(), fgetws(), getwc(), getwchar(), fwscanf(), wscanf(), vfwscanf(), vwscanf(), fputwc(), fputws(), putwc(), putwchar(), fwprintf(), wprintf(), vfwprintf(), vwprintf() and ungetwc(). It also includes the mbstate_t type.

freopen() will always report an error on return.

Not all format specifiers or length modifiers for the *printf() and *scanf() families of functions are supported. For example: the 'a' and 'A' floating-point format specifiers, the 'j' length modifier for intmax_t / uintmax_t, or the 't' length modifier for ptrdiff_t. Also the 'l' length modifier where its behaviour is intended to treat the associated characters/string as wide characters.

<stdlib.h>

The llabs() and lldiv() functions, and associated lldiv_t type are not provided.

The strtold() function is not supported.

The strtod() and strtof() functions (and implicitly atof()) do not accept input text of the form: “a 0x or 0X, then a nonempty sequence of hexadecimal digits optionally containing a decimal-point character, then an optional binary exponent part”. They also do not recognise the special strings INF, INFINITY, or any NAN strings.

The `aligned_alloc()` function is not provided.

The `_Exit()`, `quick_exit()` and `at_quick_exit()` functions are not provided.

As eCos is designed for embedded systems, it is not intended for its main process to exit, as there is no other process to return to. Therefore while functions like `abort()`, `exit()`, and `atexit()` exist and are implemented, for that reason they may not behave in the expected way that developers using Unix systems may expect. Depending on eCos configuration, exiting may cause the system to halt, or only cause the `main()` thread to exit, allowing other threads to continue running.

<string.h>

No compliance issues noticed.

<tgmath.h>

This header file is not supported.

<time.h>

Some conversion specifiers for `strftime()` are not supported, for example: `%C`, `%F`, `%g`, `%G`, `%h`, `%n`, `%r`, `%R`, `%t`, `%u`, `%V`, `%z`. Also, the ‘`E`’ and ‘`O`’ modifiers are not supported.

<wchar.h>

This header file is not supported.

<wctype.h>

This header file is not supported.

C11 specific headers

<stdalign.h>

No compliance issues noticed.

<stdatomic.h>

Although eCosCentric has not tested this functionality, no compliance issues have been noticed.

<threads.h>

This header file is not supported.

<uchar.h>

This header file is not supported.

Part IV. eCosPro Standard C++ library support package

Table of Contents

Chapter 11. Introduction

This documentation describes the eCos support for the GNU standard C++ library v3 which is a component of the GNU Compiler Collection (GCC). This library, also known as libstdc++, has been designed to fully implement the requirements of the ISO 14822 standard C++ specification, and also provides some of the underlying support for language features such as C++ exceptions and run-time type identification (RTTI).

As with normal GNU toolchains, the standard C++ library is prebuilt alongside the toolchain. The library itself is not contained in this eCos package. Instead the purpose of this package is to provide any ancillary support for the library, provide the CDL definitions required for the correct operation of the library, provide a rigorous and broad testsuite for the library, and of course provide this documentation.

Although the standard C++ library is part of the toolchain, some enhancements have been made to the GCC compiler specifically to support eCos, details of which are found in Chapter 14, *Toolchain*.

Overview of features

The GNU standard C++ library implements virtually all the library requirements of the C++ standard. Details of the status of the library including known issues may be found on the GNU C++ Standard Library documentation pages.

In summary, the library provides support for standard C++ functionality such as:

- C++ exceptions
- Run-time type identification (RTTI) and type information
- Memory allocation routines: new, delete, allocators, etc.
- I/O streams, string streams and I/O manipulators
- C++ friendly numeric limits
- Strings and character traits
- Containers: queues, deques, lists, stacks, vectors, maps, sets and bitsets
- Iterators
- Algorithms such as sort, find, compare, count, replace, etc. that usually operate on containers and iterators
- Complex numbers
- Numeric arrays
- Numeric algorithms such as accumulate, inner product, partial sum, adjacent difference
- etc…

This eCos package for libstdc++ also provides support for thread-safe exceptions when using the eCos kernel, as well as expressing with CDL the requirements that the C++ library has on the rest of the eCos system. This is in fact an option within the package named `CYGPKG_LIBSTDCXX_LIBRARY`, which may be overridden and disabled, although this must be done at the developer's own risk.

This package also contains a large number of tests, including some rigorous tests of core functionality such as C++ exceptions (and in particular their thread-safety and correct operation in a multi-threaded environment), RTTI, and the main library features.

These may be found in the `tests` subdirectory within this package. The GNU libstdc++ v3 testsuite has also been imported and is found in the `tscpp` subdirectory.

The GNU libstdc++ implementation configures itself on the basis of underlying OS support. In a few areas, where underlying eCos support does not exist, the library configures itself to avoid the requirement for that support. This is normally of little consequence, for example due to libstdc++ providing an alternative implementation with a minor performance impact, or some trivial divergence from strict C++ standard semantics. In some cases the affected functionality is optional in the first place, for example for aspects of C99 standard support. There is one notable area which is affected however, which is that eCos contains very little support for wide characters (wchar). As such, libstdc++ configures itself to omit its own wide character interface that would have been implemented using the underlying OS wide character support. For example, this removes provision of the various wstring and wstreams classes and functions.

Chapter 12. Usage

The easiest way to start using eCos for C++ development is to use the special configuration template included in this release for this purpose. With command line configuration it may be used as in the following example for the Atmel EB40A target:

```
$ ecosconfig new eb40a libstdc++
```

If using the graphical tool, the template may be selected with the `Build->Templates` menu item.

Once the eCos libraries are configured and built, you may link your application. Be sure to append *`-lstdC++`* to the end of the link line. If you wish to use C++ exceptions, be sure to either remove *`-fno-exceptions`* from your compilation line, or append *`-fexceptions`* at the end of the compilation line. Similarly, to use RTTI, either remove *`-fno-rtti`* from your compilation line, or append *`-frtti`* to the end of the compilation line. Finally, despite what some targets may have used for their default compiler flags it is important that the option *`-fvtable-gc`* is *not* used.

Requirements

As noted earlier, this package uses CDL to set constraints on the rest of the eCos system for correct and standards compliant operation of the C++ library. By selecting with the libstdc++ configuration template, you will be able to start with a configuration with all the necessary packages included and options set.

Building C++ programs, particularly those that use templates heavily (either directly, or using the templates from libstdc++), can take a lot of memory on the build machine - figures in excess of 220Mb have been observed building the testsuite included with this package. Be sure to have sufficient RAM to prevent extended build times.

This package requires a patched version of the GNU compiler in order to correctly support thread-safe C++ exceptions, and avoid problems with common infrastructure underlying most standard C++ library classes. Refer to the tools building notes below for further details.

Warning

If a compiler is used which was not supplied by eCosCentric, nor built with eCosCentric's patch, the facilities provided by the standard C++ library will *not* be thread-safe. This may result in corruption, unexpected behaviour or a crash. In particular, C++ exceptions will not be thread-safe. Even if an application does not use exceptions directly, they may be used internally within the standard C++ library. Furthermore, certain infrastructure used by multiple C++ library objects (such as allocators) will also not be thread-safe.

The multi-thread protection provided by the standard C++ library intentionally only extends to subsystems shared by multiple classes. It does not mean that multiple threads can safely access individual object instances. If an individual object may be accessed by multiple threads simultaneously, access to that object will still need to be protected separately by the user at the application level, for example with a mutex. The thread-safety protection provided by the eCosCentric-enhanced version of the standard C++ library only ensures that threads can safely access different instances of C++ library objects without special protection by the user, despite many of these objects using functionality which requires shared global state. This approach is an intentional design decision in order to avoid unnecessary locking overhead.

Due partly to this specialised toolchain support it is not possible to use this package with the synthetic target, as native toolchains are built with specialised knowledge of the C++ runtime installed on the native OS. This is not solely due to the aforementioned patches, but also because of direct assumptions made as part of the GNU toolchain build procedure. As such, use under the synthetic target is unlikely ever to be possible.

It has been observed that GDB releases prior to GDB 6.1 can have difficulty debugging complex C++ applications, particularly those that extensively include template classes containing virtual functions. GDB 6.1 or above is recommended.

Issues to consider

Using C++ exceptions

There are a number of considerations when using C++ exceptions:

1. Care should be taken when compiling C++ code with `-fexceptions` (the default). GNU C++ has been designed so that exceptions do not necessarily add overhead to functions. However they may add overhead in the following circumstances. Namely, when:

    a. Exceptions are actually used; OR

    b. i. The function (funcA) calls another function (funcB) with a non-null exception specifier or no exception specifier; AND

        ii. that function (funcA) contains an automatic object; AND

        iii. that object is defined to use a destructor, and would therefore need to have the destructor called if the called function (funcB) threw an exception through this stack frame.

2. Not all eCos API functions have null exception specifiers yet, which may lead to very small unnecessary overhead when used from C functions in certain circumstances described earlier. Annotating all functions with null exception specifiers throughout the entirety of eCos is a massive job beyond the scope of the work done to provide C++ support. However many of the key APIs can be updated. In the current eCos sources, some obvious APIs have been updated such as all of the kernel C API and much of the ISO C/POSIX APIs.

3. Exceptions thrown from signal handlers are not supported.

4. Exceptions are not supported in ISRs, DSRs, nor ASRs. It is neither feasible nor sensible to support exceptions in ISRs or DSRs. Support for ASRs may be added at a future date, although there are no plans at present.

5. Use of C++ support from this package can increase the thread stack requirements markedly. For example, if you use C++ exceptions, you should expect to add around 4Kbytes to your stack requirements for each thread which can throw exceptions. Developers may find it useful to enable kernel thread stack overflow checking (`CYGFUN_KERNEL_THREADS_STACK_CHECKING` and possibly also `CYGFUN_KERNEL_ALL_THREADS_STACK_CHECKING`), especially if erratic behaviour is observed in threads using C++ features.

Application size

It is widely acknowledged that when using C++ libraries, memory can quickly be consumed, particularly code (ROM/Flash) space. Small targets may have difficulty running even short C++ programs. For example, it is recommended to use the MEC01 memory extension card on the Atmel AT91 evaluation board platforms (EB40, EB40A, EB42, EB55) to provide extra space for applications. The eCosPro AT91EB40A port can take advantage of the MEC01 if eCos is configured with CYGHWR_HAL_ARM_AT91_EB40A_MEC01_RAM enabled.

Similarly, because of the generally larger code size, download times can be lengthy if using a slow transfer mechanism such as 38400 bps serial. Alternative download options such as ethernet or fast JTAG emulator should be considered for an efficient development/debug cycle.

It may be possible in future to reduce the code size overhead using linker garbage collection more fully. Currently linker garbage collection is not performed on the GNU standard C++ library itself. However it is anticipated the savings will turn out to be small.

C++ exceptions in callbacks

eCos itself is not built with exception support (`-fexceptions`) for the reasons given earlier concerning the overhead of exception support. As a consequence throwing exceptions from callbacks will not work, e.g. when using `qsort()`, `bsearch()`, etc. eCos does not yet support a means of building individual files with differing flags - flags are manipulated only for complete packages or by using custom build rules which would be unacceptable due to maintenance overheads.

Licensing

The GNU standard C++ library has its own license distinct from that of eCos. As a basis it uses, like eCos, the GNU General Public License. Also like eCos it includes an exception that permits the use of the library in proprietary applications. The exception is as follows:

> As a special exception, you may use this file as part of a free software library without restriction. Specifically, if other files instantiate templates or use macros or inline functions from this file, or you compile this file and link it with other files to produce an executable, this file does not by itself cause the resulting executable to be covered by the GNU General Public License. This exception does not however invalidate any other reasons why the executable file might be covered by the GNU General Public License.

This exception is very similar to the eCos GPL exception, and is compatible with it. Further information on this license can be found in the C++Introduction of the libstdc++ online documentation set.

Most of the test files imported from the libstdc++ testsuite are covered by the full GPL without any exception. This means that distributing binaries of the test executables themselves gives a requirement to make available the full source code of that binary under the terms of the GPL. This is not considered an onerous obligation as distributing test binaries for this testsuite publically is unlikely to be a common requirement.

Standards Compliance

Versions of eCosPro which are shipped with GCC 7.3 or later are broadly compliant with the ISO/IEC 14882:2011 C++ standard (also known as C++11), albeit with some notable exceptions.

Information on GCC 7.3's standards compliance can be found at https://gcc.gnu.org/onlinedocs/gcc-7.3.0/gcc/Standards.html, or elsewhere on the same website for other GCC release versions.

In particular, there is more detail on the compliance efforts with the various C++ standards described at https://www.gnu.org/software/gcc/projects/cxx-status.html.

The C++11 standard in turn assumes that the library features of the system are compliant with the ISO/IEC 9899:1999 C standard (also known as C99). Information on eCosPro compliance with ISO C standards can be found in the relevant section of the eCos C and Math library documentation.

Futher notes on compliance with the C++11 standard are:

- Any programs requiring C++11 library features must include the eCos package "ISO standard C++" (`CYGPKG_LIBSTDCXX`) in the eCos configuration, with the "C++ library support" (`CYGPKG_LIBSTDCXX_LIBRARY`) option enabled.
- As noted earlier, a particularly notable divergence of eCos from the standards is the absence of most wide character support and functions.
- The level of functionality and standards compliance of the clocks provided for use with the `<chrono>` header are highly dependent on the eCos configuration in use, such as the presence of the common clock package (`CYGPKG_CLOCK_COMMON`), POSIX clocks (`CYGPKG_POSIX_CLOCKS`) and/or the eCos wallclock subsystem (`CYGPKG_IO_WALLCLOCK`).

  Additionally the “`steady_clock`” is not provided in the eCosPro implementation, and any use of it will result in the normal system clock being used instead.
- Although the C11 `<complex.h>` is not supported, the `<complex>` header defined by C++11 is.

- At the time of writing, the thread support library portion of C++11 (section 30) provided by the headers `<thread>`, `<mutex>`, `<shared_mutex>`, `<condition_variable>` and `<future>` are not yet of production quality, and despite appearing to be usable in eCosPro, their use cannot yet be considered supportable.

- C++ destructors for global C++ objects are not run on program exit.

Open issues

GCC 3.3.x issues

At this time there are only two significant known open issues that developers should be aware of which may impact development:

- GCC 3.3.x misoptimizes code in functions with complex number parameters. The workaround is to compile without -O2 (or append -O0 to the end of the compile line). This issue has been filed with the GCC project as bug #15061. As a consequence of this compiler bug, the complex2 test in this package is likely to fail.

- GCC 3.3.x fails to return NULL when using the `std::nothrow` variant of the `new` operator when an amount of memory is requested beyond what the system has available. Instead of NULL, 4 is returned. This is listed with the GCC project as bug #13215 and the problem is not going to be addressed in the GCC 3.3.x series. The problem is fixed in GCC 3.4. As a consequence of this compiler bug, the new1 test in this package will fail with GCC 3.3.x.

GCC 3.4.x issues

The only known issue affecting the use of GCC 3.4.x is specific to M68K/Coldfire, where the software floating point emulation is too imprecise, and causes a small number of tests within the libstdc++ package to fail, primarily those that test long double support.

Generic issues

It is worth mentioning that, as previously mentioned above, wide character support is not included. Support for wide characters may be developed in due course, but it would require significant development in the underlying eCos C library.

Chapter 13. Testing

As noted earlier, tests have been written to verify the operation of certain specific areas of interest in the C++ library support, particularly the use of exceptions from multiple threads which is addressed in the `throw*` tests.

The GNU libstdc++ v3 testsuite has been imported into this package and may be found under the `tscpp` subdirectory of this package. There are a large number of tests within the libstdc++ testsuite of varying rigour. An analysis of the coverage has been made, and any notable gaps in the test coverage have been addressed in the custom tests in the `tests` subdirectory of this package.

The testsuite is quite large and takes some time to build, and so although built by default it may disabled with the `CYGPKG_LIBSTDCXX_OFFICIAL_TESTSUITE` CDL option. Some tests contain aspects which only operate if the RAM filesystem package is enabled, therefore to test the library more thoroughly developers may wish to consider enabling the RAM filesystem.

Notes on how the libstdc++ testsuite was imported, including what types of changes were made and what the results were, are available within this package in the `tscpp/NOTES` text file.

Chapter 14. Toolchain

To build GCC for use with this package, it is necessary to follow some additional steps compared with what would ordinarily be required for building the compiler. These steps are required to provide the eCos header files which are used by the GCC build, to determine properties of the run-time system and to apply a set of changes (a “patch”) to allow eCos to provide C++ exception support in a flexible and future-proof way. This patch takes particular care to ensure that the compiler and libstdc++ continue to behave correctly when no eCos kernel is present.

1. With eCos installed, the `ECOS_REPOSITORY` environment variable set and **ecosconfig** in your `PATH` variable, run the following commands at a **bash** shell prompt in an empty directory, choosing a TARGET of the appropriate architecture:

   ```
   $ ecosconfig new TARGET libstdc++
     $ ecosconfig tree
     $ make headers
   ```

2. Take the header tree generated under `install/include` and install it in the `TARGET/sys-include` subdirectory where you intend to install your tools. For example if you wish to install the new tools to `/opt/newtools`, then place the headers in a new directory `/opt/newtools/TARGET/sys-include`. (Note you must ensure you have write-access to `/opt` in this example, or you can choose an alternate path).

3. A C++ exception support patch is supplied on the eCosPro Developer's Kit CD-ROM. Once the patch has been applied, it is necessary to run the following command:

   ```
    $ contrib/gcc_update --touch
   ```

4. Configure GCC from within an empty build directory as follows, ensuring that the GNU binary utilities are at the head of the `PATH`:

   ```
    $ /src/gcc-3.x.x/configure --target=TARGET \
             --prefix=/opt/newtools --enable-languages=c,C++ \
             --with-gnu-as --with-gnu-ld --with-newlib \
             --enable-threads
   ```

Part V. eCos Support for Dynamic Memory Allocation

Name

malloc, calloc, realloc, free, mallinfo, operator new, operator new[], operator delete and operator delete[] — Access the System Heap

Synopsis

#include <stdlib.h>

#include <new>

`void* malloc (size);`

`void* calloc (nmemb, size);`

`void* realloc (ptr, size);`

`void free (ptr);`

`struct mallinfo mallinfo ();`

`void* operator new (size);`

`void* operator new[] (size);`

`void* operator new (size, );`

`void* operator new(nothrow)[] (size, );`

`void operator delete (ptr);`

`void operator delete[] (ptr);`

`void operator delete (ptr, );`

`void operator delete[] (ptr, );`

Description

The dynamic memory allocation package `CYGPKG_MEMALLOC` provides support for the ISO standard C functions `malloc`, `calloc`, `realloc` and `free`. Optionally it can provide the C++ `new` and `delete` operators. There is extensive support for debugging various problems associated with dynamic memory allocation.

Some of the available target RAM will be needed for application code and static data. If the target uses RedBoot or another ROM monitor for bootstrap then that may also reserve some of the available RAM. On most targets the system heap occupies all remaining RAM, and this is used to satisfy the memory allocation requests. By default the Doug Lea memory allocator (dlmalloc) code is used to manage the heap. This provides a good trade off between efficient use of the memory, fast operation, and resistance to fragmentation. If the eCos configuration includes the kernel then by default the various memory allocation routines will be thread-safe.

To complement the standard APIs the memory allocation package provides support for custom memory pools.

C library functions

The main dynamic memory allocation routines defined by standard C is `malloc()`: this allocates a chunk of memory from the heap at least as large as the amount requested, satisfying any alignment restrictions imposed by the architecture. The initial contents of the allocated chunk is undefined. If the heap cannot satisfy the allocation request then a null pointer will be returned.

The standard does not define what happens when `malloc()` is passed a size of 0. In eCos this is controlled by a configuration option `CYGSEM_MEMALLOC_MALLOC_ZERO_RETURNS_NULL`. By default the option is disabled and an argument of *0* will still result in an allocation of the smallest size supported by the memory allocator. If the option is enabled then a null pointer will be returned instead.

`calloc()` tries to allocate a memory chunk of at least `nmemb*size` bytes. If the allocation succeeds then the memory will be filled with zeroes. Otherwise a null pointer is returned.

`realloc()` tries to change the size of an existing allocation while leaving the contents unchanged. This may involve resizing the chunk in situ, or it may involve a `malloc()`/`memcpy()`/`free()` sequence. If the operation succeeds a valid pointer will be returned, which may or may not be the same as the original pointer. If the operation fails then a null pointer will be returned and the original data remains intact. There are two special cases: if the *ptr* argument is a null pointer then `realloc()` will act like `malloc()`; otherwise if the *size* argument is 0 then `realloc()` will act like `free()`.

`free()` takes a pointer previously returned by `malloc()`, `calloc()` or `realloc()` and returns the memory to the heap.

`mallinfo()` is not defined by the C standard but is provided for compatibility with other systems. It returns information about the current state of the heap in the form of a mallinfo structure:

```
struct mallinfo {
    int arena;    /* total size of memory arena */
    int ordblks;  /* number of ordinary memory blocks */
    int uordblks; /* space used by ordinary memory blocks */
    int fordblks; /* space free for ordinary blocks */
    int maxfree;  /* size of largest free block */
};
```

arena gives the total heap size. *ordblks* and *uordblks* give some information on current allocations, and *fordblks* indicates how much is left. The remaining memory may be fragmented so *maxfree* indicates the largest allocation that is currently possible. A mallinfo structure contains a number of other fields but those are not used by eCos and exist only for compatibility reasons.

C++ operators

C++ applications can use the standard C library routines for dynamic memory allocation, but it is more common to use the C++ `new` and `delete` operators. There are a number of different implementations of these:

1. The infrastructure package contains empty versions of the delete operators which do not interact with the system heap in any way. This is necessary because of the way the **g++** compiler handles certain language constructs. Whenever there is a class with a virtual destructor the generated code always contains a reference to the `delete` operator. The linker is unable to delete this. Therefore if the application uses such a class, directly or indirectly, the final executable will contain a `delete` implementation - even if there is no dynamic allocation. The usual `delete` operator would pull in the system heap and hence the memory allocation package, significantly increasing code size for no good reason. Providing an empty `delete` avoids this.

   Unfortunately this solution is imperfect. If instead the application does want to create and destroy objects on the heap, by default the empty `delete` operators will still get linked in and the memory never gets freed. It is not possible to handle both scenarios cleanly with current tools, so instead the application developer has to configure eCos appropriately. To suppress the empty delete operators the configuration option `CYGFUN_INFRA_EMPTY_DELETE_FUNCTIONS` should be disabled. If an eCos package performs dynamic memory allocation using C++ `new` and `delete` then it should automatically disable this option via a CDL **requires** property.

2. The next implementation of `new` and `delete` comes in the C++ support library `libsupc++.a`, which is normally available as part of the GNU toolchain. These versions are straightforward, simply calling `malloc()` and `free()` to access the system heap. When linking an application with an eCos linker script the C++ support library is searched automatically, so application developers only need to worry about disabling `CYGFUN_INFRA_EMPTY_DELETE_FUNCTIONS`.

3. Finally the memory allocation package can also provide implementations of the C++ operators. These access the system heap directly rather than going via `malloc()` and `free()` so can be marginally faster, but at the cost of some increased code size.

There is a significant difference of the system is configured for collecting memory debug data. These implementations of `new` and `delete` integrate directly with the debug data code, so more information will be collected. This is especially useful on architectures where the compiler only provides limited backtrace support.

The configuration option `CYGFUN_MEMALLOC_MALLOC_CXX_OPERATORS` controls whether or not the memory allocation package's versions of the C++ operators get built. By default this option is disabled, unless `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA` is enabled. When linking an application with an eCos linker script these operators will automatically be used in preference to the ones in `libsupc++.a`.

Debug Support

An application that uses dynamic memory allocation is often more difficult to debug than one that relies entirely on static allocation. To assist developers the memory allocation package provides a number of debugging facilities. The main one involves the collection of additional debug data for every memory allocation. This debug data can be transferred to the host and analyzed using a custom tool **ecosmdd**. Full documentation on this is provided elsewhere.

This package also provides support for some simple debugging techniques which can help detect certain problems. The first is memory guards: every allocated chunk is surrounded by a number of guard bytes. When the chunk is freed, using `free()` or the appropriate C++ `delete` operator, the guards are checked and any discrepancy is treated as an assertion failure. The head guard can detect certain buffer overflows in the previously allocated chunk. If the chunk contains a thread stack and the architecture involves a descending stack then the head guard can also detect stack overflows. The tail guard can detect certain overflows in the chunk being freed and underflows in the next chunk. The guards are reset during a free operation, which can help to catch attempts to free the same chunk twice. Guard checks only happen during a free operation so a corruption may go undetected for a long time, possibly too long, but are still better to never detecting corruption.

Memory guards are controlled by the configuration option `CYGDBG_MEMALLOC_MALLOC_DEBUG_GUARDS`. By default they are enabled if system-wide debugging (`CYGPKG_INFRA_DEBUG`) is enabled, otherwise disabled.

The second debugging technique is to fill memory chunks when they are freed. This helps to catch some attempts to use a pointer which is no longer valid. Such problems are particularly common in multi-threaded applications where thread A frees a chunk that thread B is still using. When freed chunks are filled thread B will suddenly see spurious data, often resulting in bus errors or other exceptions. The relevant configuration option is `CYGDBG_MEMALLOC_MALLOC_DEBUG_FILL_FREE`, which by default is also enabled if `CYGPKG_INFRA_DEBUG` is enabled. The option's value determines what the freed chunk gets filled with, usually 0xff.

Name

cyg_mempool_fix_*() and cyg_mempool_var_*() — Additional Memory Pools

Synopsis

void **cyg_mempool_var_get_info** (*varpool*, *info*);

Description

The memory allocation package provides support for additional memory pools, to complement the system heap. These pools are not created automatically by the system, they have to be created by application code or by other packages. There are exported APIs for two types of pool: fixed and variable.

Allocating memory from a fixed memory pool is very fast and, more importantly, deterministic. However the size of each allocation is fixed at the time the pool is created. This is not a problem if the required allocations are all the same size, or nearly so, but otherwise the memory will be used inefficiently. The pool cannot become fragmented.

Variable memory pools provide essentially the same functionality as the system heap, so are rarely used. However on some targets not all free memory is assigned automatically to the system heap. For example there may be a small area of fast on-chip memory as well as the slower external memory. The system heap will only use the latter. A variable memory pool can be created for the former, allowing application code to dynamically allocate fast memory where appropriate.

If the eCos configuration includes the kernel then by default the memory pool functions will be thread-safe. The pool functions do not implement the `malloc()` guard and free-fill debug facilities, nor the debug data support.

Fixed Memory Pools

A fixed memory pool must be created explicitly, for example:

```
#define BLOCK_SIZE    1024
#define BLOCK_COUNT   64

static cyg_uint32      pool_memory[((BLOCK_COUNT * BLOCK_SIZE)+3) / 4];
static cyg_handle_t    pool_handle;
static cyg_mempool_fix pool_data;

…

cyg_mempool_fix_create( (void*) pool_memory,
                        BLOCK_COUNT * BLOCK_SIZE,
                        BLOCK_SIZE,
                        &pool_handle, &pool_data );
```

This creates a pool of 63 1K blocks. *pool_memory* is normally allocated statically, but could also be a pointer to a special area of memory such as on-chip RAM, or it could even be dynamically allocated using `malloc()`. The pointer should be suitably aligned for the target architecture, usually to either a 32 or a 64 bit boundary. *pool_handle* can be used for subsequent pool operations. *pool_data* is a small data structure providing the space needed to administer the pool.

The above pool only provides 63 blocks, not 64. The administration overhead depends on the number of blocks so cannot all be allowed for in the *pool_data* structure. A small amount of the pool memory is consumed as well, effectively using up all of the first block. To eliminate this inefficiency:

```
#define BLOCK_SIZE    1024
#define BLOCK_COUNT   64
#define OVERHEAD      (((BLOCK_COUNT + 31) / 32) * sizeof(cyg_uint32))
#define ACTUAL_SIZE   ((BLOCK_SIZE * BLOCK_COUNT) + OVERHEAD)

static cyg_uint32      pool_memory[(ACTUAL_SIZE + 3) / 4];
static cyg_handle_t    pool_handle;
static cyg_mempool_fix pool_data;

…

cyg_mempool_fix_create( pool_memory,
                        ACTUAL_SIZE,
                        BLOCK_SIZE,
                        &pool_handle, &pool_data );
```

There are three functions for allocating memory. `cyg_mempool_fix_try_alloc()` is analogous to `malloc()`: it attempts to allocate a block from the pool, returning a null pointer if all blocks are currently in use. There is no need to specify the allocation size because all blocks are the same size. The other two functions are only available in configurations containing the eCos kernel. `cyg_mempool_fix_alloc()` will allocate a free block if there is one available, otherwise the current thread will be suspended until a block becomes available. A null pointer will only be returned if the thread is woken up again via `cyg_thread_release()`. `cyg_mempool_fix_timed_alloc()` may also suspend the current thread, but only for a number of clock ticks. If no block becomes free before the specified time is reached then a null pointer will be returned. The *abstime* argument is an absolute time, typically calculated by adding a cyg_tick_count_t timeout to the result of `cyg_current_time()`. In other words the pool API works in exactly the same way as kernel functions such as `cyg_semaphore_timed_wait()`. `cyg_mempool_fix_waiting()` can be used to check whether any threads are currently suspended waiting for a free block.

A block can be released using `cyg_mempool_fix_free()`. If a pool is no longer required it can be destroyed by a call to `cyg_mempool_fix_delete()`. Information about the current state of a pool can be obtained with `cyg_mempool_fix_get_info()`, in the form of a cyg_mempool_info structure:

```
typedef struct {
    cyg_int32 totalmem;
    cyg_int32 freemem;
    void*     base;
    cyg_int32 size;
    cyg_int32 blocksize;
    cyg_int32 maxfree;                  // The largest free block
} cyg_mempool_info;
```

Variable Memory Pools

The variable memory pool API is very similar to the fixed pool API. The key differences are:

1. `cyg_mempool_var_create()` does not take a block size parameter since the pool supports allocations of any size.

2. There is no special need to worry about overheads when creating the pool. The overheads will be shared between the allocations so spread throughout the pool

3. The block size is no longer implicit, so the three allocation routines need an explicit *`size`* argument.

4. Allocation operations are not deterministic and may take significantly longer than a fixed pool allocation. A variable pool is also vulnerable to memory fragmentation.

Name

mdd_dump and ecosmdd — Analyze Memory Usage

Synopsis

`mdd_dump`

`mdd_dumpnow`

`mdd_reset`

`ecosmdd stats` *`mddout.0`*

`ecosmdd dump` [options] [*`exe`*] *`mddout.0`*

`ecosmdd history` [options] [*`exe`*] *`mddout.0`* [*`mddout.1`* ...]

`ecosmdd diff` [options] [*`exe`*] *`mddout.0`* *`mddout.1`*

Description

Generally it is more difficult to debug an application that allocates memory dynamically than one that relies entirely on static allocation. Some problems such as buffer overflows can affect both. However the locations of static variables are readily determined from the linker map and debug information, so it is much easier to figure out which static buffer overflowed and then find the offending code. With dynamic allocation buffer overflows can still be detected, but it is much harder to figure out what each buffer is used for.

Another problem is excessive memory usage. A typical embedded system is designed with the smallest amount of memory that should suffice for the application. Often the application uses more memory than expected, and it is necessary to find out exactly where it is all going and where savings could be made. The alternative is a hardware redesign, associated delays, and increased manufacturing costs. A linker map gives details of the static data but not of dynamic allocations.

A third problem is memory leaks. If an application allocates memory that does not get freed then the heap will eventually run out. Usually this causes a system failure and means a reboot. It may take hours, days or even weeks, but any system failure is at best undesirable and at worst totally unacceptable.

The memory allocation package provides a debug data facility to assist developers faced with these problems. This involves storing additional metadata on the target for each allocated memory chunk, for example the function where the allocation occurred and the time that it happened. Configuration options control exactly what metadata gets collected. The debug data can be transferred from the target to the host in a gdb session, and then analyzed using the **ecosmdd** program. This provides a number of sub-commands: **stats**, **dump**, **history** and **diff**. It also provides various options for filtering, sorting and formatting the debug data.

Configuration Options

Memory debug data is not free. Collecting the debug data on the target requires extra memory and cpu cycles. To be useful the debug data has to be transferred to the host, and this can be time-consuming. If the application developer is tracking down problems with running out of memory then the debug data exacerbates the situation. Hence by default memory debug data is disabled, and there are configuration options to control exactly what gets enabled.

The first option to consider is `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA`. This has to be explicitly enabled by the developer. If it is left disabled then no debug data functionality is available.

Once the main debug data option has been enabled the memory allocation code will collect information about all current allocations. The minimum information needed is a pointer to the allocated data, the number of bytes involved, a 32-bit sequence number to allow the host-side to identify and sort the allocations, plus another pointer for linked list management. This gives a minimum overhead of 16 bytes per allocated chunk (assuming a typical 32-bit processor). However this allows for only limited analysis. Additional fields are controlled by separate configuration options:

`CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_ACTUAL_SIZE`

When the application requests say 12 bytes of data the memory allocation code will actually allocate more than this. There is some unavoidable overhead to keep track of the various allocations. There may be alignment restrictions. Optional Debug guards add to the overhead. If `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_ACTUAL_SIZE` is enabled then the debug data will include the actual size of each allocation, not just the requested size. By default this option is enabled. The cost is an extra size_t, usually four bytes, in each allocation record.

`CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_TIMESTAMP`

Every allocation record in the debug data contains a unique sequence number, a simple 32-bit counter. Amongst other uses this allows host-side tools to sort allocation events in time-order. However a sequence number does not give any information about the time elapsed between allocations. More detailed time information can be very useful, for example to associate allocations with external events. This takes the form of a cyg_tick_count_t as returned by the kernel function `cyg_current_time()`. The typical cost is an extra eight bytes in each allocation record.

`CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_TIMESTAMP` is enabled by default if the eCos kernel `CYGPKG_KERNEL` is present. It cannot be enabled if the configuration does not include the kernel.

`CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD`

In multi-threaded applications it can be useful to know which thread allocated which chunk of memory. For example if the application is structured as a set of mostly independent subsystems operating in a separate threads then each subsystem's memory usage can be analyzed separately. Optionally the debug data can include thread information, consisting of a unique numerical thread id, the cyg_handle_t identifying the thread, and the thread name as passed to `cyg_thread_create()`. The overhead is a 32-bit integer in each allocation record, plus a small amount of extra memory to keep track of the threads that have performed memory allocations.

`CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD` is enabled by default if the eCos kernel `CYGPKG_KERNEL` is present. It cannot be enabled if the configuration does not include the kernel.

`CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_BACKTRACE`

Arguably the most useful information about each memory allocation is a partial backtrace, identifying the code responsible for each allocation. On the target side this is implemented using the support function `__builtin_return_address()` provided by the **gcc** compiler. On the host-side the executable can be disassembled to map a return address onto the calling function. If the executable contains *`-g`* debug information then it may also be possible to work out the corresponding source file name and line number, and hence the exact line of code that performed the allocation.

`CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_BACKTRACE` is enabled by default, with a value of 1. This means the debug data will contain a single level of backtrace, e.g. the function that called `malloc()`. The backtrace level can be increased up to a maximum of 8, giving more detailed information about each allocation. This is especially useful when allocations occur inside library code since it gives a closer association between application actions and memory allocations. Higher levels do involve extra memory overhead, a 32-bit integer per level per allocation record, and extra cpu cycles.

Important

On many architectures the GNU tools only provided limited backtrace functionality. Often only a single level of backtrace is available. If `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_BACKTRACE` is set to a value greater than 1 the compiler will issue warnings when building the memory allocation package, and the extra debug data backtrace slots will just be filled with zeroes.

Even if backtrace information is available it is not always as useful as might be thought. Because of compiler optimizations the relation between the generated code and the original source is not always obvious, so when the host-side tools convert a return address to a source file and line number the results may not be exactly correct. For backtrace levels greater than 1 the results may even be completely wrong. The details will vary from architecture to architecture. When the code involves C++ template instantiation the compiler may not provide enough debug information to allow the backtrace pointers to be analyzed fully.

Depending on which options and how many backtrace levels are enabled, each allocation record will take up between 16 and 64 bytes of data on a 32-bit processor, and somewhat more on a 64-bit processor.

By default memory debug data is collected only for current allocations. This is sufficient for many debug purposes. For example if the problem is a buffer overflow then looking at the current allocations usually allows the developer to determine what the buffer and the surrounding allocations are used for. A complete dump of all current allocations can be used to figure out what all the memory is being used for. Examining two dumps separated in time can be used to track down memory leaks. However sometimes it is necessary to know about free operations as well as current allocations. A good example is identifying which thread freed a chunk that other threads still believe to be usable. To support this it is possible to collect historical debug data as well as the details of all current allocations.

There is a major problem with historical debug data. The number of current allocations is limited by the memory available on the target, so typically will be somewhere between 100 and 10000. The corresponding debug data will occupy between 2K and 640K of the available target-side memory, and there is an implicit upper bound. Historical data does not have an upper bound: an application may make millions of `malloc()` and `free()` calls yet never have more than a 100 allocations at any one time. Those millions of history records would occupy many megabytes of target-side memory. Typical targets do not have such amounts of spare memory, and even if they do transferring the history to the host for analysis would be very time-consuming. Therefore it is not practical to keep a full history. Instead the history debug data goes into a circular buffer, so only the last `n` records are kept. Overflows are detected and the application developer can take action, if desired.

By default history is disabled, controlled by the configuration option `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_HISTORY`. If enabled the number of entries in the history circular buffer is controlled by `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_HISTORY_RECORDS`, with a default value of 2048. Each history record stores both allocation and free debug data, so is approximately twice the size of an allocation record. With default settings the history circular buffer will occupy approximately 100K of target-side memory.

Enabling memory debug data does not affect the memory allocation APIs: applications just call `malloc()` and `free()` as usual. Similarly C++ applications can use the `new` and `delete` operators, but to get the maximum benefits of the backtrace info it is desirable to enable `CYGFUN_MEMALLOC_MALLOC_CXX_OPERATORS`.

Dumping the Debug Data with GDB

When an application is linked with a suitable eCos configuration, the memory debug data will be collected automatically on the target-side. This debug data needs to be transferred to the host, and a number of gdb macros are provided for this purpose. The application is debugged in a gdb session as usual. At an appropriate time the target is halted and the appropriate gdb macro is invoked. This will transfer the current debug data to the host, generating a file `mddout.0` which can then be fed into the **ecosmdd** analysis program.

The gdb macros can be found in the file `mdd.gdb` in the memory allocation packages' `host` subdirectory. Typically this gdb script will be **source**'d by the user's own `.gdbinit` gdb initialization script, so that the macros are always available. Alternatively the macros can be copied directly into that file, albeit at the risk of complications if the macros get updated in a future version of this package. The `host` subdirectory also contains a program **ecosmdd** (actually a portable Tcl script). This must be installed in an appropriate location that is on the user's `PATH`. The gdb macros rely on being able to execute this program.

The main macro is **mdd_dump**. It does not take any arguments. Usually it will just transfer the memory debug data to the host. However there is a problem if the target-side code was in the middle of updating the debug data: that data may not be in an entirely consistent state. To avoid problems the **mdd_dump** will check a target-side busy flag. If appropriate it will report that a dump may currently be unsafe, instead of proceeding with the dump anyway. The function `cyg_memalloc_dd_done` will be called once the debug data has been updated, so an application developer can set a temporary breakpoint on that function and let the application continue briefly. Alternatively there is a separate macro **mdd_dumpnow**. This will ignore the busy flag and proceed with the dump, irrespective of what the target happened to be doing when it was halted. There is a very small possibility that the resulting dump file will have problems.

Note

The memory allocation code treats the actual allocation and the updating of the debug info as separate steps. Hence it is possible that a chunk of memory has just been allocated or freed, but the `mddout.0` dump file will not yet show this. Usually this temporary discrepancy is not important: it can only matter if the application developer is analysing the debug data and the target-side state concurrently. However application developers should be aware of the possibility. An alternative implementation involving more locking would be possible, but at the cost of potentially significant changes in the application's behaviour.

The time taken to generate a dump file will depend both on how much debug data is collected and on the debug communication channel. It can take anywhere from several seconds to many minutes. Enabling the history circular support can significantly increase the time needed.

Sometimes it is desirable to generate more than one `mddout` dump file in a single debug session. For example the user may want to halt the application at two specific points in the run and find out what allocations have occurred between these points. The first invocation of **mdd_dump** or **mdd_dumpnow** will produce a dump file `mddout.0`. Subsequent invocations will produce dump files `mddout.1`, `mddout.2`, and so on. If desired the numbering can be reset using the **mdd_reset** macro. The next debug session will again produce files `mddout.0`, `mddout.1` and so on, overwriting the previous run's results. The macro scripting facilities in gdb are rather limited, so the file naming is actually handled by invoking the **ecosmdd** program.

If the debug data includes the history circular buffer there is special support for handling overflows. This makes it possible to collect complete history information, spread over a number of `mddout` dump files, which can then be analyzed together. When an overflow occurs the target-side will call the function `cyg_memalloc_dd_history_overflow()`. Application developers can set a breakpoint on this function, and use **mdd_dump** whenever the breakpoint is hit to generate another dump file with a whole buffer's worth of history records. **mdd_dump** will automatically reset the circular buffer. `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_HISTORY_RECORDS` can be increased to reduce the number of dump files that are needed, at the cost of target-side memory.

A similar technique can be used for other purposes. For example the application developer may want to know the state of the heap once it has reached approximately 80% full. One way of achieving this is to have a separate high-priority thread which calls `mallinfo` at regular intervals. When it detects the desired condition it calls a special function. The developer sets a breakpoint on that function and can then take appropriate action when the condition is satisfied.

Extracting Statistics

The **ecosmdd stats** command is the simplest of the available analysis tools. It just takes a single argument, an `mddout` dump file:

```
$ ecosmdd stats mddout.0
mddout.0: statistics
Heap      : 0x00097d68 to 0x01ffffff, size 32160K (32932504 bytes)
History   : 132773 memory allocations, 130257 frees
Current   : 1268K (1298850 bytes) used in 2516 allocations
Actual    : approximately 1508K (1544784 bytes)
Overhead  : approximately 240K (245934 bytes), 15%
Debugdata : approximately 107K (110280 bytes) static, 92K (94628 bytes) dynamic
          : (debug data is in addition to other overheads)
Allocators:
malloc() 1009
new(nothrow) 788
new(nothrow)[] 451
calloc() 251
realloc() 17
Threads   :
        1 : handle 0x00075670, Idle Thread
        2 : handle 0x00093af8, main
        3 : handle 0x000739b0, thread_0
        4 : handle 0x00073a50, thread_1
        5 : handle 0x00073af0, thread_2
        6 : handle 0x00073b90, thread_3
Options   : actual_size enabled, time stamps enabled, thread info enabled
          : backtrace enabled, 1 levels
          : history enabled, 2048 records max
```

The fields in the output are as follows:

1. The start and end address of the heap and its size. This example is for a development board with a generous 32MB. Approximately 600K is used for application code and static data and for RedBoot, leaving most of the memory available for dynamic memory allocation.

2. Total numbers of past allocations and frees, with the difference corresponding to the number of current allocations. Note that the total size of past allocations is not recorded because of the likelihood of an overflow and hence misleading data.

3. Totals for the current allocations, giving the size as requested by application code.

4. The actual amount of memory used for these allocations, allowing for overhead. This information is only available if `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_ACTUAL_SIZE` is enabled. Note that the numbers are approximate: they only count per-allocation overhead; there may be additional costs for pool data structures and the like which are not included; usually these are sufficiently small that they can be ignored.

5. The difference between the above two fields. For this example the overhead is comparatively high. The configuration included support for debug guards which adds an extra 12 bytes to each allocation plus whatever was needed by the allocation code itself. Most of the allocations were small, so the guards have a disproportionate effect.

6. Additional memory needed for the debug data, both static and dynamic. The configuration included a history circular buffer with default settings, accounting for most of the static cost. The debug data for 2516 current allocations account for most of the dynamic costs, and is not included in the earlier figures. The results of `mallinfo()` will include the dynamic debug data.

7. Counts for the various types of dynamic memory allocation.

8. A list of the various threads: unique id, a cyg_handle_t handle, and the name passed to `cyg_thread_create`. This information is only available if `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD` is enabled. The ids can be used in a filter to show only allocations performed by the specified thread. The code only keeps track of threads involved with dynamic memory allocation, not every thread in the system. It is actually unlikely that the idle thread allocated any memory. Instead allocations during system initialization, before the scheduler was started, will usually be ascribed to the idle thread.

9. Details of the relevant configuration options. This can be useful when figuring out what filters, sort keys, or format specifiers are permitted, as an alternative to checking the configuration options.

Dumping Current Allocations

The **ecosmdd dump** can be used to analyze an `mddout` dump file and report on all current allocations.

```
$ ecosmdd dump consume mddout.0
0x00097d78 : malloc() 256 bytes, actual size 272 (+16), seqno 0, time 0
  By thread 1, 0x00075670 Idle Thread
  1) backtrace 0x0004da74 function Cyg_StdioStreamBuffer::set_buffer(unsigned, unsigned char*)
    /opt/ecos/packages/language/c/libc/stdio/current/src/common/streambuf.cxx:96
    "        malloced_buf = (cyg_uint8 * )malloc( size );"
0x000c0f50 : malloc() 13 bytes, actual size 32 (+19), seqno 229605, time 3960
  By thread 3, 0x000739b0 thread_0
  1) backtrace 0x00040ed8 function worker2()
    /tmp/mdd/consume.cxx:393
    "            allocs[index].data.c    = malloc(size);"
0x000c0f70 : new(nothrow) 1024 bytes, actual size 1040 (+16), seqno 251083, time 4329
```

```
  By thread 5, 0x00073af0 thread_2
  1) backtrace 0x00040c48 function worker1(int)
    /tmp/mdd/consume.cxx:315
    "            allocs[index].data.large    = new(std::nothrow) Large;"
…
```

`consume` is the executable. This output shows the first three allocation records, sorted in address order. The fields are as follows:

1. The address of the allocated chunk. This is the pointer that would be returned by e.g. `malloc()`. The memory allocation code may store some header information before this address, but that is transparent to the application. There is a big gap between the first and second records because the application freed a large buffer just before the dump file was generated.

2. The memory allocation function that was called to get this chunk. This may be a standard C library function or a C++ operator.

3. The allocation size requested by the application.

4. The actual allocation size and, in brackets, the overhead. This is provided only if `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_ACTUAL_SIZE` is enabled.

5. A sequence number. The first record shows the very first dynamic memory allocation in this test run, performed by the standard I/O initialization code. Sequence numbers are generated using a simple incrementing counter and are unique within a test run. The counter can overflow, but that is only likely to happen if an application makes very intensive use of `malloc()` and runs for several days.

6. A timestamp. This is a kernel cyg_tick_count_t as returned by the kernel function `cyg_current_time()`. Usually it corresponds to a counter running at 100Hz, so the second record is for a `malloc()` that occurred about 40 seconds into the run. Timestamps are only listed if `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_TIMESTAMP` is enabled.

7. A line of thread information showing the thread id, handle and name. This requires `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD`.

8. The level 1 backtrace. The first line gives the return address and the calling function. The second line gives a source code file name and line number. The third line shows the actual source line. In the third record the source code shows a C++ Large object being created. If enabled, additional levels of backtrace will follow.

   The function name is only available if the executable is specified on the command line. The file name and line number are only available if the executable contains *`-g`* debug information for the specified function. Usually this will be true for the application code itself and for eCos code, but not for other libraries supplied in binary format. The source line is only available if the file name and line number are known and the relevant file can be found on the current system. Again this may not be true for libraries supplied in binary format.

The executable does not have to be specified on the command line. Disassembling it can take considerable time, and serves only to provide more detailed backtrace information. Typical output without an executable would look like:

```
$ ecosmdd dump mddout.0 | more
0x00097d78 : malloc() 256 bytes, actual size 272 (+16), seqno 0, time 0
  By thread 1, 0x00075670 Idle Thread
  1) backtrace return address 0x0004da74
…
```

The **dump** subcommand accepts the standard options for architecture, ignoring certain files, sorting the output, applying filters, and formatting each record. For example to show only partial information for the allocations performed by thread 4 between approximately 40 and 42 seconds into the run, sorted by size with largest first, then by allocation time earliest first, the following can be used:

```
$ ecosmdd dump -Fthread=4 -Ftime_min=4000 -Ftime_max=4200 -SNs \
        -f '%p %a %n @ %T' mddout.0
0x002a43e8 malloc() 1553 @ 4079
0x000f9308 malloc() 1139 @ 4149
0x000c2a80 new(nothrow) 1024 @ 4104
```

```
0x00292428 new(nothrow)[] 388 @ 4194
0x000e0998 malloc() 240 @ 4147
0x00275678 new(nothrow) 128 @ 4013
0x00238c40 new(nothrow) 128 @ 4104
0x0023f7a8 new(nothrow) 128 @ 4194
0x000e1048 malloc() 18 @ 4014
0x0032cfe8 new(nothrow) 16 @ 4106
0x00131fa0 malloc() 8 @ 4107
0x0015d1a8 malloc() 8 @ 4125
0x002162d8 malloc() 7 @ 4129
0x001217c0 malloc() 7 @ 4190
```

The options should immediately follow the **dump** subcommand, before the executable or `mddout` file.

Showing the History

```
$ ecosmdd history consume mddout.0
Caution: history is incomplete.

malloc() 256 bytes: 0x00097d78 , actual size 272 (+16), seqno 0, time 0
  By thread 1, 0x00075670 Idle Thread
  1) backtrace 0x0004da74 function Cyg_StdioStreamBuffer::set_buffer(unsigned, unsigned char*)
    /opt/ecos/packages/language/c/libc/stdio/current/src/common/streambuf.cxx:96
    "        malloced_buf = (cyg_uint8 * )malloc( size );"
malloc() 131072 bytes: 0x00097e88 (freed) , actual size 131088 (+16), seqno 1, time 0
  By thread 2, 0x00093af8 main
  1) backtrace 0x000415b4 function main
    /tmp/mdd/consume.cxx:575
    "    spare   = malloc(128 * 1024);"
new(nothrow) 16 bytes: 0x00319270 (freed) , actual size 32 (+16), seqno 223425, time 3851
  By thread 3, 0x000739b0 thread_0
  1) backtrace 0x00040f4c function worker2()
    /tmp//consume.cxx:409
    "            allocs[index].data.small    = new(std::nothrow) Small;"
…
delete 16 bytes: 0x00156218 , actual size 40 (+24), seqno 258950, time 4461
  By thread 5, 0x000739b0 thread_0
  1) backtrace 0x00040cb8 function worker1(int)
    /tmp/mdd/consume.cxx:251
    "        break;"
free() 347 bytes: 0x001e6b08 , actual size 368 (+21), seqno 258951, time 4461
  By thread 6, 0x000739b0 thread_0
  1) backtrace 0x000409a4 function worker1(int)
    /tmp/mdd/consume.cxx:216
    "            free(allocs[index].data.c);"
…
```

Here **ecosmdd** has processed the executable and read in both the history data and the current allocation records from `mddout.0`. The file does not contain complete history information: there have been at least 258951 allocation and free operations, and the history buffer only stores the last 2048 frees. Each record is output in a similar format to **ecosmdd dump**. However history analysis is based around the order of events rather than the current state of the heap so the allocation function is shown before the heap.

The first record shows the first allocation in the system, and it is still allocated. Next comes the second allocation, which has been freed. This information will have come from the history circular buffer, implying that the buffer was freed in one of the last 2048 free operations. The third record shows another buffer that has been freed recently. There are no records between sequence numbers 1 and 223425, so all memory that has been allocated in the interval has already been freed and the relevant records are no longer in the history buffer.

The next two records show `delete` and `free()` operations. The format is essentially the same. The sequence number, timestamp, thread and backtrace information correspond to the free operation, not the allocation. Note that for the delete operation **ecosmdd** failed to get the source line number right: the `delete` invocation actually occurred a couple of lines earlier. Unfortunately the debug information in the executable was not sufficiently precise.

By default the history records will be shown earliest first. This order can be reversed with a `-r` option. **ecosmdd history** also accepts the standard options for architecture, ignoring certain files, applying filters, and formatting each record. The standard sort option is not supported because history implies sorting in time order. For example:

```
$ ecosmdd history -r -f '%a %p, %n bytes, seqno %s' consume mddout.0
Caution: history is incomplete.

free() 0x00097e88, 131072 bytes, seqno 263029
free() 0x00302490, 11 bytes, seqno 263028
new(nothrow) 0x00182cc0, 128 bytes, seqno 263027
…
```

If the desired history information is spread over more than one `mddout` file then they can all be passed to **ecosmdd history**. For example:

```
$ ecosmdd history -r consume mddout.0 mddout.1 mddout.2 mddout3
…
```

Options and the executable are handled as before. The `mddout` files should be listed in order of creation, and should correspond to a single test run. **ecosmdd** will extract both the history circular buffer and the current allocation data for the last file, but only the history buffers for the earlier ones - details of their current allocations can be found in later files. Obviously if eCos has been configured with `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_HISTORY` disabled then only the last file will contain useful information.

Comparing Two mddout Files

Sometimes, especially when tracking down a memory leak, it is useful to compare two dump files taken at different times and see what has changed. This functionality is provided by **ecosmdd diff**:

```
$ ecosmdd diff consume mddout.1 mddout.2
File mddout.1 : 1496K (1532048 bytes) used in 2543 allocations.
File mddout.2 : 1488K (1523769 bytes) used in 2483 allocations.
1331 new allocations in mddout.2 but not in mddout.1
1391 allocations in mddout.1 but freed in mddout.2

New allocations in mddout.2 but not in mddout.1
0x000ba8a8 : new(nothrow)[] 228 bytes, actual size 256 (+28), seqno 11001, time 214
  By thread 3, 0x000739b0 thread_0
  1) backtrace 0x00040fc0 function worker2()
    /tmp/mdd/consume.cxx:417
    "            allocs[index].data.smallv   = new(std::nothrow) Small[count];"
0x000ba9a8 : new(nothrow) 128 bytes, actual size 144 (+16), seqno 11528, time 222
  By thread 5, 0x00073af0 thread_2
  1) backtrace 0x00040b78 function worker1(int)
    /tmp/mdd/consume.cxx:296
    "            allocs[index].data.medium    = new(std::nothrow) Medium;"
…
Allocations in mddout.1 but freed in mddout.2
0x000ba9a8 : new(nothrow) 128 bytes, actual size 144 (+16), seqno 8213, time 162
  By thread 5, 0x00073af0 thread_2
  1) backtrace 0x00040b78 function worker1(int)
    /tmp/mdd/consume.cxx:296
    "            allocs[index].data.medium    = new(std::nothrow) Medium;"
0x000baa68 : new(nothrow) 128 bytes, actual size 144 (+16), seqno 9539, time 185
  By thread 6, 0x00073b90 thread_3
  1) backtrace 0x00041028 function worker2()
    /tmp/mdd/consume.cxx:424
    "            allocs[index].data.medium    = new(std::nothrow) Medium;"
…
```

The output begins with some statistics about the two dump files. Next comes a list of all memory chunks allocated in the second file but not in the first, and of all chunks allocated in the first but not the second. The diff uses the unique sequence number so will not be fooled if a chunk is freed and then allocated again.

ecosmdd diff accepts the standard options for architecture, ignoring certain files, sorting the output, applying filters, and formatting each record. Optionally these options can be followed by the executable, to get extended backtrace information. Finally there should be two `mddout` files:

```
$ ecosmdd diff -Fsize_min=10240 -f '%n bytes at %p by %f1' -SN \
        consume mddout.1 mddout.2
File mddout.1 : 1496K (1532048 bytes) used in 2543 allocations.
File mddout.2 : 1488K (1523769 bytes) used in 2483 allocations.
1331 new allocations in mddout.2 but not in mddout.1
1391 allocations in mddout.1 but freed in mddout.2

New allocations in mddout.2 but not in mddout.1
19691 bytes at 0x0025d498 by worker1(int)
19233 bytes at 0x00273758 by worker2()
…

Allocations in mddout.1 but freed in mddout.2
19858 bytes at 0x0025d498 by worker2()
18085 bytes at 0x001a2bf8 by worker2()
…
```

Standard Options

The various **ecosmdd** subcommands accept a number of standard options for specifying the architecture, ignoring certain source files, sorting and filtering the output, and formatting each record.

Specifying the Architecture

To provide extended backtrace information **ecosmdd** needs to disassemble the supplied executable. This involves running the appropriate **objdump** command, for example **arm-elf-objdump** or **m68k-elf-objdump**. **ecosmdd** reads in the executable's ELF header and uses this to work out the architecture. If it fails the architecture must instead be specified on the command line, for example:

```
$ ecosmdd dump -Adeepthought-elf …
```

ecosmdd will now try to run **deepthought-elf-objdump** to disassemble the executable.

Ignoring Selected Source Files

When the application involves extended use of header files with inline functions, the backtrace information can get even more confused than usual. Consider a function `tom()` which invokes an inline function `dick()` in a header file `<harry.h`, and `dick()` makes a memory allocation call. At run-time, because of the inlining the return address will be inside function `tom()`. However the debug information for the return address will usually specify the header file, not the source file containing `tom()`. This can make it much more difficult to interpret the backtrace.

There is no perfect solution to this problem, but **ecosmdd** contains an attempt at a partial solution. When disassembling an executable by default it will ignore any debug info where the file name matches the glob pattern `*/include/*`, if more accurate information for the current function is already available. This should catch inline functions in eCos, gcc and libstdc++ headers, and hence the backtrace output should more closely match what is actually happening in the application.

The default behaviour can be suppressed using the *-n* option, for example:

```
$ ecosmdd dump -n consume mddout.0
…
```

Alternatively a different glob pattern can be specified with the *-I* option (taking care to stop the shell from expanding the glob pattern prematurely):

```
$ ecosmdd dump -I\*.h consume mddout.0
```

Sorting the Output

By default the **dump** and **diff** will output their results sorted by increasing address. A different sort can be specified using the *-S* option, for example:

```
$ ecosmdd dump -SNs consume mddout.0
```

The *-S* should be followed by one or more sort keys. In the above example the primary sort key is `N`, specifying sort by decreasing allocation size so the largest allocations come first. When two allocations are the same size the secondary sort key (if specified) comes into play. Here the secondary key is `s`, meaning by increasing sequence number, so two allocations of the same size will be shown in history order. Any number of sort keys can be specified but it does not make sense to repeat a sort key or its inverse. Sequence numbers are unique so it also does not make sense to specify another sort key after `s` or `S`. If two allocations remain unsorted after all the specified sort keys have been processed then the output order is undefined. The available sort keys are:

p	Sort by increasing address, so the lowest address comes first.
P	Sort by decreasing address, so the highest address comes first.
n	Sort by increasing allocation size, so the smallest allocations come first.
N	Sort by decreasing allocation size, so the largest allocations come first.
s	Sort by increasing sequence numbers, so oldest allocations come first.
S	Sort by decreasing sequence number, so newest allocations come first.
a	Sort by memory allocation function, so for example all `realloc()` allocations will be grouped together.
t	Sort by increasing thread id. **ecosmdd stats** can be used to get details of the various threads. This sort key is only available if `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD` is enabled.
T	Sort by decreasing thread id. **ecosmdd stats** can be used to get details of the various threads. This sort key is only available if `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD` is enabled.

Filtering out Unwanted Data

Non-trivial applications can result in very large amounts of memory debug data. **ecosmdd** provides a number of filters to eliminate unwanted data. For example, to show only allocations of 1K or larger:

```
$ ecosmdd dump -Fsize_min=1024 consume mddout.0
…
```

A filter takes the form *-F<key>=<value>*. The supported keys are:

thread=<id>	Only show allocations performed by the specified thread. This filter can only be used if `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD` is enabled.
size_min=<size>	Ignore any allocations smaller than the specified size.
size_max=<size>	Ignore any allocations larger than the specified size.
seqno_min=<start>	Only show the event identified by the sequence number and subsequent ones.
seqno_max=<end>	Only show events up to and including the one identified by the sequence number.
time_min=<start>	Discard any records prior to the specified time.
time_max=<end>	Discard any records after the specified time.
ptr_min=<base>	Filter out allocations before the specified address.
ptr_max=<limit>	Filter out allocations after the specified address.

Multiple filters can be specified. For example to show only allocations performed by thread 6 which are larger than 4K and which occurred in a certain time interval:

```
$ ecosmdd dump -Fthread=6 -Fsize_min=4096 -Ftime_min=4000 -Ftime_max=5000 \
    consume mddout.0
```

Formatting the Output

By default **ecosmdd** outputs all available information for each record. Sometimes it is better to see only some of the fields. At other times a different format may be preferred, for example to feed the **ecosmdd** output into some other tool. Hence it is possible to specify a custom format string, along similar lines to the C `strftime` and `printf` functions:

```
$ ecosmdd dump -f '%a for %n bytes -> %p'
malloc() for 256 bytes -> 0x00097d78
malloc() for 131072 bytes -> 0x00097e88
malloc() for 4 bytes -> 0x000b7e98
calloc() for 3724 bytes -> 0x000b7eb0
…
```

A % character introduces a conversion sequence. Other characters are just passed straight through. The supported conversion sequences are:

%%	A single % character.
%p	The address of the allocated chunk.
%n	The requested allocation size.
%m	The actual allocation size. This requires `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_ACTUAL_SIZE`.
%o	The allocation overhead for this chunk. This requires `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_ACTUAL_SIZE`.
%s	The sequence number.
%a	The allocating function, for example `malloc()`
%T	A timestamp for the event. This requires `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_TIMESTAMP`
%t	The thread identifier. This requires `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD`
%h	The thread handle. This requires `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD`
%N	The thread name. This requires `CYGDBG_MEMALLOC_DEBUG_DEBUGDATA_THREAD`
%b1 to %b8	The backtrace return address for the appropriate level. It is an error to specify a level greater than what is actually present in the `mddout` file.
%f1 to %f8	The backtrace function name for the appropriate level. This can only be used if the executable has been specified on the command line.
%w1 to %w8	The backtrace location for the appropriate level, in the form filename:linenumber. This can only be used if the executable has been specified on the command line, and even then the information is not always available.
%l1 to %l8	The backtrace source line for the appropriate level. This can only be used if the executable has been specified on the command line, and even then the information is not always available.

The usual format string for a dump operation, assuming default configuration settings, is: '%p : %a %n bytes, %m (+%o), seqno %s, time %T\n By thread %t, %h %N\n 1) backtrace %b1 function %f1\n %w1\n \"%l1\"'

Part VI. I/O Package (Device Drivers)

Table of Contents

Chapter 15. Introduction

The I/O package is designed as a general purpose framework for supporting device drivers. This includes all classes of drivers from simple serial to networking stacks and beyond.

Components of the I/O package, such as device drivers, are configured into the system just like all other components. Additionally, end users may add their own drivers to this set.

While the set of drivers (and the devices they represent) may be considered static, they must be accessed via an opaque “handle”. Each device in the system has a unique name and the `cyg_io_lookup()` function is used to map that name onto the handle for the device. This “hiding” of the device implementation allows for generic, named devices, as well as more flexibility. Also, the `cyg_io_lookup()` function provides drivers the opportunity to initialize the device when usage actually starts.

All devices have a name. The standard provided devices use names such as `“/dev/console”` and `“/dev/serial0”`, where the `“/dev/”` prefix indicates that this is the name of a device.

The entire I/O package API, as well as the standard set of provided drivers, is written in C.

Basic functions are provided to send data to and receive data from a device. The details of how this is done is left to the device [class] itself. For example, writing data to a block device like a disk drive may have different semantics than writing to a serial port.

Additional functions are provided to manipulate the state of the driver and/or the actual device. These functions are, by design, quite specific to the actual driver.

This driver model supports layering; in other words, a device may actually be created “on top of” another device. For example, the “tty” (terminal-like) devices are built on top of simple serial devices. The upper layer then has the flexibility to add features and functions not found at the lower layers. In this case the “tty” device provides for line buffering and editing not available from the simple serial drivers.

Some drivers will support visibility of the layers they depend upon. The “tty” driver allows information about the actual serial device to be manipulated by passing get/set config calls that use a serial driver “key” down to the serial driver itself.

Chapter 16. User API

All functions, except `cyg_io_lookup()` require an I/O "handle".

All functions return a value of the type Cyg_ErrNo. If an error condition is detected, this value will be negative and the absolute value indicates the actual error, as specified in `cyg/error/codes.h`. The only other legal return value will be `ENOERR`. All other function arguments are pointers (references). This allows the drivers to pass information efficiently, both into and out of the driver. The most striking example of this is the "length" value passed to the read and write functions. This parameter contains the desired length of data on input to the function and the actual transferred length on return.

```
// Lookup a device and return its handle
Cyg_ErrNo cyg_io_lookup(
    const char      *name,
    cyg_io_handle_t *handle )
```

This function maps a device name onto an appropriate handle. If the named device is not in the system, then the error `-ENOENT` is returned. If the device is found, then the handle for the device is returned by way of the handle pointer *`*handle`*.

```
// Write data to a device
Cyg_ErrNo cyg_io_write(
    cyg_io_handle_t handle,
    const void      *buf,
    cyg_uint32      *len )
```

This function sends data to a device. The size of data to send is contained in *`*len`* and the actual size sent will be returned in the same place.

```
// Read data from a device
Cyg_ErrNo  cyg_io_read(
    cyg_io_handle_t handle,
    void            *buf,
    cyg_uint32      *len )
```

This function receives data from a device. The desired size of data to receive is contained in *`*len`* and the actual size obtained will be returned in the same place.

```
// Get the configuration of a device
Cyg_ErrNo cyg_io_get_config(
    cyg_io_handle_t handle,
    cyg_uint32      key,
    void *          buf,
    cyg_uint32 *    len )
```

This function is used to obtain run-time configuration about a device. The type of information retrieved is specified by the *`key`*. The data will be returned in the given buffer. The value of *`*len`* should contain the amount of data requested, which must be at least as large as the size appropriate to the selected key. The actual size of data retrieved is placed in *`*len`*. The appropriate key values differ for each driver and are all listed in the file `<cyg/io/config_keys.h>`.

```
// Change the configuration of a device
Cyg_ErrNo  cyg_io_set_config(
    cyg_io_handle_t handle,
    cyg_uint32      key,
    const void      *buf,
    cyg_uint32      *len )
```

This function is used to manipulate or change the run-time configuration of a device. The type of information is specified by the *`key`*. The data will be obtained from the given buffer. The value of *`*len`* should contain the amount of data provided, which must match the size appropriate to the selected key. The appropriate key values differ for each driver and are all listed in the file `<cyg/io/config_keys.h>`.

Chapter 17. Serial driver details

Two different classes of serial drivers are provided as a standard part of the eCos system. These are described as “raw serial” (serial) and “tty-like” (tty).

Raw Serial Driver

Use the include file `<cyg/io/serialio.h>` for this driver.

The raw serial driver is capable of sending and receiving blocks of raw data to a serial device. Controls are provided to configure the actual hardware, but there is no manipulation of the data by this driver.

There may be many instances of this driver in a given system, one for each serial channel. Each channel corresponds to a physical device and there will typically be a device module created for this purpose. The device modules themselves are configurable, allowing specification of the actual hardware details, as well as such details as whether the channel should be buffered by the serial driver, etc.

Runtime Configuration

Runtime configuration is achieved by exchanging data structures with the driver via the `cyg_io_set_config()` and `cyg_io_get_config()` functions.

```
typedef struct {
    cyg_serial_baud_rate_t baud;
    cyg_serial_stop_bits_t stop;
    cyg_serial_parity_t parity;
    cyg_serial_word_length_t word_length;
    cyg_uint32 flags;
} cyg_serial_info_t;
```

The field *`word_length`* contains the number of data bits per word (character). This must be one of the values:

```
CYGNUM_SERIAL_WORD_LENGTH_5
CYGNUM_SERIAL_WORD_LENGTH_6
CYGNUM_SERIAL_WORD_LENGTH_7
CYGNUM_SERIAL_WORD_LENGTH_8
```

The field *`baud`* contains a baud rate selection. If the configuration does not implement the `CYGINT_IO_SERIAL_BAUD_ARBITRARY` interface support for arbitrary baud rate values then this field must be one of the values:

```
CYGNUM_SERIAL_BAUD_50
CYGNUM_SERIAL_BAUD_75
CYGNUM_SERIAL_BAUD_110
CYGNUM_SERIAL_BAUD_134_5
CYGNUM_SERIAL_BAUD_150
CYGNUM_SERIAL_BAUD_200
CYGNUM_SERIAL_BAUD_300
CYGNUM_SERIAL_BAUD_600
CYGNUM_SERIAL_BAUD_1200
CYGNUM_SERIAL_BAUD_1800
CYGNUM_SERIAL_BAUD_2400
CYGNUM_SERIAL_BAUD_3600
CYGNUM_SERIAL_BAUD_4800
CYGNUM_SERIAL_BAUD_7200
CYGNUM_SERIAL_BAUD_9600
CYGNUM_SERIAL_BAUD_14400
CYGNUM_SERIAL_BAUD_19200
CYGNUM_SERIAL_BAUD_38400
CYGNUM_SERIAL_BAUD_57600
```

```
CYGNUM_SERIAL_BAUD_115200
CYGNUM_SERIAL_BAUD_234000
```

For configurations where `CYGINT_IO_SERIAL_BAUD_ARBITRARY` is enabled then the manifests above define the respective baud rate, but the underlying device driver is capable of accepting arbitrary baud rate values as required. e.g. `76800`.

The field *`stop`* contains the number of stop bits. This must be one of the values:

```
CYGNUM_SERIAL_STOP_1
CYGNUM_SERIAL_STOP_1_5
CYGNUM_SERIAL_STOP_2
```

Note

On most hardware, a selection of 1.5 stop bits is only valid if the word (character) length is 5.

The field *`parity`* contains the parity mode. This must be one of the values:

```
CYGNUM_SERIAL_PARITY_NONE
CYGNUM_SERIAL_PARITY_EVEN
CYGNUM_SERIAL_PARITY_ODD
CYGNUM_SERIAL_PARITY_MARK
CYGNUM_SERIAL_PARITY_SPACE
```

The field *`flags`* is a bitmask which controls the behavior of the serial device driver. It should be built from the values `CYG_SERIAL_FLAGS_xxx` defined below:

```
#define CYG_SERIAL_FLAGS_RTSCTS 0x0001
```

If this bit is set then the port is placed in “hardware handshake” mode. In this mode, the CTS and RTS pins control when data is allowed to be sent/received at the port. This bit is ignored if the hardware does not support this level of handshake.

```
typedef struct {
    cyg_int32 rx_bufsize;
    cyg_int32 rx_count;
    cyg_int32 tx_bufsize;
    cyg_int32 tx_count;
} cyg_serial_buf_info_t;
```

The field *`rx_bufsize`* contains the total size of the incoming data buffer. This is set to zero on devices that do not support buffering (i.e. polled devices).

The field *`rx_count`* contains the number of bytes currently occupied in the incoming data buffer. This is set to zero on devices that do not support buffering (i.e. polled devices).

The field *`tx_bufsize`* contains the total size of the transmit data buffer. This is set to zero on devices that do not support buffering (i.e. polled devices).

The field *`tx_count`* contains the number of bytes currently occupied in the transmit data buffer. This is set to zero on devices that do not support buffering (i.e. polled devices).

API Details

cyg_io_write

```
cyg_io_write(handle, buf, len)
```

Send the data from *`buf`* to the device. The driver maintains a buffer to hold the data. The size of the intermediate buffer is configurable within the interface module. The data is not modified at all while it is being buffered. On return, *`*len`* contains the amount of characters actually consumed .

It is possible to configure the write call to be blocking (default) or non-blocking. Non-blocking mode requires both the configuration option `CYGOPT_IO_SERIAL_SUPPORT_NONBLOCKING` to be enabled, and the specific device to be set to non-blocking mode for writes (see `cyg_io_set_config()`).

In blocking mode, the call will not return until there is space in the buffer and the entire contents of *`buf`* have been consumed.

In non-blocking mode, as much as possible gets consumed from *`buf`*. If everything was consumed, the call returns `ENOERR`. If only part of the *`buf`* contents was consumed, `-EAGAIN` is returned and the caller must try again. On return, *`*len`* contains the number of characters actually consumed .

The call can also return `-EINTR` if interrupted via the `cyg_io_get_config()`/`ABORT` key.

cyg_io_read

```
cyg_io_read(handle, buf, len)
```

Receive data into the buffer, *`buf`*, from the device. No manipulation of the data is performed before being transferred. An interrupt driven interface module will support data arriving when no read is pending by buffering the data in the serial driver. Again, this buffering is completely configurable. On return, *`*len`* contains the number of characters actually received.

It is possible to configure the read call to be blocking (default) or non-blocking. Non-blocking mode requires both the configuration option `CYGOPT_IO_SERIAL_SUPPORT_NONBLOCKING` to be enabled, and the specific device to be set to non-blocking mode for reads (see `cyg_io_set_config()`).

In blocking mode, the call will not return until the requested amount of data has been read.

In non-blocking mode, data waiting in the device buffer is copied to *`buf`*, and the call returns immediately. If there was enough data in the buffer to fulfill the request, `ENOERR` is returned. If only part of the request could be fulfilled, `-EAGAIN` is returned and the caller must try again. On return, *`*len`* contains the number of characters actually received.

The call can also return `-EINTR` if interrupted via the `cyg_io_get_config()`/`ABORT` key.

cyg_io_get_config

```
cyg_io_get_config(handle, key, buf, len)
```

This function returns current [runtime] information about the device and/or driver.

`CYG_IO_GET_CONFIG_SERIAL_INFO`

Buf type: cyg_serial_info_t

Function: This function retrieves the current state of the driver and hardware. This information contains fields for hardware baud rate, number of stop bits, and parity mode. It also includes a set of flags that control the port, such as hardware flow control.

`CYG_IO_GET_CONFIG_SERIAL_BUFFER_INFO`

Buf type: cyg_serial_buf_info_t

Function: This function retrieves the current state of the software buffers in the serial drivers. For both receive and transmit buffers it returns the total buffer size and the current number of bytes occupied in the buffer. It does not take into account any buffering such as FIFOs or holding registers that the serial device itself may have.

`CYG_IO_GET_CONFIG_SERIAL_OUTPUT_DRAIN`

Buf type: void *

Function: This function waits for any buffered output to complete. This function only completes when there is no more data remaining to be sent to the device.

CYG_IO_GET_CONFIG_SERIAL_OUTPUT_FLUSH

Buf type: void *

Function: This function discards any buffered output for the device.

CYG_IO_GET_CONFIG_SERIAL_INPUT_DRAIN

Buf type: void *

Function: This function discards any buffered input for the device.

CYG_IO_GET_CONFIG_SERIAL_ABORT

Buf type: void*

Function: This function will cause any pending read or write calls on this device to return with -EABORT.

CYG_IO_GET_CONFIG_SERIAL_READ_BLOCKING

Buf type: cyg_uint32 (values 0 or 1)

Function: This function will read back the blocking-mode setting for read calls on this device. This call is only available if the configuration option CYGOPT_IO_SERIAL_SUPPORT_NONBLOCKING is enabled.

CYG_IO_GET_CONFIG_SERIAL_WRITE_BLOCKING

Buf type: cyg_uint32 (values 0 or 1)

Function: This function will read back the blocking-mode setting for write calls on this device. This call is only available if the configuration option CYGOPT_IO_SERIAL_SUPPORT_NONBLOCKING is enabled.

cyg_io_set_config

```
cyg_io_set_config(handle, key, buf,len)
```

This function is used to update or change runtime configuration of a port.

CYG_IO_SET_CONFIG_SERIAL_INFO

Buf type: cyg_serial_info_t

Function: This function updates the information for the driver and hardware. The information contains fields for hardware baud rate, number of stop bits, and parity mode. It also includes a set of flags that control the port, such as hardware flow control.

CYG_IO_SET_CONFIG_SERIAL_READ_BLOCKING

Buf type: cyg_uint32 (values 0 or 1)

Function: This function will set the blocking-mode for read calls on this device. This call is only available if the configuration option CYGOPT_IO_SERIAL_SUPPORT_NONBLOCKING is enabled.

CYG_IO_SET_CONFIG_SERIAL_WRITE_BLOCKING

Buf type: cyg_uint32 (values 0 or 1)

Function: This function will set the blocking-mode for write calls on this device. This call is only available if the configuration option `CYGOPT_IO_SERIAL_SUPPORT_NONBLOCKING` is enabled.

TTY driver

Use the include file `<cyg/io/ttyio.h>` for this driver.

This driver is built on top of the simple serial driver and is typically used for a device that interfaces with humans such as a terminal. It provides some minimal formatting of data on output and allows for line-oriented editing on input.

Runtime configuration

Runtime configuration is achieved by exchanging data structures with the driver via the `cyg_io_set_config()` and `cyg_io_get_config()` functions.

```
typedef struct {
    cyg_uint32 tty_out_flags;
    cyg_uint32 tty_in_flags;
} cyg_tty_info_t;
```

The field *`tty_out_flags`* is used to control what happens to data as it is send to the serial port. It contains a bitmap comprised of the bits as defined by the `CYG_TTY_OUT_FLAGS_xxx` values below.

```
#define CYG_TTY_OUT_FLAGS_CRLF 0x0001 // Map '\n' => '\r\n' on output
```

If this bit is set in *`tty_out_flags`*, any occurrence of the character "\n" will be replaced by the sequence "\r\n" before being sent to the device.

The field *`tty_in_flags`* is used to control how data is handled as it comes from the serial port. It contains a bitmap comprised of the bits as defined by the `CYG_TTY_IN_FLAGS_xxx` values below.

```
#define CYG_TTY_IN_FLAGS_CR 0x0001 // Map '\r' => '\n' on input
```

If this bit is set in *`tty_in_flags`*, the character "\r" (“return” or “enter” on most keyboards) will be mapped to "\n".

```
#define CYG_TTY_IN_FLAGS_CRLF 0x0002 // Map '\r\n' => '\n' on input
```

If this bit is set in *`tty_in_flags`*, the character sequence "\r\n" (often sent by DOS/Windows based terminals) will be mapped to "\n".

```
#define CYG_TTY_IN_FLAGS_ECHO 0x0004 // Echo characters as processed
```

If this bit is set in *`tty_in_flags`*, characters will be echoed back to the serial port as they are processed.

```
#define CYG_TTY_IN_FLAGS_BINARY 0x0008 // No input processing
```

If this bit is set in *`tty_in_flags`*, the input will not be manipulated in any way before being placed in the user,s buffer.

API details

```
cyg_io_read(handle, buf, len)
```

This function is used to read data from the device. In the default case, data is read until an end-of-line character ("\n" or "\r") is read. Additionally, the characters are echoed back to the [terminal] device. Minimal editing of the input is also supported.

Note

When connecting to a remote target via GDB it is not possible to provide console input while GDB is connected. The GDB remote protocol does not support input. Users must disconnect from GDB if this functionality is required.

```
cyg_io_write(handle, buf, len)
```

This function is used to send data to the device. In the default case, the end-of-line character "\n" is replaced by the sequence "\r\n".

```
cyg_io_get_config(handle, key, buf, len)
```

This function is used to get information about the channel,s configuration at runtime.

`CYG_IO_GET_CONFIG_TTY_INFO`

Buf type:	cyg_tty_info_t
Function:	This function retrieves the current state of the driver.

Serial driver keys (see above) may also be specified in which case the call is passed directly to the serial driver.

```
cyg_io_set_config(handle, key, buf, len)
```

This function is used to modify the channel,s configuration at runtime.

`CYG_IO_SET_CONFIG_TTY_INFO`

Buf type:	cyg_tty_info_t
Function:	This function changes the current state of the driver.

Serial driver keys (see above) may also be specified in which case the call is passed directly to the serial driver.

Chapter 18. How to Write a Driver

A device driver is nothing more than a named entity that supports the basic I/O functions - read, write, get config, and set config. Typically a device driver also uses and manages interrupts from the device. While the interface is generic and device driver independent, the actual driver implementation is completely up to the device driver designer.

That said, the reason for using a device driver is to provide access to a device from application code in as general purpose a fashion as reasonable. Most driver writers are also concerned with making this access as simple as possible while being as efficient as possible.

Most device drivers are concerned with the movement of information, for example data bytes along a serial interface, or packets in a network. In order to make the most efficient use of system resources, interrupts are used. This will allow other application processing to take place while the data transfers are under way, with interrupts used to indicate when various events have occurred. For example, a serial port typically generates an interrupt after a character has been sent “down the wire” and the interface is ready for another. It makes sense to allow further application processing while the data is being sent since this can take quite a long time. The interrupt can be used to allow the driver to send a character as soon as the current one is complete, without any active participation by the application code.

The main building blocks for device drivers are found in the include file: `<cyg/io/devtab.h>`

All device drivers in *eCos* are described by a device table entry, using the cyg_devtab_entry_t type. The entry should be created using the `DEVTAB_ENTRY()` macro, like this:

```
DEVTAB_ENTRY(l, name, dep_name, handlers, init, lookup, priv)
```

Arguments

`l` The "C" label for this device table entry.

`name` The "C" string name for the device.

`dep_name` For a layered device, the "C" string name of the device this device is built upon.

`handlers` A pointer to the I/O function "handlers" (see below).

`init` A function called when eCos is initialized. This function can query the device, setup hardware, etc.

`lookup` A function called when `cyg_io_lookup()` is called for this device.

`priv` A placeholder for any device specific data required by the driver.

The interface to the driver is through the *`handlers`* field. This is a pointer to a set of functions which implement the various `cyg_io_XXX()` routines. This table is defined by the macro:

```
DEVIO_TABLE(l, write, read, get_config, set_config)
```

Arguments

`l` The "C" label for this table of handlers.

write The function called as a result of `cyg_io_write()`.

read The function called as a result of `cyg_io_read()`.

get_config The function called as a result of `cyg_io_get_config()`.

set_config The function called as a result of `cyg_io_set_config()`.

When *eCos* is initialized (sometimes called “boot” time), the `init()` function is called for all devices in the system. The `init()` function is allowed to return an error in which case the device will be placed “off line” and all I/O requests to that device will be considered in error.

The `lookup()` function is called whenever the `cyg_io_lookup()` function is called with this device name. The lookup function may cause the device to come “on line” which would then allow I/O operations to proceed. Future versions of the I/O system will allow for other states, including power saving modes, etc.

How to Write a Serial Hardware Interface Driver

The standard serial driver supplied with *eCos* is structured as a hardware independent portion and a hardware dependent interface module. To add support for a new serial port, the user should be able to use the existing hardware independent portion and just add their own interface driver which handles the details of the actual device. The user should have no need to change the hardware independent portion.

The interfaces used by the serial driver and serial implementation modules are contained in the file `<cyg/io/serial.h>`

Note

In the sections below we use the notation <<xx>> to mean a module specific value, referred to as “xx” below.

DevTab Entry

The interface module contains the devtab entry (or entries if a single module supports more than one interface). This entry should have the form:

```
DEVTAB_ENTRY(<<module_name>>,
    <<device_name>>,
    0,
    &serial_devio,
    <<module_init>>,
    <<module_lookup>>,
    &<<serial_channel>>
);
```

Arguments

module_name
The "C" label for this devtab entry

device_name
The "C" string for the device. E.g. `/dev/serial0`.

serial_devio
The table of I/O functions. This set is defined in the hardware independent serial driver and should be used.

module_init
The module initialization function.

module_lookup
The device lookup function. This function typically sets up the device for actual use, turning on interrupts, configuring the port, etc.

serial_channel
This table (defined below) contains the interface between the interface module and the serial driver proper.

Serial Channel Structure

Each serial device must have a “serial channel”. This is a set of data which describes all operations on the device. It also contains buffers, etc., if the device is to be buffered. The serial channel is created by the macro:

```
SERIAL_CHANNEL_USING_INTERRUPTS(l, funs, dev_priv, baud,stop, parity, word_length,
    flags, out_buf, out_buflen, in_buf, in_buflen)
```

Arguments

l
The "C" label for this structure.

funs
The set of interface functions (see below).

dev_priv
A placeholder for any device specific data for this channel.

baud
The initial baud rate value (cyg_serial_baud_t).

stop
The initial stop bits value (cyg_serial_stop_bits_t).

parity
The initial parity mode value (cyg_serial_parity_t).

word_length
The initial word length value (cyg_serial_word_length_t).

flags
The initial driver flags value.

out_buf
Pointer to the output buffer. `NULL` if none required.

out_buflen
The length of the output buffer.

in_buf
pointer to the input buffer. `NULL` if none required.

in_buflen
The length of the input buffer.

If either buffer length is zero, no buffering will take place in that direction and only polled mode functions will be used.

The interface from the hardware independent driver into the hardware interface module is contained in the *funs* table. This is defined by the macro:

Serial Functions Structure

```
SERIAL_FUNS(l, putc, getc, set_config, start_xmit, stop_xmit)
```

Arguments

l
The "C" label for this structure.

putc
`bool (*putc)(serial_channel *priv, unsigned char c)`

This function sends one character to the interface. It should return `true` if the character is actually consumed. It should return `false` if there is no space in the interface

getc
`unsigned char (*getc)(serial_channel *priv)`

This function fetches one character from the interface. It will be only called in a non-interrupt driven mode, thus it should wait for a character by polling the device until ready.

set_config
`bool (*set_config)(serial_channel *priv,cyg_serial_info_t *config)`

This function is used to configure the port. It should return `true` if the hardware is updated to match the desired configuration. It should return `false` if the port cannot support some parameter specified by the given configuration. E.g. selecting 1.5 stop bits and 8 data bits is invalid for most serial devices and should not be allowed.

start_xmit

`void (*start_xmit)(serial_channel *priv)`

In interrupt mode, turn on the transmitter and allow for transmit interrupts.

stop_xmit

`void (*stop_xmit)(serial_channel *priv)`

In interrupt mode, turn off the transmitter.

Callbacks

The device interface module can execute functions in the hardware independent driver via `chan->callbacks`. These functions are available:

```
void (*serial_init)( serial_channel *chan )
```

This function is used to initialize the serial channel. It is only required if the channel is being used in interrupt mode.

```
void (*xmt_char)( serial_channel *chan )
```

This function would be called from an interrupt handler after a transmit interrupt indicating that additional characters may be sent. The upper driver will call the `putc` function as appropriate to send more data to the device.

```
void (*rcv_char)( serial_channel *chan, unsigned char c )
```

This function is used to tell the driver that a character has arrived at the interface. This function is typically called from the interrupt handler.

Furthermore, if the device has a FIFO it should require the hardware independent driver to provide block transfer functionality (driver CDL should include "implements CYGINT_IO_SERIAL_BLOCK_TRANSFER"). In that case, the following functions are available as well:

```
bool (*data_xmt_req)( serial_channel  *chan,
                      int             space,
                      int*            chars_avail,
                      unsigned char** chars)
void (*data_xmt_done)(serial_channel *chan)
```

Instead of calling `xmt_char()` to get a single character for transmission at a time, the driver should call `data_xmt_req()` in a loop, requesting character blocks for transfer. Call with a *`space`* argument of how much space there is available in the FIFO.

If the call returns `true`, the driver can read *`chars_avail`* characters from *`chars`* and copy them into the FIFO.

If the call returns `false`, there are no more buffered characters and the driver should continue without filling up the FIFO.

When all data has been unloaded, the driver must call `data_xmt_done()`.

```
bool (*data_rcv_req)( serial_channel  *chan,
                      int             avail,
                      int             *space_avail,
                      unsigned char** space)
void (*data_rcv_done)(serial_channel *chan)
```

Instead of calling `rcv_char()` with a single character at a time, the driver should call `data_rcv_req()` in a loop, requesting space to unload the FIFO to. *`avail`* is the number of characters the driver wishes to unload.

If the call returns `true`, the driver can copy *`space_avail`* characters to *`space`*.

If the call returns `false`, the input buffer is full. It is up to the driver to decide what to do in that case (callback functions for registering overflow are being planned for later versions of the serial driver).

When all data has been unloaded, the driver must call `data_rcv_done()`.

Serial testing with ser_filter

Rationale

Since some targets only have one serial connection, a serial testing harness needs to be able to share the connection with GDB (however, the test and GDB can also run on separate lines).

The *serial filter* (ser_filter) sits between the serial port and GDB and monitors the exchange of data between GDB and the target. Normally, no changes are made to the data.

When a test request packet is sent from the test on the target, it is intercepted by the filter.

The filter and target then enter a loop, exchanging protocol data between them which GDB never sees.

In the event of a timeout, or a crash on the target, the filter falls back into its pass-through mode. If this happens due to a crash it should be possible to start regular debugging with GDB. The filter will stay in the pass-though mode until GDB disconnects.

The Protocol

The protocol commands are prefixed with an `"@"` character which the serial filter is looking for. The protocol commands include:

`PING`

> Allows the test on the target to probe for the filter. The filter responds with `OK`, while GDB would just ignore the command. This allows the tests to do nothing if they require the filter and it is not present.

`CONFIG`

> Requests a change of serial line configuration. Arguments to the command specify baud rate, data bits, stop bits, and parity. [This command is not fully implemented yet - there is no attempt made to recover if the new configuration turns out to cause loss of data.]

`BINARY`

> Requests data to be sent from the filter to the target. The data is checksummed, allowing errors in the transfer to be detected. Sub-options of this command control how the data transfer is made:
>
> `NO_ECHO`
>
> > (serial driver receive test) Just send data from the filter to the target. The test verifies the checksum and PASS/FAIL depending on the result.
>
> `EOP_ECHO`
>
> > (serial driver half-duplex receive and send test) As `NO_ECHO` but the test echoes back the data to the filter. The filter does a checksum on the received data and sends the result to the target. The test PASS/FAIL depending on the result of both checksum verifications.
>
> `DUPLEX_ECHO`
>
> > (serial driver duplex receive and send test) Smaller packets of data are sent back and forth in a pattern that ensures that the serial driver will be both sending and receiving at the same time. Again, checksums are computed and verified resulting in PASS/FAIL.

`TEXT`

This is a test of the text translations in the TTY layer. Requests a transfer of text data from the target to the filter and possibly back again. The filter treats this as a binary transfer, while the target ma be doing translations on the data. The target provides the filter with checksums for what it should expect to see. This test is not implemented yet.

The above commands may be extended, and new commands added, as required to test (new) parts of the serial drivers in eCos.

The Serial Tests

The serial tests are built as any other eCos test. After running the **make tests** command, the tests can be found in `install/tests/io_serial/`

`serial1`

A simple API test.

`serial2`

A simple serial send test. It writes out two strings, one raw and one encoded as a GDB O-packet

`serial3` [requires the serial filter]

This tests the half-duplex send and receive capabilities of the serial driver.

`serial4` [requires the serial filter]

This test attempts to use a few different serial configurations, testing the driver's configuration/setup functionality.

`serial5` [requires the serial filter]

This tests the duplex send and receive capabilities of the serial driver.

All tests should complete in less than 30 seconds.

Serial Filter Usage

Running the ser_filter program with no (or wrong) arguments results in the following output:

```
Usage: ser_filter [-t -S] TcpIPport SerialPort BaudRate
    or: ser_filter -n [-t -S] SerialPort BaudRate

  -t: Enable tracing.
  -S: Output data read from serial line.
  -c: Output data on console instead of via GDB.
  -n: No GDB.
```

The normal way to use it with GDB is to start the filter:

```
$ ser_filter -t 9000 com1 38400
```

In this case, the filter will be listening on port 9000 and connect to the target via the serial port `COM1` at 38400 baud. On a UNIX host, replace "`COM1`" with a device such as "`/dev/ttyS0`".

The `-t` option enables tracing which will cause the filter to describe its actions on the console.

Now start GDB with one of the tests as an argument:

```
$ mips-tx39-elf-gdb -nw install/tests/io_serial/serial3
```

Then connect to the filter:

```
(gdb) target remote localhost:9000
```

This should result in a connection in exactly the same way as if you had connected directly to the target on the serial line.

```
(gdb) c
```

Which should result in output similar to the below:

```
Continuing.
INFO:<BINARY:16:1!>
PASS:<Binary test completed>
INFO:<BINARY:128:1!>
PASS:<Binary test completed>
INFO:<BINARY:256:1!>
PASS:<Binary test completed>
INFO:<BINARY:1024:1!>
PASS:<Binary test completed>
INFO:<BINARY:512:0!>
PASS:<Binary test completed>
…
PASS:<Binary test completed>
INFO:<BINARY:16384:0!>
PASS:<Binary test completed>
PASS:<serial13 test OK>
EXIT:<done>
```

If any of the individual tests fail the testing will terminate with a `FAIL`.

With tracing enabled, you would also see the filter's status output:

The `PING` command sent from the target to determine the presence of the filter:

```
[400 11:35:16] Dispatching command PING
[400 11:35:16] Responding with status OK
```

Each of the binary commands result in output similar to:

```
[400 11:35:16] Dispatching command BINARY
[400 11:35:16] Binary data (Size:16, Flags:1).
[400 11:35:16] Sending CRC: '170231!', len: 7.
[400 11:35:16] Reading 16 bytes from target.
[400 11:35:16] Done. in_crc 170231, out_crc 170231.
[400 11:35:16] Responding with status OK
[400 11:35:16] Received DONE from target.
```

This tracing output is normally sent as O-packets to GDB which will display the tracing text. By using the `-c` option, the tracing text can be redirected to the console from which ser_filter was started.

A Note on Failures

A serial connection (especially when driven at a high baud rate) can garble the transmitted data because of noise from the environment. It is not the job of the serial driver to ensure data integrity - that is the job of protocols layering on top of the serial driver.

In the current implementation the serial tests and the serial filter are not resilient to such data errors. This means that the test may crash or hang (possibly without reporting a `FAIL`). It also means that you should be aware of random errors - a `FAIL` is not necessarily caused by a bug in the serial driver.

Ideally, the serial testing infrastructure should be able to distinguish random errors from consistent errors - the former are most likely due to noise in the transfer medium, while the latter are more likely to be caused by faulty drivers. The current implementation of the infrastructure does not have this capability.

Debugging

If a test fails, the serial filter's output may provide some hints about what the problem is. If the option `-S` is used when starting the filter, data received from the target is printed out:

```
[400 11:35:16] 0000 50 41 53 53 3a 3c 42 69 'PASS:<Bi'
[400 11:35:16] 0008 6e 61 72 79 20 74 65 73 'nary.tes'
[400 11:35:16] 0010 74 20 63 6f 6d 70 6c 65 't.comple'
[400 11:35:16] 0018 74 65 64 3e 0d 0a 49 4e 'ted>..IN'
[400 11:35:16] 0020 46 4f 3a 3c 42 49 4e 41 'FO:<BINA'
[400 11:35:16] 0028 52 59 3a 31 32 38 3a 31 'RY:128:1'
[400 11:35:16] 0030 21 3e 0d 0a 40 42 49 4e '!..@BIN'
[400 11:35:16] 0038 41 52 59 3a 31 32 38 3a 'ARY:128:'
[400 11:35:16] 0040 31 21 .. .. .. .. .. .. '1!'
```

In the case of an error during a testing command the data received by the filter will be printed out, as will the data that was expected. This allows the two data sets to be compared which may give some idea of what the problem is.

Chapter 19. Device Driver Interface to the Kernel

This chapter describes the API that device drivers may use to interact with the kernel and HAL. It is primarily concerned with the control and management of interrupts and the synchronization of ISRs, DSRs and threads.

The same API will be present in configurations where the kernel is not present. In this case the functions will be supplied by code acting directly on the HAL.

Interrupt Model

eCos presents a three level interrupt model to device drivers. This consists of Interrupt Service Routines (ISRs) that are invoked in response to a hardware interrupt; Deferred Service Routines (DSRs) that are invoked in response to a request by an ISR; and threads that are the clients of the driver.

Hardware interrupts are delivered with minimal intervention to an ISR. The HAL decodes the hardware source of the interrupt and calls the ISR of the attached interrupt object. This ISR may manipulate the hardware but is only allowed to make a restricted set of calls on the driver API. When it returns, an ISR may request that its DSR should be scheduled to run.

A DSR will be run when it is safe to do so without interfering with the scheduler. Most of the time the DSR will run immediately after the ISR, but if the current thread is in the scheduler, it will be delayed until the thread is finished. A DSR is allowed to make a larger set of driver API calls, including, in particular, being able to call `cyg_drv_cond_signal()` to wake up waiting threads.

Finally, threads are able to make all API calls and in particular are allowed to wait on mutexes and condition variables.

For a device driver to receive interrupts it must first define ISR and DSR routines as shown below, and then call `cyg_drv_interrupt_create()`. Using the handle returned, the driver must then call `cyg_drv_interrupt_attach()` to actually attach the interrupt to the hardware vector.

Synchronization

There are three levels of synchronization supported:

1. Synchronization with ISRs. This normally means disabling interrupts to prevent the ISR running during a critical section. In an SMP environment, this will also require the use of a spinlock to synchronize with ISRs, DSRs or threads running on other CPUs. This is implemented by the `cyg_drv_isr_lock()` and `cyg_drv_isr_unlock()` functions. This mechanism should be used sparingly and for short periods only. For finer grained synchronization, individual spinlocks are also supplied.

2. Synchronization with DSRs. This will be implemented in the kernel by taking the scheduler lock to prevent DSRs running during critical sections. In non-kernel configurations it will be implemented by non-kernel code. This is implemented by the `cyg_drv_dsr_lock()` and `cyg_drv_dsr_unlock()` functions. As with ISR synchronization, this mechanism should be used sparingly. Only DSRs and threads may use this synchronization mechanism, ISRs are not allowed to do this.

3. Synchronization with threads. This is implemented with mutexes and condition variables. Only threads may lock the mutexes and wait on the condition variables, although DSRs may signal condition variables.

Any data that is accessed from more than one level must be protected against concurrent access. Data that is accessed by ISRs must be protected with the ISR lock, or a spinlock at all times, *even in ISRs*. Data that is shared between DSRs and threads should be protected with the DSR lock. Data that is only accessed by threads must be protected with mutexes.

SMP Support

Some eCos targets contain support for Symmetric Multi-Processing (SMP) configurations, where more than one CPU may be present. This option has a number of ramifications for the way in which device drivers must be written if they are to be SMP-compatible.

Since it is possible for the ISR, DSR and thread components of a device driver to execute on different CPUs, it is important that SMP-compatible device drivers use the driver API routines correctly.

Synchronization between threads and DSRs continues to require that the thread-side code use `cyg_drv_dsr_lock()` and `cyg_drv_dsr_unlock()` to protect access to shared data. While it is not strictly necessary for DSR code to claim the DSR lock, since DSRs are run with it claimed already, it is good practice to do so.

Synchronization between ISRs and DSRs or threads requires that access to sensitive data be protected, in all places, by calls to `cyg_drv_isr_lock()` and `cyg_drv_isr_unlock()`. Disabling or masking interrupts is not adequate, since the thread or DSR may be running on a different CPU and interrupt enable/disable only work on the current CPU.

The ISR lock, for SMP systems, not only disables local interrupts, but also acquires a spinlock to protect against concurrent access from other CPUs. This is necessary because ISRs are not run with the scheduler lock claimed. Hence they can run in parallel with the other components of the device driver.

The ISR lock provided by the driver API is just a shared spinlock that is available for use by all drivers. If a driver needs to implement a finer grain of locking, it can use private spinlocks, accessed via the `cyg_drv_spinlock_*()` functions.

Device Driver Models

There are several ways in which device drivers may be built. The exact model chosen will depend on the properties of the device and the behavior desired. There are three basic models that may be adopted.

The first model is to do all device processing in the ISR. When it is invoked the ISR programs the device hardware directly and accesses data to be transferred directly in memory. The ISR should also call `cyg_drv_interrupt_acknowledge()`. When it is finished it may optionally request that its DSR be invoked. The DSR does nothing but call `cyg_drv_cond_signal()` to cause a thread to be woken up. Thread level code must call `cyg_drv_isr_lock()`, or `cyg_drv_interrupt_mask()` to prevent ISRs running while it manipulates shared memory.

The second model is to defer device processing to the DSR. The ISR simply prevents further delivery of interrupts by either programming the device, or by calling `cyg_drv_interrupt_mask()`. It must then call `cyg_drv_interrupt_acknowledge()` to allow other interrupts to be delivered and then request that its DSR be called. When the DSR runs it does the majority of the device handling, optionally signals a condition variable to wake a thread, and finishes by calling `cyg_drv_interrupt_unmask()` to re-allow device interrupts. Thread level code uses `cyg_drv_dsr_lock()` to prevent DSRs running while it manipulates shared memory. The eCos serial device drivers use this approach.

The third model is to defer device processing even further to a thread. The ISR behaves exactly as in the previous model and simply blocks and acknowledges the interrupt before request that the DSR run. The DSR itself only calls `cyg_drv_cond_signal()` to wake the thread. When the thread awakens it performs all device processing, and has full access to all kernel facilities while it does so. It should finish by calling `cyg_drv_interrupt_unmask()` to re-allow device interrupts. The eCos ethernet device drivers are written to this model.

The first model is good for devices that need immediate processing and interact infrequently with thread level. The second model trades a little latency in dealing with the device for a less intrusive synchronization mechanism. The last model allows device processing to be scheduled with other threads and permits more complex device handling.

Synchronization Levels

Since it would be dangerous for an ISR or DSR to make a call that might reschedule the current thread (by trying to lock a mutex for example) all functions in this API have an associated synchronization level. These levels are:

Thread
: This function may only be called from within threads. This is usually the client code that makes calls into the device driver. In a non-kernel configuration, this will be code running at the default non-interrupt level.

DSR
: This function may be called by either DSR or thread code.

ISR
: This function may be called from ISR, DSR or thread code.

The following table shows, for each API function, the levels at which is may be called:

	Callable from:		
Function	ISR	DSR	Thread
cyg_drv_isr_lock	X	X	X
cyg_drv_isr_unlock	X	X	X
cyg_drv_spinlock_init			X
cyg_drv_spinlock_destroy			X
cyg_drv_spinlock_spin	X	X	X
cyg_drv_spinlock_clear	X	X	X
cyg_drv_spinlock_try	X	X	X
cyg_drv_spinlock_test	X	X	X
cyg_drv_spinlock_spin_intsave	X	X	X
cyg_drv_spinlock_clear_intsave	X	X	X
cyg_drv_dsr_lock		X	X
cyg_drv_dsr_unlock		X	X
cyg_drv_mutex_init			X
cyg_drv_mutex_destroy			X
cyg_drv_mutex_lock			X
cyg_drv_mutex_trylock			X
cyg_drv_mutex_unlock			X
cyg_drv_mutex_release			X
cyg_drv_cond_init			X
cyg_drv_cond_destroy			X
cyg_drv_cond_wait			X
cyg_drv_cond_signal		X	X
cyg_drv_cond_broadcast		X	X
cyg_drv_interrupt_create			X
cyg_drv_interrupt_delete			X
cyg_drv_interrupt_attach	X	X	X
cyg_drv_interrupt_detach	X	X	X
cyg_drv_interrupt_mask	X	X	X
cyg_drv_interrupt_unmask	X	X	X
cyg_drv_interrupt_acknowledge	X	X	X
cyg_drv_interrupt_configure	X	X	X
cyg_drv_interrupt_level	X	X	X
cyg_drv_interrupt_set_cpu	X	X	X
cyg_drv_interrupt_get_cpu	X	X	X

The API

This section details the Driver Kernel Interface. Note that most of these functions are identical to Kernel C API calls, and will in most configurations be wrappers for them. In non-kernel configurations they will be supported directly by the HAL, or by code to emulate the required behavior.

This API is defined in the header file `<cyg/hal/drv_api.h>`.

cyg_drv_isr_lock

Function: `void cyg_drv_isr_lock()`

Arguments: None

Result: None

Level: ISR

Description: Disables delivery of interrupts, preventing all ISRs running. This function maintains a counter of the number of times it is called.

cyg_drv_isr_unlock

Function: `void cyg_drv_isr_unlock()`

Arguments: None

Result: None

Level: ISR

Description: Re-enables delivery of interrupts, allowing ISRs to run. This function decrements the counter maintained by `cyg_drv_isr_lock()`, and only re-allows interrupts when it goes to zero.

cyg_drv_spinlock_init

Function: `void cyg_drv_spinlock_init(cyg_spinlock_t *lock, cyg_bool_t locked )`

Arguments: *lock* - pointer to spinlock to initialize

locked - initial state of lock

Result: None

Level: Thread

Description: Initialize a spinlock. The *locked* argument indicates how the spinlock should be initialized: `TRUE` for locked or `FALSE` for unlocked state.

cyg_drv_spinlock_destroy

Function: `void cyg_drv_spinlock_destroy(cyg_spinlock_t *lock )`

Arguments: *lock* - pointer to spinlock destroy

Result: None

Level: Thread

Description: Destroy a spinlock that is no longer of use. There should be no CPUs attempting to claim the lock at the time this function is called, otherwise the behavior is undefined.

cyg_drv_spinlock_spin

Function: `void cyg_drv_spinlock_spin(cyg_spinlock_t *lock )`

Arguments: *lock* - pointer to spinlock to claim

Result: None

Level: ISR

Description: Claim a spinlock, waiting in a busy loop until it is available. Wherever this is called from, this operation effectively pauses the CPU until it succeeds. This operations should therefore be used sparingly, and in situations where deadlocks/livelocks cannot occur. Also see `cyg_drv_spinlock_spin_intsave()`.

cyg_drv_spinlock_clear

Function: `void cyg_drv_spinlock_clear(cyg_spinlock_t *lock )`

Arguments: *lock* - pointer to spinlock to clear

Result: None

Level: ISR

Description: Clear a spinlock. This clears the spinlock and allows another CPU to claim it. If there is more than one CPU waiting in `cyg_drv_spinlock_spin()` then just one of them will be allowed to proceed.

cyg_drv_spinlock_try

Function: `cyg_bool_t cyg_drv_spinlock_try(cyg_spinlock_t *lock )`

Arguments: *lock* - pointer to spinlock to try

Result: `TRUE` if the spinlock was claimed, `FALSE` otherwise.

Level: ISR

Description: Try to claim the spinlock without waiting. If the spinlock could be claimed immediately then `TRUE` is returned. If the spinlock is already claimed then the result is `FALSE`.

cyg_drv_spinlock_test

Function: `cyg_bool_t cyg_drv_spinlock_test(cyg_spinlock_t *lock )`

Arguments: *lock* - pointer to spinlock to test

Result: `TRUE` if the spinlock is available, `FALSE` otherwise.

Level: ISR

Description: Inspect the state of the spinlock. If the spinlock is not locked then the result is `TRUE`. If it is locked then the result will be `FALSE`.

cyg_drv_spinlock_spin_intsave

Function:

```
void cyg_drv_spinlock_spin_intsave( cyg_spinlock_t *lock,
                                    cyg_addrword_t *istate )
```

Arguments: *lock* - pointer to spinlock to claim

istate - pointer to interrupt state save location

Result: None

Level: ISR

Description: This function behaves exactly like `cyg_drv_spinlock_spin()` except that it also disables interrupts before attempting to claim the lock. The current interrupt enable state is saved in **istate*. Interrupts remain disabled once the spinlock had been claimed and must be restored by calling `cyg_drv_spinlock_clear_intsave()`.

In general, device drivers should use this function to claim and release spinlocks rather than the non-`_intsave()` variants, to ensure proper exclusion with code running on both other CPUs and this CPU.

cyg_drv_spinlock_clear_intsave

Function:

```
void cyg_drv_spinlock_clear_intsave( cyg_spinlock_t *lock,
                                     cyg_addrword_t istate )
```

Arguments: *lock* - pointer to spinlock to clear

istate - interrupt state to restore

Result: None

Level: ISR

Description: This function behaves exactly like `cyg_drv_spinlock_clear()` except that it also restores an interrupt state saved by `cyg_drv_spinlock_spin_intsave()`. The *istate* argument must have been initialized by a previous call to `cyg_drv_spinlock_spin_intsave()`.

cyg_drv_dsr_lock

Function:

```
void cyg_drv_dsr_lock()
```

Arguments: None

Result: None

Level: DSR

Description: Disables scheduling of DSRs. This function maintains a counter of the number of times it has been called.

cyg_drv_dsr_unlock

Function:

```
void cyg_drv_dsr_unlock()
```

Arguments: None

Result:

None

Level: DSR

Description: Re-enables scheduling of DSRs. This function decrements the counter incremented by `cyg_drv_dsr_lock()`. DSRs are only allowed to be delivered when the counter goes to zero.

cyg_drv_mutex_init

Function: `void cyg_drv_mutex_init(cyg_drv_mutex_t *mutex)`

Arguments: *`mutex`* - pointer to mutex to initialize

Result: None

Level: Thread

Description: Initialize the mutex pointed to by the `mutex` argument.

cyg_drv_mutex_destroy

Function: `void cyg_drv_mutex_destroy( cyg_drv_mutex_t *mutex )`

Arguments: *`mutex`* - pointer to mutex to destroy

Result: None

Level: Thread

Description: Destroy the mutex pointed to by the *`mutex`* argument. The mutex should be unlocked and there should be no threads waiting to lock it when this call in made.

cyg_drv_mutex_lock

Function: `cyg_bool cyg_drv_mutex_lock( cyg_drv_mutex_t *mutex )`

Arguments: *`mutex`* - pointer to mutex to lock

Result: `TRUE` it the thread has claimed the lock, `FALSE` otherwise.

Level: Thread

Description: Attempt to lock the mutex pointed to by the *`mutex`* argument. If the mutex is already locked by another thread then this thread will wait until that thread is finished. If the result from this function is `FALSE` then the thread was broken out of its wait by some other thread. In this case the mutex will not have been locked.

cyg_drv_mutex_trylock

Function: `cyg_bool cyg_drv_mutex_trylock( cyg_drv_mutex_t *mutex )`

Arguments: *`mutex`* - pointer to mutex to lock

Result: `TRUE` if the mutex has been locked, `FALSE` otherwise.

Level: Thread

Description: Attempt to lock the mutex pointed to by the *`mutex`* argument without waiting. If the mutex is already locked by some other thread then this function returns `FALSE`. If the function can lock the mutex without waiting, then `TRUE` is returned.

cyg_drv_mutex_unlock

Function: `void cyg_drv_mutex_unlock( cyg_drv_mutex_t *mutex )`

Arguments: *mutex* - pointer to mutex to unlock

Result: None

Level: Thread

Description: Unlock the mutex pointed to by the *mutex* argument. If there are any threads waiting to claim the lock, one of them is woken up to try and claim it.

cyg_drv_mutex_release

Function: `void cyg_drv_mutex_release( cyg_drv_mutex_t *mutex )`

Arguments: `mutex` - pointer to mutex to release

Result: None

Level: Thread

Description: Release all threads waiting on the mutex pointed to by the *mutex* argument. These threads will return from `cyg_drv_mutex_lock()` with a `FALSE` result and will not have claimed the mutex. This function has no effect on any thread that may have the mutex claimed.

cyg_drv_cond_init

Function: `void cyg_drv_cond_init( cyg_drv_cond_t *cond, cyg_drv_mutex_t *mutex )`

Arguments: *cond* - condition variable to initialize

mutex - mutex to associate with this condition variable

Result: None

Level: Thread

Description: Initialize the condition variable pointed to by the *cond* argument. The *mutex* argument must point to a mutex with which this condition variable is associated. A thread may only wait on this condition variable when it has already locked the associated mutex. Waiting will cause the mutex to be unlocked, and when the thread is reawakened, it will automatically claim the mutex before continuing.

cyg_drv_cond_destroy

Function: `void cyg_drv_cond_destroy( cyg_drv_cond_t *cond )`

Arguments: *cond* - condition variable to destroy

Result: None

Level: Thread

Description: Destroy the condition variable pointed to by the *cond* argument.

cyg_drv_cond_wait

Function:

```
void cyg_drv_cond_wait( cyg_drv_cond_t *cond )
```

Arguments: *cond* - condition variable to wait on

Result: None

Level: Thread

Description: Wait for a signal on the condition variable pointed to by the *cond* argument. The thread must have locked the associated mutex, supplied in `cyg_drv_cond_init()`, before waiting on this condition variable. While the thread waits, the mutex will be unlocked, and will be re-locked before this function returns. It is possible for threads waiting on a condition variable to occasionally wake up spuriously. For this reason it is necessary to use this function in a loop that re-tests the condition each time it returns. Note that this function performs an implicit scheduler unlock/relock sequence, so that it may be used within an explicit `cyg_drv_dsr_lock()`... `cyg_drv_dsr_unlock()` structure.

cyg_drv_cond_signal

Function:

```
void cyg_drv_cond_signal( cyg_drv_cond_t *cond )
```

Arguments: *cond* - condition variable to signal

Result: None

Level: DSR

Description: Signal the condition variable pointed to by the *cond* argument. If there are any threads waiting on this variable at least one of them will be awakened. Note that in some configurations there may not be any difference between this function and `cyg_drv_cond_broadcast()`.

cyg_drv_cond_broadcast

Function:

```
void cyg_drv_cond_broadcast( cyg_drv_cond_t *cond )
```

Arguments: *cond* - condition variable to broadcast to

Result: None

Level: DSR

Description: Signal the condition variable pointed to by the *cond* argument. If there are any threads waiting on this variable they will all be awakened.

cyg_drv_interrupt_create

Function:

```
void cyg_drv_interrupt_create(
    cyg_vector_t    vector,
    cyg_priority_t  priority,
    cyg_addrword_t  data,
    cyg_ISR_t       *isr,
    cyg_DSR_t       *dsr,
    cyg_handle_t    *handle,
    cyg_interrupt   *intr)
```

Arguments: *vector* - vector to attach to

priority - queuing priority

data - data pointer

isr - interrupt service routine

dsr - deferred service routine

handle - returned handle

intr - put interrupt object here

Result: None

Level: Thread

Description: Create an interrupt object and returns a handle to it. The object contains information about which interrupt vector to use and the ISR and DSR that will be called after the interrupt object is attached to the vector. The interrupt object will be allocated in the memory passed in the *intr* parameter. The interrupt object is not immediately attached; it must be attached with the `cyg_interrupt_attach()` call.

The *data* argument will be passed to both the registered ISR and DSR. Typically it will be a pointer to some data structure.

cyg_drv_interrupt_delete

Function:

```
void cyg_drv_interrupt_delete( cyg_handle_t interrupt )
```

Arguments: *interrupt* - interrupt to delete

Result: None

Level: Thread

Description: Detach the interrupt from the vector and free the memory passed in the *intr* argument to `cyg_drv_interrupt_create()` for reuse.

cyg_drv_interrupt_attach

Function:

```
void cyg_drv_interrupt_attach( cyg_handle_t interrupt )
```

Arguments: *interrupt* - interrupt to attach

Result: None

Level: ISR

Description: Attach the interrupt to the vector so that interrupts will be delivered to the ISR when the interrupt occurs.

cyg_drv_interrupt_detach

Function:

```
void cyg_drv_interrupt_detach( cyg_handle_t interrupt )
```

Arguments: *interrupt* - interrupt to detach

Result: None

Level: ISR

Description: Detach the interrupt from the vector so that interrupts will no longer be delivered to the ISR.

cyg_drv_interrupt_mask

Function: `void cyg_drv_interrupt_mask(cyg_vector_t vector )`

Arguments: *`vector`* - vector to mask

Result: None

Level: ISR

Description: Program the interrupt controller to stop delivery of interrupts on the given vector. On architectures which implement interrupt priority levels this may also disable all lower priority interrupts.

cyg_drv_interrupt_mask_intunsafe

Function: `void cyg_drv_interrupt_mask_intunsafe(cyg_vector_t vector )`

Arguments: *`vector`* - vector to mask

Result: None

Level: ISR

Description: Program the interrupt controller to stop delivery of interrupts on the given vector. On architectures which implement interrupt priority levels this may also disable all lower priority interrupts. This version differs from `cyg_drv_interrupt_mask()` in not being interrupt safe. So in situations where, for example, interrupts are already known to be disabled, this may be called to avoid the extra overhead.

cyg_drv_interrupt_unmask

Function: `void cyg_drv_interrupt_unmask(cyg_vector_t vector )`

Arguments: *`vector`* - vector to unmask

Result: None

Level: ISR

Description: Program the interrupt controller to re-allow delivery of interrupts on the given *`vector`*.

cyg_drv_interrupt_unmask_intunsafe

Function: `void cyg_drv_interrupt_unmask_intunsafe(cyg_vector_t vector )`

Arguments: *`vector`* - vector to unmask

Result: None

Level: ISR

Description: Program the interrupt controller to re-allow delivery of interrupts on the given *vector*. This version differs from `cyg_drv_interrupt_unmask()` in not being interrupt safe.

cyg_drv_interrupt_acknowledge

Function:

```
void cyg_drv_interrupt_acknowledge( cyg_vector_t vector )
```

Arguments: *vector* - vector to acknowledge

Result: None

Level: ISR

Description: Perform any processing required at the interrupt controller and in the CPU to cancel the current interrupt request on the *vector*. An ISR may also need to program the hardware of the device to prevent an immediate re-triggering of the interrupt.

cyg_drv_interrupt_configure

Function:

```
void cyg_drv_interrupt_configure( cyg_vector_t vector,
                                  cyg_bool_t level,
                                  cyg_bool_t up)
```

Arguments: *vector* - vector to configure

level - level or edge triggered

up - rising/falling edge, high/low level

Result: None

Level: ISR

Description: Program the interrupt controller with the characteristics of the interrupt source. The *level* argument chooses between level- or edge-triggered interrupts. The *up* argument chooses between high and low level for level triggered interrupts or rising and falling edges for edge triggered interrupts. This function only works with interrupt controllers that can control these parameters.

cyg_drv_interrupt_level

Function:

```
void cyg_drv_interrupt_level( cyg_vector_t vector,
                              cyg_priority_t level)
```

Arguments: *vector* - vector to configure

level - level to set

Result: None

Level: ISR

Description: Program the interrupt controller to deliver the given interrupt at the supplied priority level. This function only works with interrupt controllers that can control this parameter.

cyg_drv_interrupt_set_cpu

Function:

```
void cyg_drv_interrupt_set_cpu( cyg_vector_t vector,
                                        cyg_cpu_t cpu)
```

Arguments: *vector* - interrupt vector to route

cpu - destination CPU

Result: None

Level: ISR

Description: This function causes all interrupts on the given vector to be routed to the specified CPU. Subsequently, all such interrupts will be handled by that CPU. This only works if the underlying hardware is capable of performing this kind of routing. This function does nothing on a single CPU system.

cyg_drv_interrupt_get_cpu

Function:

```
cyg_cpu_t cyg_drv_interrupt_set_cpu( cyg_vector_t vector )
```

Arguments: *vector* - interrupt vector to query

Result: The CPU to which this vector is routed

Level: ISR

Description: In multi-processor systems this function returns the id of the CPU to which interrupts on the given vector are current being delivered. In single CPU systems this function returns zero.

cyg_ISR_t

Type:

```
typedef cyg_uint32 cyg_ISR_t(
    cyg_vector_t    vector,
    cyg_addrword_t  data
)
```

Fields: *vector* - vector being delivered

data - data value supplied by client

Result: Bit mask indicating whether interrupt was handled and whether the DSR should be called.

Description: Interrupt Service Routine definition. A pointer to a function with this prototype is passed to `cyg_interrupt_create()` when an interrupt object is created. When an interrupt is delivered the function will be called with the vector number and the data value that was passed to `cyg_interrupt_create()`.

The return value is a bit mask containing one or both of the following bits:

CYG_ISR_HANDLED indicates that the interrupt was handled by this ISR. It is a configuration option whether this will prevent further ISR being run.

CYG_ISR_CALL_DSR causes the DSR that was passed to `cyg_interrupt_create()` to be scheduled to be called.

cyg_DSR_t

Type:

```
typedef void cyg_DSR_t(
        cyg_vector_t    vector,
        cyg_ucount32    count,
        cyg_addrword_t  data
)
```

Fields: *`vector`* - vector being delivered

`count` - number of times DSR has been scheduled

`data` - data value supplied by client

Result: None

Description: Deferred Service Routine prototype. A pointer to a function with this prototype is passed to `cyg_interrupt_create()` when an interrupt object is created. When the ISR requests the scheduling of its DSR, this function will be called at some later point. In addition to the *`vector`* and *`data`* arguments, which will be the same as those passed to the ISR, this routine is also passed a *`count`* of the number of times the ISR has requested that this DSR be scheduled. This counter is zeroed each time the DSR actually runs, so it indicates how many interrupts have occurred since it last ran.

Instrumentation

If the system instrumentation support is enabled then the I/O package provides support for generating instrumentation records for various events within the general purpose I/O framework.

Instrumentation records will only be generated if the `CYGIMP_IO_INSTRUMENTATION` option is enabled, and then only if the relevant individual event code sub-options are also enabled. The default state is for all the instrumentation to be disabled. Some options will generate a lot of instrumentation records in a heavily loaded system and so care may need to be taken regarding the instrumentation that is enabled vs the instrumentation recording mechanism being used to avoid missing events. Depending on why the I/O framework instrumentation is being enabled (debugging, timing validation, etc.) the user can choose which events they wish to record by enabling the specific CDL options.

Part VII. File System Support Infrastructure

Table of Contents

Chapter 20. Introduction

This document describes the filesystem infrastructure provided in eCos. This is implemented by the FILEIO package and provides POSIX compliant file and IO operations together with the BSD socket API. These APIs are described in the relevant standards and original documentation and will not be described here. See the Posix Standard Support documentation for details of which parts of the POSIX standard are supported.

This document is concerned with the interfaces presented to client filesystems and network protocol stacks.

The FILEIO infrastructure consist mainly of a set of tables containing pointers to the primary interface functions of a file system. This approach avoids problems of namespace pollution (for example several filesystems can have a function called `read()`, so long as they are static). The system is also structured to eliminate the need for dynamic memory allocation.

New filesystems can be written directly to the interfaces described here. Existing filesystems can be ported very easily by the introduction of a thin veneer porting layer that translates FILEIO calls into native filesystem calls.

The term filesystem should be read fairly loosely in this document. Object accessed through these interfaces could equally be network protocol sockets, device drivers, fifos, message queues or any other object that can present a file-like interface.

Chapter 21. File System Table

The filesystem table is an array of entries that describe each filesystem implementation that is part of the system image. Each resident filesystem should export an entry to this table using the `FSTAB_ENTRY()` macro.

Note

At present we do not support dynamic addition or removal of table entries. However, an API similar to `mount()` would allow new entries to be added to the table.

The table entries are described by the following structure:

```
struct cyg_fstab_entry
{
    const char          *name;          // filesystem name
    CYG_ADDRWORD        data;           // private data value
    cyg_uint32          syncmode;       // synchronization mode

    int     (*mount)    ( cyg_fstab_entry *fste,
                          cyg_mtab_entry  *mte );
    int     (*umount)   ( cyg_mtab_entry  *mte,
                          cyg_bool        force );
    int     (*open)     ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name,
                          int             mode,
                          cyg_file        *fte );
    int     (*unlink)   ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name );
    int     (*mkdir)    ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name );
    int     (*rmdir)    ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name );
    int     (*rename)   ( cyg_mtab_entry  *mte,
                          cyg_dir         dir1,
                          const char      *name1,
                          cyg_dir         dir2,
                          const char      *name2 );
    int     (*link)     ( cyg_mtab_entry  *mte,
                          cyg_dir         dir1,
                          const char      *name1,
                          cyg_dir         dir2,
                          const char      *name2,
                          int             type );
    int     (*opendir)  ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name,
                          cyg_file        *fte );
    int     (*chdir)    ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name,
                          cyg_dir         *dir_out );
    int     (*stat)     ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name,
                          struct stat     *buf);
    int     (*getinfo)  ( cyg_mtab_entry  *mte,
                          cyg_dir         dir,
                          const char      *name,
                          int             key,
                          char             *buf,
                          int              len );
    int     (*setinfo)  ( cyg_mtab_entry   *mte,
                          cyg_dir          dir,
                          const char       *name,
                          int              key,
                          char             *buf,
                          int              len );
};
```

The *name* field points to a string that identifies this filesystem implementation. Typical values might be "romfs", "fatfs", "ext2" etc.

The *data* field contains any private data that the filesystem needs, perhaps the root of its data structures.

The *syncmode* field contains a description of the locking protocol to be used when accessing this filesystem. It will be described in more detail in Chapter 25, *Synchronization*.

The remaining fields are pointers to functions that implement filesystem operations that apply to files and directories as whole objects. The operation implemented by each function should be obvious from the names, with a few exceptions:

The `opendir()` function pointer opens a directory for reading. See Chapter 24, *Directories* for details.

The `getinfo()` and `setinfo()` function pointers provide support for various minor control and information functions such as `pathconf()` and `access()`.

With the exception of the `mount()` and `umount()` functions, all of these functions take three standard arguments, a pointer to a mount table entry (see later) a directory pointer (also see later) and a file name relative to the directory. These should be used by the filesystem to locate the object of interest.

Chapter 22. Mount Table

The mount table records the filesystems that are actually active. These can be seen as being analogous to mount points in Unix systems.

There are two sources of mount table entries. Filesystems (or other components) may export static entries to the table using the `MTAB_ENTRY()` macro. Alternatively, new entries may be installed at run time using the `mount()` function. Both types of entry may be unmounted with the `umount()` function.

A mount table entry has the following structure:

```
struct cyg_mtab_entry
{
    const char          *name;          // name of mount point
    const char          *fsname;        // name of implementing filesystem
    const char          *devname;       // name of hardware device
    const char          *options;       // mount option string
    CYG_ADDRWORD        data;           // private data value
    cyg_bool            valid;          // Valid entry?
    cyg_fstab_entry     *fs;            // pointer to fstab entry
    cyg_dir             root;           // root directory pointer
};
```

The *name* field identifies the mount point. This is used to direct rooted filenames (filenames that begin with "/") to the correct filesystem. When a file name that begins with "/" is submitted, it is matched against the *name* fields of all valid mount table entries. The entry that yields the longest match terminating before a "/", or end of string, wins and the appropriate function from the filesystem table entry is then passed the remainder of the file name together with a pointer to the table entry and the value of the *root* field as the directory pointer.

For example, consider a mount table that contains the following entries:

```
{ "/",    "fatfs", "/dev/hd0", … }
{ "/fd",  "fatfs", "/dev/fd0", … }
{ "/rom", "romfs", "", … }
{ "/tmp", "ramfs", "", … }
{ "/dev", "devfs", "", … }
```

An attempt to open "/tmp/foo" would be directed to the RAM filesystem while an open of "/bar/bundy" would be directed to the hard disc FATFS filesystem. Opening "/dev/tty0" would be directed to the device management filesystem for lookup in the device table.

Unrooted file names (those that do not begin with a '/') are passed straight to the filesystem that contains the current directory. The current directory is represented by a pair consisting of a mount table entry and a directory pointer.

The *fsname* field points to a string that should match the *name* field of the implementing filesystem. During initialization the mount table is scanned and the *fsname* entries looked up in the filesystem table. For each match, the filesystem's _mount_ function is called and if successful the mount table entry is marked as valid and the *fs* pointer installed.

The *devname* field contains the name of the device that this filesystem is to use. This may match an entry in the device table (see later) or may be a string that is specific to the filesystem if it has its own internal device drivers.

The *data* field is a private data value. This may be installed either statically when the table entry is defined, or may be installed during the `mount()` operation.

The *valid* field indicates whether this mount point has actually been mounted successfully. Entries with a false *valid* field are ignored when searching for a name match.

The *fs* field is installed after a successful `mount()` operation to point to the implementing filesystem.

The *`root`* field contains a directory pointer value that the filesystem can interpret as the root of its directory tree. This is passed as the *`dir`* argument of filesystem functions that operate on rooted filenames. This field must be initialized by the filesystem's `mount()` function.

Chapter 23. File Table

Once a file has been opened it is represented by an open file object. These are allocated from an array of available file objects. User code accesses these open file objects via a second array of pointers which is indexed by small integer offsets. This gives the usual Unix file descriptor functionality, complete with the various duplication mechanisms.

A file table entry has the following structure:

```
struct CYG_FILE_TAG
{
    cyg_uint32                  f_flag;         /* file state                   */
    cyg_uint16                  f_ucount;       /* use count                    */
    cyg_uint16                  f_type;         /* descriptor type              */
    cyg_uint32                  f_syncmode;     /* synchronization protocol     */
    struct CYG_FILEOPS_TAG      *f_ops;         /* file operations              */
    off_t                       f_offset;       /* current offset               */
    CYG_ADDRWORD                f_data;         /* file or socket               */
    CYG_ADDRWORD                f_xops;         /* extra type specific ops      */
    cyg_mtab_entry              *f_mte;         /* mount table entry            */
};
```

The *f_flag* field contains some FILEIO control bits and some bits propagated from the *flags* argument of the `open()` call (defined by `CYG_FILE_MODE_MASK`).

The *f_ucount* field contains a use count that controls when a file will be closed. Each duplicate in the file descriptor array counts for one reference here. It is also incremented around each I/O operation to ensure that the file cannot be closed while it has current I/O operations.

The *f_type* field indicates the type of the underlying file object. Some of the possible values here are `CYG_FILE_TYPE_FILE`, `CYG_FILE_TYPE_SOCKET` or `CYG_FILE_TYPE_DEVICE`.

The *f_syncmode* field is copied from the *syncmode* field of the implementing filesystem. Its use is described in Chapter 25, *Synchronization*.

The *f_offset* field records the current file position. It is the responsibility of the file operation functions to keep this field up to date.

The *f_data* field contains private data placed here by the underlying filesystem. Normally this will be a pointer to, or handle on, the filesystem object that implements this file.

The *f_xops* field contains a pointer to any extra type specific operation functions. For example, the socket I/O system installs a pointer to a table of functions that implement the standard socket operations.

The *f_mte* field contains a pointer to the parent mount table entry for this file. It is used mainly to implement the synchronization protocol. This may contain a pointer to some other data structure in file objects not derived from a filesystem.

The *f_ops* field contains a pointer to a table of file I/O operations. This has the following structure:

```
struct CYG_FILEOPS_TAG
{
    int (*fo_read)      (struct CYG_FILE_TAG *fp, struct CYG_UIO_TAG *uio);
    int (*fo_write)     (struct CYG_FILE_TAG *fp, struct CYG_UIO_TAG *uio);
    int (*fo_lseek)     (struct CYG_FILE_TAG *fp, off_t *pos, int whence );
    int (*fo_ioctl)     (struct CYG_FILE_TAG *fp, CYG_ADDRWORD com, CYG_ADDRWORD data);
    int (*fo_select)    (struct CYG_FILE_TAG *fp, int which, CYG_ADDRWORD info);
    int (*fo_fsync)     (struct CYG_FILE_TAG *fp, int mode );
    int (*fo_close)     (struct CYG_FILE_TAG *fp);
    int (*fo_fstat)     (struct CYG_FILE_TAG *fp, struct stat *buf );
    int (*fo_getinfo)   (struct CYG_FILE_TAG *fp, int key, char *buf, int len );
    int (*fo_setinfo)   (struct CYG_FILE_TAG *fp, int key, char *buf, int len );
};
```

It should be obvious from the names of most of these functions what their responsibilities are. The `fo_getinfo()` and `fo_setinfo()` function pointers, like their counterparts in the filesystem structure, implement minor control and info functions such as `fpathconf()`.

The second argument to the `fo_read()` and `fo_write()` function pointers is a pointer to a UIO structure:

```
struct CYG_UIO_TAG
{
    struct CYG_IOVEC_TAG  *uio_iov;     /* pointer to array of iovecs */
    int                   uio_iovcnt;   /* number of iovecs in array */
    off_t                 uio_offset;   /* offset into file this uio corresponds to */
    ssize_t               uio_resid;    /* residual i/o count */
    enum cyg_uio_seg      uio_segflg;   /* see above */
    enum cyg_uio_rw       uio_rw;       /* see above */
};

struct CYG_IOVEC_TAG
{
    void                  *iov_base;    /* Base address. */
    ssize_t               iov_len;      /* Length. */
};
```

This structure encapsulates the parameters of any data transfer operation. It provides support for scatter/gather operations and records the progress of any data transfer. It is also compatible with the I/O operations of any BSD-derived network stacks and filesystems.

When a file is opened (or a file object created by some other means, such as `socket()` or `accept()`) it is the responsibility of the filesystem open operation to initialize all the fields of the object except the *f_ucount*, *f_syncmode* and *f_mte* fields. Since the *f_flag* field will already contain bits belonging to the FILEIO infrastructure, any changes to it must be made with the appropriate logical operations.

Chapter 24. Directories

Filesystem operations all take a directory pointer as one of their arguments. A directory pointer is an opaque handle managed by the filesystem. It should encapsulate a reference to a specific directory within the filesystem. For example, it may be a pointer to the data structure that represents that directory (such as an inode), or a pointer to a pathname for the directory.

The `chdir()` filesystem function pointer has two modes of use. When passed a pointer in the *`dir_out`* argument, it should locate the named directory and place a directory pointer there. If the *`dir_out`* argument is NULL then the *`dir`* argument is a previously generated directory pointer that can now be disposed of. When the infrastructure is implementing the `chdir()` function it makes two calls to filesystem `chdir()` functions. The first is to get a directory pointer for the new current directory. If this succeeds the second is to dispose of the old current directory pointer.

The `opendir()` function is used to open a directory for reading. This results in an open file object that can be read to return a sequence of struct dirent objects. The only operations that are allowed on this file are `read`, `lseek` and `close`. Each read operation on this file should return a single struct dirent object. When the end of the directory is reached, zero should be returned. The only seek operation allowed is a rewind to the start of the directory, by supplying an offset of zero and a *`whence`* specifier of `SEEK_SET`.

Most of these considerations are invisible to clients of a filesystem since they will access directories via the POSIX `opendir()`, `readdir()` and `closedir()` functions. The struct dirent object returned by `readdir()` will always contain d_name as required by POSIX. When `CYGPKG_FILEIO_DIRENT_DTYPE` is enabled it will also contain d_type, which is not part of POSIX, but often implemented by OSes. Currently only the FATFS, RAMFS, ROMFS and JFFS2 filesystem sets this value. For other filesystems a value of 0 will be returned in the member.

Support for the `getcwd()` function is provided by three mechanisms. The first is to use the `FS_INFO_GETCWD` getinfo key on the filesystem to use any internal support that it has for this. If that fails it falls back on one of the two other mechanisms. If `CYGPKG_IO_FILEIO_TRACK_CWD` is set then the current directory is tracked textually in `chdir()` and the result of that is reported in getcwd(). Otherwise an attempt is made to traverse the directory tree to its root using ".." entries.

This last option is complicated and expensive, and relies on the filesystem supporting "." and ".." entries. This is not always the case, particularly if the filesystem has been ported from a non-UNIX-compatible source. Tracking the pathname textually will usually work, but might not produce optimum results when symbolic links are being used.

Chapter 25. Synchronization

The FILEIO infrastructure provides a synchronization mechanism for controlling concurrent access to filesystems. This allows existing filesystems to be ported to eCos, even if they do not have their own synchronization mechanisms. It also allows new filesystems to be implemented easily without having to consider the synchronization issues.

The infrastructure maintains a mutex for each entry in each of the main tables: filesystem table, mount table and file table. For each class of operation each of these mutexes may be locked before the corresponding filesystem operation is invoked.

The synchronization protocol required by a filesystem is described by the *syncmode* field of the filesystem table entry. This is a combination of the following flags:

`CYG_SYNCMODE_FILE_FILESYSTEM`

Lock the filesystem table entry mutex during all filesystem level operations.

`CYG_SYNCMODE_FILE_MOUNTPOINT`

Lock the mount table entry mutex during all filesystem level operations.

`CYG_SYNCMODE_IO_FILE`

Lock the file table entry mutex during all I/O operations.

`CYG_SYNCMODE_IO_FILESYSTEM`

Lock the filesystem table entry mutex during all I/O operations.

`CYG_SYNCMODE_IO_MOUNTPOINT`

Lock the mount table entry mutex during all I/O operations.

`CYG_SYNCMODE_SOCK_FILE`

Lock the file table entry mutex during all socket operations.

`CYG_SYNCMODE_SOCK_NETSTACK`

Lock the network stack table entry mutex during all socket operations.

`CYG_SYNCMODE_NONE`

Perform no locking at all during any operations.

The value of the *syncmode* field in the filesystem table entry will be copied by the infrastructure to the open file object after a successful `open()` operation.

Chapter 26. Initialization and Mounting

As mentioned previously, mount table entries can be sourced from two places. Static entries may be defined by using the `MTAB_ENTRY()` macro. Such entries will be automatically mounted on system startup. For each entry in the mount table that has a non-null *`name`* field the filesystem table is searched for a match with the *`fsname`* field. If a match is found the filesystem's *`mount`* entry is called and if successful the mount table entry marked valid and the *`fs`* field initialized. The `mount()` function is responsible for initializing the *`root`* field.

The size of the mount table is defined by the configuration value `CYGNUM_FILEIO_MTAB_MAX`. Any entries that have not been statically defined are available for use by dynamic mounts.

A filesystem may be mounted dynamically by calling `mount()`. This function has the following prototype:

```
int mount(const char *devname,
          const char *dir,
          const char *fsname);
```

The *`devname`* argument identifies a device that will be used by this filesystem and will be assigned to the *`devname`* field of the mount table entry.

The *`dir`* argument is the mount point name, it will be assigned to the *`name`* field of the mount table entry.

The *`fsname`* argument is the name of the implementing filesystem, it will be assigned to the *`fsname`* entry of the mount table entry. This argument may also contain options that control the mode in which the filesystem is mounted.

Since these three arguments are assigned directly to the mount table entry, the memory pointed to by these arguments must not change for the duration of the mount. This means they must be allocated from memory that will persist unchanged until unmounting, such as constant strings, dynamically allocated memory, or static or automatic variables that do not pass out of scope or get their values changed before unmounting.

The options attached to the *`fsname`* argument consist of a comma separated list of single keywords or keyword=value pairs separated from the filesystem name by a colon. For example, to mount the FAT filesystem with write-through cache synchronization the string would be: `"fatfs:sync=write"` and to mount it read-only: `"fatfs:readonly"`.

The process of mounting a filesystem dynamically is as follows. First a search is made of the mount table for an entry with a NULL *`name`* field to be used for the new mount point. The filesystem table is then searched for an entry whose name matches *`fsname`*. If this is successful then the mount table entry is initialized and the filesystem's `mount()` operation called. If this is successful, the mount table entry is marked valid and the *`fs`* field initialized.

Mounting a filesystem dynamically at the current working directory name, does not in fact change the current directory to one on the newly mounted filesystem. Instead the current working directory remains on the previous filesystem (or no filesystem in the case of '/' with no filesystems previously mounted). This is in line with usual POSIX/UNIX behaviour. To change to the new filesystem, a `chdir()` call must be made, even if it is to the current directory name as given by `getcwd()`. This is especially relevant when mounting a filesystem on '/' as the current working directory is usually also '/' .

Normally you can access files and directories with both absolute paths (for example '`/fs/dir1/file1.txt`') or paths relative to the current working directory (for example '`./dir1/file1.txt`' or just '`dir1/file1.txt`'). As a special exception, you cannot use relative paths if your current working directory is the root directory '/', unless there is a filesystem mounted directly on '/'. This is a deliberate simplification due to the fact that the current working directory is not really a valid directory and there is no true filesystem at '/' to navigate within. Instead it is recommended to either change directory into a filesystem after mounting using `chdir()`, use absolute paths, or mount a filesystem at '/'.

It should also be noted that there is no requirement for there to be a directory entry for a filesystem mount point if mounted within another filesystem. So for example, there need not be a directory named “`/dev`” in the directory list of “`/`” even though there is a filesystem mounted on “`/dev`”.

Unmounting a filesystem is done by the `umount()` function. This can unmount filesystems whether they were mounted statically or dynamically.

The `umount()` function has the following prototype:

```
int umount( const char *name );
```

The mount table is searched for a match between the *`name`* argument and the entry *`name`* field. When a match is found the filesystem's `umount()` operation, with the *`force`* argument set to `false` is called and if successful, the mount table entry is invalidated by setting its *`valid`* field false and the *`name`* field to NULL.

There is also an `umount_force()` function with the following prototype:

```
int umount_force( const char *name );
```

The main difference between this and the standard `umount()` function is that it forces the filesystem to be unmounted. In the FILEIO package this means that all open files will be forced to close, the current directory will be moved away from the filesystem if it points to it and any threads waiting for access to the filesystem will be forced to return. In general, any buffered data not yet written to the medium will be lost; such buffering may take place in libraries like C standard I/O, C++ streams or the filesystem itself. If the programmer wishes for buffered data to be committed beforehand, they must use whatever mechanism has been provided by the layers performing the buffering. This is not always the case however, such as if the reason to force an unmounting is because the medium has been removed. When the filesystem's `umount()` function is called, the *`force`* argument will be set `true`, and the filesystem should take steps to free all resources and detach from the underlying device.

Care must be taken if mounting a filesystem on “`/`” as it will not be possible to unmount the filesystem later if it is in use as the current working directory. Instead it will be necessary to change directory to a different filesystem before unmounting.

Chapter 27. Automounter

Where removable media is supported by the filesystem and the hardware device driver (currently only the FAT filesystem and the eCosPro USB mass storage device driver have this support) it is possible to configure an automounter which will automatically mount any filesystems found on any device that is inserted. It will also automatically unmount the filesystem when the device is removed.

The automounter is controlled by a number of configuration options:

`CYGPKG_IO_FILEIO_AUTOMOUNT`

> This option enables the eCos automounter. It is only active if there are device drivers present that are capable of dealing with removable media.
>
> Default value: 0

`CYGDAT_IO_FILEIO_AUTOMOUNT_ROOT`

> Any automounted filesystems will be mounted under this root directory.
>
> Default value: "/auto"

`CYGDAT_IO_FILEIO_AUTOMOUNT_DEVICES`

> This option is a list of device names of the devices that will be monitored by the automounter. Each entry is two strings within braces, with separate entries separated by commas. The first string gives the device name, the second the stub for making the mount point name under the automount root. The name of the filesystem root will be manufactured by appending the disk number and partition number to the name stub, separated by underscores. For example with the default values typical filesystem root names might be: "/auto/usb_0_1" or "/auto/usb_1_2".
>
> Default value: { "/dev/usbmass/", "usb" }

The Automounter also defines a callback that may be used by applications to receive notifications that new filesystems have been mounted or unmounted. The `fileio.h` header contains the following definitions if the automounter is enabled:

```
typedef void cyg_automount_handler( int event, char *mountpoint, CYG_ADDRWORD data );
#define CYG_AUTOMOUNT_MOUNT     1
#define CYG_AUTOMOUNT_UMOUNT    2

__externC int cyg_automount_register_handler( char *devname,
                                              cyg_automount_handler *handler,
                                              CYG_ADDRWORD data );
```

The function `cyg_automount_register_handler()` causes the callback handler to be registered. The *`devname`* identifies the device to which the callback will be attached, it should match one of the device names defined in `CYGDAT_IO_FILEIO_AUTOMOUNT_DEVICES`. The *`handler`* argument is the callback function and *`data`* is a user defined data value.

When the handler is called, the *`event`* argument indicates the event being notified, `CYG_AUTOMOUNT_MOUNT` or `CYG_AUTOMOUNT_UMOUNT`. The *`mountpoint`* argument is the name of the root of the filesystem being notified, it will be composed as described above from `CYGDAT_IO_FILEIO_AUTOMOUNT_ROOT` and the stub part of the relevant `CYGDAT_IO_FILEIO_AUTOMOUNT_DEVICES` entry. The *`data`* argument is the data value passed in from `cyg_automount_register_handler()`.

The handler will be called by the automounter just after the filesystem has been mounted, or just before it is unmounted. Application code should avoid running too much code in the handler and offload long running tasks to another thread. This is because the handler is called directly from the automounter thread and while it is executing, no other automount operations can be run.

Chapter 28. Sockets

If a network stack is present, then the FILEIO infrastructure also provides access to the standard BSD socket calls.

The netstack table contains entries which describe the network protocol stacks that are in the system image. Each resident stack should export an entry to this table using the `NSTAB_ENTRY()` macro.

Each table entry has the following structure:

```
struct cyg_nstab_entry
{
    cyg_bool            valid;          // true if stack initialized
    cyg_uint32          syncmode;       // synchronization protocol
    char                *name;          // stack name
    char                *devname;       // hardware device name
    CYG_ADDRWORD        data;           // private data value

    int     (*init)( cyg_nstab_entry *nste );
    int     (*socket)( cyg_nstab_entry *nste, int domain, int type,
    int protocol, cyg_file *file );
};
```

This table is analogous to a combination of the filesystem and mount tables.

The *`valid`* field is set `true` if the stack's `init()` function returned successfully and the *`syncmode`* field contains the `CYG_SYNCMODE_SOCK_*` bits described above.

The *`name`* field contains the name of the protocol stack.

The *`devname`* field names the device that the stack is using. This may reference a device under "/dev", or may be a name that is only meaningful to the stack itself.

The `init()` function pointer is called during system initialization to start the protocol stack running. If it returns non-zero the *`valid`* field is set false and the stack will be ignored subsequently.

The `socket()` function is called to attempt to create a socket in the stack. When the `socket()` API function is called the netstack table is scanned and for each valid entry the `socket()` function pointer is called. If this returns non-zero then the scan continues to the next valid stack, or terminates with an error if the end of the table is reached.

The result of a successful socket call is an initialized file object with the *`f_xops`* field pointing to the following structure:

```
struct cyg_sock_ops
{
    int (*bind)      ( cyg_file *fp, const sockaddr *sa, socklen_t len );
    int (*connect)   ( cyg_file *fp, const sockaddr *sa, socklen_t len );
    int (*accept)    ( cyg_file *fp, cyg_file *new_fp,
                       struct sockaddr *name, socklen_t *anamelen );
    int (*listen)    ( cyg_file *fp, int len );
    int (*getname)   ( cyg_file *fp, sockaddr *sa, socklen_t *len, int peer );
    int (*shutdown)  ( cyg_file *fp, int flags );
    int (*getsockopt)( cyg_file *fp, int level, int optname,
                       void *optval, socklen_t *optlen);
    int (*setsockopt)( cyg_file *fp, int level, int optname,
                       const void *optval, socklen_t optlen);
    int (*sendmsg)   ( cyg_file *fp, const struct msghdr *m,
                       int flags, ssize_t *retsize );
    int (*recvmsg)   ( cyg_file *fp, struct msghdr *m,
                       socklen_t *namelen, ssize_t *retsize );
};
```

It should be obvious from the names of these functions which API calls they provide support for. The `getname()` function pointer provides support for both `getsockname()` and `getpeername()` while the `sendmsg()` and `recvmsg()` function pointers provide support for `send()`, `sendto()`, `sendmsg()`, `recv()`, `recvfrom()` and `recvmsg()` as appropriate.

Chapter 29. Select

The infrastructure provides support for implementing a select mechanism. This is modeled on the mechanism in the BSD kernel, but has been modified to make it implementation independent.

The main part of the mechanism is the `select()` API call. This processes its arguments and calls the `fo_select()` function pointer on all file objects referenced by the file descriptor sets passed to it. If the same descriptor appears in more than one descriptor set, the `fo_select()` function will be called separately for each appearance.

The *`which`* argument of the `fo_select()` function will either be `CYG_FREAD` to test for read conditions, `CYG_FWRITE` to test for write conditions or zero to test for exceptions. For each of these options the function should test whether the condition is satisfied and if so return true. If it is not satisfied then it should call `cyg_selrecord()` with the *`info`* argument that was passed to the function and a pointer to a cyg_selinfo structure.

The cyg_selinfo structure is used to record information about current select operations. Any object that needs to support select must contain an instance of this structure. Separate cyg_selinfo structures should be kept for each of the options that the object can select on - read, write or exception.

If none of the file objects report that the select condition is satisfied, then the `select()` API function puts the calling thread to sleep waiting either for a condition to become satisfied, or for the optional timeout to expire.

A selectable object must have some asynchronous activity that may cause a select condition to become true - either via interrupts or the activities of other threads. Whenever a selectable condition is satisfied, the object should call `cyg_selwakeup()` with a pointer to the appropriate cyg_selinfo structure. If the thread is still waiting, this will cause it to wake up and repeat its poll of the file descriptors. This time around, the object that caused the wakeup should indicate that the select condition is satisfied, and the `select()` API call will return.

Note that `select()` does not exhibit real time behaviour: the iterative poll of the descriptors, and the wakeup mechanism mitigate against this. If real time response to device or socket I/O is required then separate threads should be devoted to each device of interest and should use blocking calls to wait for a condition to become ready.

Chapter 30. Devices

Devices are accessed by means of a pseudo-filesystem, "devfs", that is mounted on "/dev". Open operations are translated into calls to `cyg_io_lookup()` and if successful result in a file object whose *`f_ops`* functions translate filesystem API functions into calls into the device API.

Chapter 31. Writing a New Filesystem

To create a new filesystem it is necessary to define the fstab entry and the file IO operations. The easiest way to do this is to copy an existing filesystem: either the test filesystem in the FILEIO package, or the RAM or ROM filesystem packages.

To make this clearer, the following is a brief tour of the FILEIO relevant parts of the RAM filesystem.

First, it is necessary to provide forward definitions of the functions that constitute the filesystem interface:

```
//==========================================================================
// Forward definitions

// Filesystem operations
static int ramfs_mount    ( cyg_fstab_entry *fste, cyg_mtab_entry *mte );
static int ramfs_umount   ( cyg_mtab_entry *mte, cyg_bool force );
static int ramfs_open     ( cyg_mtab_entry *mte, cyg_dir dir, const char *name,
                            int mode,  cyg_file *fte );
static int ramfs_unlink   ( cyg_mtab_entry *mte, cyg_dir dir, const char *name );
static int ramfs_mkdir    ( cyg_mtab_entry *mte, cyg_dir dir, const char *name );
static int ramfs_rmdir    ( cyg_mtab_entry *mte, cyg_dir dir, const char *name );
static int ramfs_rename   ( cyg_mtab_entry *mte, cyg_dir dir1, const char *name1,
                            cyg_dir dir2, const char *name2 );
static int ramfs_link     ( cyg_mtab_entry *mte, cyg_dir dir1, const char *name1,
                            cyg_dir dir2, const char *name2, int type );
static int ramfs_opendir  ( cyg_mtab_entry *mte, cyg_dir dir, const char *name,
                            cyg_file *fte );
static int ramfs_chdir    ( cyg_mtab_entry *mte, cyg_dir dir, const char *name,
                            cyg_dir *dir_out );
static int ramfs_stat     ( cyg_mtab_entry *mte, cyg_dir dir, const char *name,
                            struct stat *buf);
static int ramfs_getinfo  ( cyg_mtab_entry *mte, cyg_dir dir, const char *name,
                            int key, void *buf, int len );
static int ramfs_setinfo  ( cyg_mtab_entry *mte, cyg_dir dir, const char *name,
                            int key, void *buf, int len );

// File operations
static int ramfs_fo_read      (struct CYG_FILE_TAG *fp, struct CYG_UIO_TAG *uio);
static int ramfs_fo_write     (struct CYG_FILE_TAG *fp, struct CYG_UIO_TAG *uio);
static int ramfs_fo_lseek     (struct CYG_FILE_TAG *fp, off_t *pos, int whence );
static int ramfs_fo_ioctl     (struct CYG_FILE_TAG *fp,
                               CYG_ADDRWORD com,
                               CYG_ADDRWORD data);
static int ramfs_fo_fsync     (struct CYG_FILE_TAG *fp, int mode );
static int ramfs_fo_close     (struct CYG_FILE_TAG *fp);
static int ramfs_fo_fstat     (struct CYG_FILE_TAG *fp, struct stat *buf );
static int ramfs_fo_getinfo   (struct CYG_FILE_TAG *fp, int key, void *buf, int len );
static int ramfs_fo_setinfo   (struct CYG_FILE_TAG *fp, int key, void *buf, int len );

// Directory operations
static int ramfs_fo_dirread   (struct CYG_FILE_TAG *fp, struct CYG_UIO_TAG *uio);
static int ramfs_fo_dirlseek  (struct CYG_FILE_TAG *fp, off_t *pos, int whence );
```

We define all of the fstab entries and all of the file IO operations. We also define alternatives for the *fo_read* and *fo_lseek* file IO operations.

We can now define the filesystem table entry. There is a macro, FSTAB_ENTRY to do this:

```
//==========================================================================
// Filesystem table entries

// -------------------------------------------------------------------------
// Fstab entry.
// This defines the entry in the filesystem table.
// For simplicity we use _FILESYSTEM synchronization for all accesses since
// we should never block in any filesystem operations.

FSTAB_ENTRY( ramfs_fste, "ramfs", 0,
    CYG_SYNCMODE_FILE_FILESYSTEM|CYG_SYNCMODE_IO_FILESYSTEM,
    ramfs_mount,
    ramfs_umount,
    ramfs_open,
    ramfs_unlink,
    ramfs_mkdir,
    ramfs_rmdir,
    ramfs_rename,
    ramfs_link,
    ramfs_opendir,
    ramfs_chdir,
    ramfs_stat,
    ramfs_getinfo,
    ramfs_setinfo);
```

The first argument to this macro gives the fstab entry a name, the remainder are initializers for the field of the structure.

We must also define the file operations table that is installed in all open file table entries:

```
// -------------------------------------------------------------------------
// File operations.
// This set of file operations are used for normal open files.

static cyg_fileops ramfs_fileops =
{
    ramfs_fo_read,
    ramfs_fo_write,
    ramfs_fo_lseek,
    ramfs_fo_ioctl,
    cyg_fileio_seltrue,
    ramfs_fo_fsync,
    ramfs_fo_close,
    ramfs_fo_fstat,
    ramfs_fo_getinfo,
    ramfs_fo_setinfo
};
```

These all point to functions supplied by the filesystem except the *fo_select* field which is filled with a pointer to `cyg_fileio_seltrue()`. This is provided by the FILEIO package and is a select function that always returns true to all operations.

Finally, we need to define a set of file operations for use when reading directories. This table only defines the *fo_read* and *fo_lseek* operations. The rest are filled with stub functions supplied by the FILEIO package that just return an error code.

```
// -------------------------------------------------------------------------
// Directory file operations.
// This set of operations are used for open directories. Most entries
// point to error-returning stub functions. Only the read, lseek and
// close entries are functional.

static cyg_fileops ramfs_dirops =
{
    ramfs_fo_dirread,
    (cyg_fileop_write *)cyg_fileio_enosys,
    ramfs_fo_dirlseek,
    (cyg_fileop_ioctl *)cyg_fileio_enosys,
    cyg_fileio_seltrue,
    (cyg_fileop_fsync *)cyg_fileio_enosys,
    ramfs_fo_close,
    (cyg_fileop_fstat *)cyg_fileio_enosys,
    (cyg_fileop_getinfo *)cyg_fileio_enosys,
    (cyg_fileop_setinfo *)cyg_fileio_enosys
};
```

If the filesystem wants to have an instance automatically mounted on system startup, it must also define a mount table entry. This is done with the `MTAB_ENTRY` macro. This is an example from the test filesystem of how this is used:

```
MTAB_ENTRY( testfs_mte1,
      "/",
      "testfs",
      "",
      "",
      0);
```

The first argument provides a name for the table entry. The following arguments provide initialization for the *`name`*, *`fsname`*, *`devname`* *`options`* and *`data`* fields respectively.

These definitions are adequate to let the new filesystem interact with the FILEIO package. The new filesystem now needs to be fleshed out with implementations of the functions defined above. Obviously, the exact form this takes will depend on what the filesystem is intended to do. Take a look at the RAM and ROM filesystems for examples of how this has been done.

Part VIII. FAT File System Support

Table of Contents

Chapter 32. Introduction

This document describes the FAT filesystem provided in eCos. This is implemented by the FATFS package which uses the facilities of the FILEIO package to present its functionality to the user.

The FAT filesystem supports FAT12, FAT16 and FAT32 disk formats.

The FAT filesystem includes optional support for long file names. This functionality is covered by patents belonging to Microsoft in several territories, including Europe and the the USA. By default the long file name support in eCos (CYGCFG_FS_FAT_LONG_FILE_NAMES) is disabled. If you wish to enable this feature on products that are distributed within these territories then you may need to aquire a license from Microsoft.

Chapter 33. Configuring the FAT Filesystem

This chapter shows how to include the FAT filesystem into an eCos configuration and how to configure it once installed.

Including FAT Filesystem in a Configuration

The FAT filesystem is contained in a single eCos package, CYGPKG_FS_FAT. However, it depends on the services of a collection of other packages for complete functionality:

CYGPKG_IO_FILEIO

> The File IO package. This provides the POSIX compatible API by which the FAT filesystem is accessed.

CYGPKG_IO

> Device IO package. This provides all the infrastructure for the disk devices.

CYGPKG_IO_DISK

> Disk device IO support. This provides the top level generic disk driver functions. It also interprets partition tables and provides a separate access channel for each partition. This package is described in detail elsewhere.

CYGPKG_LINUX_COMPAT

> Linux compatibility library. The FAT filesystem only used the list and RBtree features of this library.

CYGPKG_LIBC_STRING

> Strings library. This provides the string and memory move and compare routines used by the filesystem.

CYGPKG_MEMALLOC

> The FAT filesystem currently uses malloc() to allocate its memory resources, such as the node and block caches, so this package is required.

To add the FAT filesystem to a configuration, it is necessary to add all of these packages. This is best done by using an import file. The following file will add the FAT filesystem and all the necessary packages to any configuration:

```
cdl_savefile_version 1;
cdl_savefile_command cdl_savefile_version {};
cdl_savefile_command cdl_savefile_command {};
cdl_savefile_command cdl_configuration { description hardware template package };
cdl_savefile_command cdl_package { value_source user_value wizard_value inferred_value };
cdl_savefile_command cdl_component { value_source user_value wizard_value inferred_value };
cdl_savefile_command cdl_option { value_source user_value wizard_value inferred_value };
cdl_savefile_command cdl_interface { value_source user_value wizard_value inferred_value };

cdl_configuration eCos {
    package CYGPKG_FS_FAT current ;
    package CYGPKG_IO_DISK current ;
    package CYGPKG_LINUX_COMPAT current ;
    package CYGPKG_IO_FILEIO current ;
    package CYGPKG_IO current ;
    package CYGPKG_LIBC_STRING current ;
    package CYGPKG_MEMALLOC current ;
};
```

In addition to these packages, hardware-specific device driver packages will be needed for the disk devices to be used. These device drivers are usually part of the target description in the eCos database and will be enabled if the CYGPKG_IO_DISK package is included.

Configuring the FAT Filesystem

Once added to the configuration, the FAT filesystem has a number of configuration options:

CYGNUM_FS_FAT_NODE_HASH_TABLE_SIZE

> This option controls the number of slots in the hash table used to store file nodes using filenames as keys.
>
> Default value: 32

CYGNUM_FS_FAT_NODE_POOL_SIZE

> This option controls the size of the node pool used for storing file nodes. This value should be set to the maximum required number of simultaneously open files plus the desired size of unused node cache.
>
> Default value: CYGNUM_FILEIO_NFILE + 2

CYGNUM_FS_FAT_BLOCK_CACHE_BLOCKSIZE

> This option controls the size of blocks in the block cache. This value should be a power-of-2 multiple of 512. It must be at least as great as the underlying disk sector size (usually 512) but can be greater, allowing multiple underlying blocks to be cached within a single cache block.
>
> With some underlying disk devices, performance can be greatly improved by increasing the size of this option, as it may allow multiple disk blocks to be transferred in one transaction. This is known to be particularly true with MMC or SD card media and it is recommended to increase the size of this option with such media.
>
> Default value: 512

CYGNUM_FS_FAT_BLOCK_CACHE_MEMSIZE

> This option controls the amount of memory used for the block cache.
>
> Default value: 20 * CYGNUM_FS_FAT_BLOCK_CACHE_BLOCKSIZE

CYGDBG_FS_FAT_NODE_CACHE_EXTRA_CHECKS

> This option controls the inclusion of extra sanity checks in node cache code.
>
> Default value: 1

CYGCFG_FS_FAT_USE_ATTRIBUTES

> This option controls whether the FAT filesystem supports or honors the FAT filesystem file attributes.
>
> Default value: 0

CYGCFG_FS_FAT_LONG_FILE_NAMES

> This option controls the FAT filesystem support for long file names.
>
> Default value: 0

CYGNUM_FS_FAT_LONG_FILE_NAME_MAX

> This option defines the maximum size of long file names supported by the filesystem. The default value of 64 corresponds to NAME_MAX, which defines the size of d_name[] in a struct dirent.
>
> Default value: 64

CYGSEM_FS_FAT_ASYNC_IO

> Normally every operation on a mounted FAT filesystem must complete before another operation can start. However sometimes a thread must block while waiting for a read or write to the underlying disk medium to complete. As a performance improvement, this option allows other threads to perform operations on the FAT filesystem while other threads are blocked. This can be especially beneficial when the operations can be performed entirely using the in-built file system block and node cache.
>
> However, a known limitation is that there is not currently sufficient protection in place to handle situations where two threads update a directory at the same time, for example, both creating, renaming or removing files or directories (Issue #1001183). Other operations should be safe, but for the time being care is advised if enabling this option, and eCosCentric cannot provide support for resulting problems if it is enabled.
>
> Default value: 0

CYGSEM_FS_FAT_FORMAT

> This option enables support for formatting a FAT filesystem on the device before mounting it. Only FAT16 and FAT32 formats are supported, FAT12 is not. The variety of options supported is also limited to choosing the format, block size, and volume label, where appropriate.
>
> Default value: 1

Normally these options should be left as they are unless you have a specific need to change them. Once the configuration had been created, it should be possible to compile eCos and link it with the application without any errors.

Chapter 34. Using the FAT Filesystem

The FAT filesystem is accessed through the FILEIO package and responds to all the standard filesystem functions such as `open()`, `close()`, `read()` and `write()`. To use these operations the filesystem must first be mounted.

A FAT filesystem may be mounted using the `mount()` function. The following is an example of how to mount a FAT filesystem:

```
    err = mount( "/dev/hd0/1", "/disk0",  "fatfs:sync=write" );
```

This function call will mount the first partition of hard disk 0 (see the documentation on the DISKIO package for a full description of the device name format). The root of this disk can then be accessed with the name "/disk0". The `mount()` function will return zero if the mount succeeded, or -1 if it failed for any reason, for example if the partition does not exist, or the filesystem is not in FAT format.

The options after the colon in the filesystem name are passed to the filesystem to control various aspects of the filesystem. The options currently supported are:

sync
: This option controls the synchronization behaviour of the block cache. If omitted then the cache is run on an entirely write-back basis and blocks are only written back to disk when they need to be replaced with new data, when `sync()` is called, or the filesystem is unmounted. This is generally the most efficient mode, but is prone to losing data or corrupting the filesystem if power is lost while the filesystem is mounted.

  If this option is set to "write" then the cache is operated on a write-back basis and every block update is written immediately back to disk. This is the least efficient mode since any extension to a file may result in several blocks being written back to disk. It does, however, keep the filesystem up to date on disk.

  If this option is set to "close" then the cache is only written back to disk whenever a file is closed. Note that this causes the entire cache to be written, not just those blocks associated with the file being closed. In terms of efficiency, this is a good compromise between performance and safety.

readonly
: This is a stand-alone option which causes the filesystem to be mounted read-only. The effect of this is to prevent the filesystem writing anything back to the disk. Under normal circumstances this cannot be guaranteed for a normal mount, even when files are only read, since the filesystem may need to update the access time for files that have been read.

When finished with, a filesystem may be unmounted using the `umount()` function. The following would unmount the filesystem mounted above:

```
    err = umount( "/disk0" );
```

Warning!

It is important to unmount any removable devices before removing them, otherwise there is no guarantee that all cached data blocks will have been written to disk. The same is true of resetting the system before unmounting non-removable devices.

Chapter 35. Removable Media Support

The FAT filesystem has support for Removable Media, which is implemented in conjunction with support in the FILEIO package, the generic DISKIO layer and the hardware disk driver. At present, the drivers which support this include the MMC/SD card driver in bus mode (not SPI mode), subject to the presence of underlying hardware support; and also the USB mass storage device driver.

To support Removable media, application code, or the automounter, should register a disk event callback to capture device insertion and removal. When an insert event is detected, an attempt to mount the filesystem should be made. If this is successful, then the files on the device can be accessed.

When the device is removed the hardware driver will reject all IO operations with an EIO response. The filesystem will propagate these errors back to any current file IO operations which will result in `read()` or `write()` returning an EIO error. Application code should be ready for this to happen.

A disk event callback will also be delivered and the application should arrange to call `umount_force()` to force the filesystem to be unmounted. The FAT filesystem handles this by releasing all resources and detaching from the disk device.

To help applications indicate to the user whether the medium may be removed (by means of a LED or an on-screen icon) the FAT filesystem supports the filesystem callback mechanism defined in the FILEIO package. This relies on the following definitions in `fileio.h`:

```
typedef void cyg_fs_callback( cyg_int32 event, CYG_ADDRWORD data );

struct cyg_fs_callback_info
{
    cyg_fs_callback     *callback;      // Callback function
    CYG_ADDRWORD        data;           // User data value
};

// Callback events
#define CYG_FS_CALLBACK_SAFE    1       // The filesystem is up to date on disk
#define CYG_FS_CALLBACK_UNSAFE  2       // The filesystem is not up to date
```

A callback function may be registered after a filesystem has been mounted by using `cyg_fs_setinfo()` as follows:

```
struct cyg_fs_callback_info callback;

…

callback.callback = fs_callback;
callback.data = my_data;
err = cyg_fs_setinfo("/disk0", FS_INFO_CALLBACK, &callback, sizeof(callback));
```

Following this, whenever the filesystem has dirty cache blocks that are not up to date on the disk, `fs_callback()` will be called with *`event`* set to `CYG_FS_CALLBACK_UNSAFE`. When all blocks become up to date on disk it will be called with `CYG_FS_CALLBACK_SAFE`.

Chapter 36. Non-ASCII Character Set Support

If long filename support is enabled (by setting `CYGCFG_FS_FAT_LONG_FILE_NAMES`) then all strings passed to and from the filesystem may be encoded using UTF-8. This allows files to be named using characters beyond the basic ASCII set.

If long filename support is disabled then file names are limited to the standard 8.3 format. However, these file names are preserved in an 8-bit clean format, if they contain non-ASCII characters, so that any multi-byte encodings are preserved.

Filesystems created by devices that do not support long filenames may have 8.3 names that are encoded using non-ASCII and non-Unicode character sets. Typically these will be encoded according to Microsoft code page character sets. To permit these names to pass through the rest of the filesystem, and compare correctly during file searches, when long filename support is enabled, these names need to be translated into Unicode. Since the filesystem has no built-in internationalization support, beyond Unicode, it is the responsibility of the application or middleware layers to supply the translation of these values to and from Unicode. The FILEIO package defines callbacks that may be used to do this:

```
typedef int cyg_fs_mbcs_to_utf16le( CYG_ADDRWORD data,
                                    const cyg_uint8 *mbcs,
                                    int size,
                                    cyg_uint16 *utf16le);

typedef int cyg_fs_utf16le_to_mbcs( CYG_ADDRWORD data,
                                    const cyg_uint16 *utf16le,
                                    int size,
                                    cyg_uint8 *mbcs);

struct cyg_fs_mbcs_translate
{
    cyg_fs_mbcs_to_utf16le      *mbcs_to_utf16le;
    cyg_fs_utf16le_to_mbcs      *utf16le_to_mbcs;
    CYG_ADDRWORD                data;
};
```

These callback functions may be registered after a filesystem has been mounted by using `cyg_fs_setinfo()` as follows:

```
struct cyg_fs_mbcs_translate translate;

…

translate.mbcs_to_utf16le = my_mbcs_to_utf16le;
translate.utf16le_to_mbcs = my_utf16le_to_mbcs;
translate.data = (CYG_ADDRWORD)my_data;
err = cyg_fs_setinfo("/disk0", FS_INFO_MBCS_TRANSLATE, &translate, sizeof(translate));
```

Following this, whenever the filesystem encounters a short file name that contains non-ASCII characters the registered `mbcs_to_utf16le()` function will be called to translate it. In the call, the *`data`* argument will be a copy of the *`data`* field of the cyg_fs_mbcs_translate structure. The *`mbcs`* argument points to the sequence of *`size`* bytes to be translated. The resulting translation should be stored in *`utf16le`* and the number of 16-bit values stored returned from the function.

When the filesystem needs to encode a string into the multibyte character set, it will call the `utf16le_to_mbcs()` function. In the call, the *`data`* argument will be a copy of the *`data`* field of the cyg_fs_mbcs_translate structure. The *`utf16le`* argument points to the sequence of *`size`* 16-bit values to be translated. The resulting translation should be stored in *`mbcs`* and the number of bytes stored returned from the function.

It is important to note that translation is to and from UTF-16LE. All 16 bit values are stored in little endian byte order and Unicode code points outside the Basic Multilingual Plane are encoded as surrogate pairs. This is the format mandated by Microsoft for long file names in the FAT filesystem. See IETF RFC2781 for details of the encoding.

In the current implementation the `utf16le_to_mbcs()` will not be called. If long filename support is disabled, then the filesystem will store multibyte characters as they are supplied. If long filename support is enabled then new files will be created with long names if any non-ASCII characters are present. Renamed files will be converted to the long name form automatically. This function is present in case future enhancements require it. For now applications should install a function that simply returns zero.

Chapter 37. Formatting Support

If the option CYGSEM_FS_FAT_FORMAT is enabled, the filesystem is able to format the chosen volume with a FAT filesystem while mounting it. This is controlled by a number of options passed to the filesystem through the mount function.

format
: This option enables formatting. If this is present without an argument, then the volume will only be formatted if the file system cannot be mounted. With an argument of force the volume will be formatted regardless of its current contents. Without this option present, the following options will be ignored.

fat16
: This option forces the file system to be formatted using FAT16.

fat32
: This option forces the file system to be formatted using FAT32. If neither the fat16 or fat32 options are provided, the formatter will choose the format based on the size of the volume. At present, any volume less than 512MiB in size will be formatted as FAT16, all others will be FAT32.

clsize
: This option takes an argument giving the size of each cluster in KiB. It should be a power of 2. If not supplied, the formatter will choose a cluster size based on the size of the volume.

label
: This option takes a name which should be up to 11 characters in length. This is used to set the volume label in the boot block and to create a volume label entry in the root directory. If not supplied a default volume label will be set (currently "eCos DISK").

A somewhat contrived example of a mount call with the format option might be as follows:

```
err = mount("/dev/hd0/1", "/disk0", "fatfs:format=force,fat16,clsize=8,label=My Volume");
```

Under normal circumstances, just giving the format option should be sufficient for most purposes:

```
err = mount("/dev/hd0/1", "/disk0", "fatfs:format");
```

This will cause the volume to be formatted according to its size, but only if it is not already mountable.

Chapter 38. Testing

There are a number of tests available for the FAT filesystem. These test various aspects of the FAT file system from basic operation to support for long file names, Unicode and code page encodings, performance, synchronization and formatting.

An important feature of these tests is that they use the `format` mount option to auto-format any volume that cannot be mounted. Therefore it is advisable not to run these tests on any device that contains data that should be retained.

Testing the FAT filesystem depends on the availability of a suitable device to perform the tests on. The following configuration options are defined in the target specific disk device driver to configure the tests for the available hardware:

CYGDAT_DEVS_DISK_TEST_DEVICE

> Device name of test disk or partition. This device will be mounted on the mountpoint given in `CYGDAT_DEVS_DISK_TEST_MOUNTPOINT` and tests carried out in the directory given by `CYGDAT_DEVS_DISK_TEST_DIRECTORY`.

CYGDAT_DEVS_DISK_TEST_MOUNTPOINT

> Mountpoint for test disk.

CYGDAT_DEVS_DISK_TEST_DIRECTORY

> Subdirectory in test device where tests can create files and directories.

CYGDAT_DEVS_DISK_TEST_DEVICE2

> Device name of optional second test disk or partition. If this is not defined then the tests will carry out any operations that would have been executed on the second disk in the test directory on the main test disk.

CYGDAT_DEVS_DISK_TEST_MOUNTPOINT2

> Mountpoint for optional second test disk. If `CYGDAT_DEVS_DISK_TEST_DEVICE2` is not defined then this option is not needed.

CYGDAT_DEVS_DISK_TEST_DIRECTORY2

> Subdirectory in optional second test device where tests can create files and directories. If `CYGDAT_DEVS_DISK_TEST_DEVICE2` is not defined then this option is not needed.

Part IX. Multimedia File System

Important

This eCosPro-MMFS Middleware package is STRICTLY LICENSED FOR NON-COMMERCIAL PURPOSES ONLY. It may not be used for Commercial purposes in full or in part in any format, including source code, binary code and object code format.

A Commercial eCosPro License version 3 (or above) which explicity includes this Middleware Package is required for Commercial use.

Table of Contents

Chapter 39. Introduction

This document describes the eCosPro Multimedia Filesystem (eCosPro-MMFS) provided with eCosPro. This is implemented by the MMFS package which uses the facilities of the FILEIO package to present its functionality to the user.

MMFS is intended to support continuous media intensive applications such as Personal Video Recorders, Video JukeBoxes and Video-on-Demand. It is designed to support the recording and playback of data streams at constant and variable rates.

MMFS was designed with the following goals:

- Provide PVR functionality allowing several data streams to be recorded simultaneously while also replaying a stream, which may be one of the streams being recorded. Provide the ability to fast-forward and rewind data streams.
- Make efficient use of disk storage, access times and bandwidth.
- Automatic recovery of disk data structures on restart after a power failure or other interruption. Automatic formatting of a new disk or one that is irretrievably corrupt.

These goals are achieved by simplifying the filesystem as much as possible. So, for example, there is only one directory that contains all files; file metadata is permanently allocated and of fixed size; caches are small and special-purpose. Many aspects are configurable so that the filesystem may be tuned to the application.

Chapter 40. Disk Data Structure

A disk consists of a linear array of 512 byte sectors addressed by a sector number. MMFS aggregates these sectors into blocks which are typically 128, 256 or 512 KiB in size. These blocks are the basic unit of addressing and allocation for MMFS. File data is transferred between the disk and memory in whole blocks, but metadata is accessed in smaller segments.

This disk is divided into four areas, the directory, the freelist, the block allocation tables (BATs) and the data area. The following sections describe these in detail.

Directory

The directory occupies the first one or two blocks of the disk. It consists of an array of directory entries. Each directory entry contains the following fields:

type
: Entry type:

  `MMFS_TYPE_EMPTY` Unused entry. Available for allocation.

  `MMFS_TYPE_VOLUME` Volume label. The `data` field contains a volume label that describes the format of the filesystem.

  `MMFS_TYPE_FILE` File. A standard data file.

  `MMFS_TYPE_RESERVED` Reserved entry. An entry that exists only to occupy a directory slot. Used to protect the volume label against overwriting while updating adjacent entries.

bat
: The block number of the Block Allocation Table for this file.

size
: File size in bytes. For streamed files this reflects the number of data blocks in the BAT. For random access files this is the offset of the last byte of the last block in the BAT.

created
: Creation time. A timestamp in seconds since the epoch implemented by the system wallclock. If no wallclock is present then this merely records the time since the last system restart.

state
: File state. This records the state of the file and aids in system recovery. The possible states are:

  `MMFS_STATE_CREATING`: The file is open for creation and is being actively extended.

  `MMFS_STATE_CREATED`: The file has been closed and will no longer be extendable. However, random access files may be extended in this state.

  `MMFS_STATE_DELETING`: The file is being deleted.

checksum
: Checksum over directory entry. This ensures that the directory entry is correct and consistent.

data
: Per-entry data. The contents of this field depend on the entry type. For the volume label it contains the filesystem format parameters. For files it may contain user-specified data. It is unused in other entry types.

name
: File name. A zero terminated string naming the file. This field is 64 bytes long so, with zero termination, filenames may be a maximum of 63 bytes. There are no limits on the characters allowed.

The data field of a volume label contains the disk format parameters. This consists of the following sub-fields:

signature1
: Volume label signature. This is used, together with `signature2`, to ensure that this is a valid volume label. If these two fields do no contain the expected values then the disk is presumed to be new or corrupt and the filesystem will reformat it.

version
Filesystem version number. Together with the revision number this is used to determine which version of the filesystem formatted this disk.

revision
Filesystem revision number.

sector_size
The size of sectors on this disk. This should match the sector size reported by the disk device itself. At present only sectors of 512 bytes are supported.

phys_block_size
Physical block size. This is the size of the physical blocks supported by this disk. This may differ from the sector size in some cases.

block_size
Size of MMFS blocks in sectors.

disk_size
Total number of blocks on the disk. If the number of sectors on the disk is not an exact multiple of the block_size then the last partial block will be unused.

rootdir_size
Size of the directory in blocks.

freelist_start
Block address of the first block of the freelist. This will be just after the directory.

freelist_size
Size of the freelist in blocks. This is calculated from `disk_size` so that the freelist is large enough to contain all the blocks on the disk.

bat_size
Size of each Block Allocation Table in blocks. The number of blocks per BAT is set during the formatting process.

bat_count
Number of BATs. The number of BATs is set during the formatting process and defaults to 200.

direntry_size
Size of a directory entry in bytes. This is currently fixed at 256 bytes. It is present to permit changes to the directory entry size in the future.

name_size
Size of the name field in a directory entry. This is currently fixed at 64 bytes. It is present to permit changes to the directory entry size in the future.

data_size
Size of the data field in a directory entry. This is currently fixed at 160 bytes. It is present to permit changes to the directory entry size in the future.

signature2
Second signature word.

Free List

The free list occupies a whole number of blocks following the directory. It is viewed as an array of block numbers and is large enough to contain the number of every block on the disk, plus enough spare to make it up to a whole number of blocks.

The free list is organized as a circular list with a head and a tail. Blocks are allocated from the head and are freed to the tail. When they reach the top of the free list, the head and tail pointers wrap back around to zero. These pointers are not stored on the disk but are discovered each time the filesystem is mounted by scanning the free list.

The free list is organized in this way for several reasons. First, it separates block allocation from freeing. Allocations need to proceed at a rate determined by the streaming of data onto the disk. Blocks are only freed when a file is deleted, and can be handled as a background task. Second, the separation makes recovery of filesystem integrity simpler, since blocks will not get reused immediately they are freed. Third, blocks that are allocated together in a particular file will be returned to the free list together, preserving locality.

Block Allocation Tables

The BAT area follows the free list. The size and number of BATs is defined when the filesystem is formatted. BATs are arrays of block addresses for the blocks that contain the data of the file. The number of BATs gives a hard upper limit to the number of files permitted. Usually this is set to equal the number of directory entries. There is little point in making it larger, but it may be useful to set it smaller if the minimal size of the directory exceeds the desired maximum number of files.

The size of each BAT represents a hard upper limit on the size of a file. BAT size should be set to cover the expected range of file sizes. Larger data sets can be handled at application level by splitting the data across several files.

Data Area

The last, and largest, area is the file data area. This comprises the rest of the disk following the last BAT. During formatting each block in this area is added to the free list.

Chapter 41. Runtime Filesystem Organization

This section covers the organization of the file system at runtime. MMFS is divided into a number of modules, each of which covers a specific area of functionality. The following sections cover these in detail.

FILEIO Interface

This module provides the interface to the FILEIO package to present a standard file system interface. This is achieved by exporting a filesystem table entry for the "mmfs" filesystem type. In fact two filesystems are exported, "mmfs" and "mmfs.format". These behave identically except that "mmfs.format" causes the filesystem to be reformatted as part of the mount operation.

File and Directory Handling

The directory module supports operations on the directory. It provides support for searching the directory for a given file, creation and deletion of entries and renaming entries.

A small cache of directory entries, called `dirnodes`, is maintained. This allows separate opens of the same file to share the directory entry and other information.

To allow easy location of unused directory entries, and to avoid searching free entries, the module maintains a bitmap of which directory entries are allocated. This map is constructed during the initial scan and maintained as entries are added and removed.

The file module supports the creation, deletion, reading and writing of the contents of a file. The standard file IO operations are supported together with streaming access. Each open file is accessed through a `file` object, which is also maintained by this module.

The block freelist is also managed by the file module, as is a bitmap recording the allocation state of all the BATs.

Caches

The filesystem has two caches. The metadata cache is used to cache portions of the directory, freelist and BATs. The data cache is used to contain blocks of file data. The two caches are identical other than that the metadata cache uses small (typically 4KiB) segments, while the data cache operates in terms of whole filesystem blocks. The caches also cause disk transfers originated from different caches to have different priorities.

The cache module exports a variety of functions for reading and writing directory entries in the directory, block numbers in the freelist and BATs, and for accessing file data. These functions perform the necessary translations into sector addresses and access the appropriate cache.

Disk Interface

The disk interface module provides support for handling transfers to and from the disk. It consists of a priority ordered queue of block descriptors plus a thread that picks the first descriptor off the queue and submits it to the disk device driver. The block descriptors used by the disk module are the same as those used by the caches.

Scan and Format

When a filesystem is mounted it performs a startup scan to determine the format of the disk and fix up any problems caused by any unexpected failures. The scan goes through the following steps:

- Scan the freelist looking for the head and tail offsets. Each block seen in the freelist is also recorded as having been seen and as being free.
- Scan the directory. For each entry, check that its checksum is correct. If not, mark the entry empty and correct the checksum. For each file, if it is in CREATING state, complete the operation by ensuring that each block in the BAT is not also in the freelist and changing its state to CREATED. If it is in DELETING state, complete the operation by returning all the blocks in its BAT to the freelist and deleting the directory entry.
- Scan the BATs of all files, recording that they have been seen and checking that they are not also in the freelist. Any block that is both in the freelist and a BAT is removed from the freelist.
- If any blocks have not yet been seen, then these orphaned blocks are inserted into the freelist.
- If any of the previous steps have updated the freelist, then the on-disk data structure is rebuilt. This has the side effect of sorting the freelist into block order, improving performance in future.

If the scan finds that the disk is corrupt or unformatted, or the filesystem has been mounted using the "mmfs.format" filesystem, then the disk is reformatted. Formatting consists of zeroing the directory and all the BATs, and building the freelist with all the blocks in the data area. Finally a volume label is written to the first entry in the directory.

Chapter 42. Configuration

Configuration Options

The format and footprint of the filesystem are controlled by a number of configuration options, described in the following sections.

General Options

The following options define the version and revision of the filesystem.

CYGNUM_FS_MMFS_VERSION

> This is the version of the filesystem supported.
>
> Default value: 1

CYGNUM_FS_MMFS_REVISION

> This is the revision of the filesystem supported.
>
> Default value: 0

Formatting Options

These options control the formatting of an MMFS disk. They are only used when a filesystem is formatted. Under normal circumstances the filesystem will fetch these values from the disk volume label.

CYGNUM_FS_MMFS_BLOCK_SIZE

> This option defines the size of filesystem blocks. The value is defined in KiB and must be a power of 2.
>
> Default value: 256

CYGNUM_FS_MMFS_ROOTDIR_SIZE

> This option defines the size of the root directory in blocks. Since all files are contained in this directory, its size gives a hard limit to the number of files that the filesystem may contain.
>
> Default value: 1

CYGNUM_FS_MMFS_BAT_SIZE

> This option defines the size of the Block Allocation Tables used to store the addresses of file data blocks. This gives a hard upper limit on the size of a file.
>
> Default value: 2

CYGNUM_FS_MMFS_BAT_COUNT

> This option defines the number of BATs allocated in the filesystem. The default is to define 200 BATs.
>
> Default value: 200

Footprint Options

These options control the memory footprint and other parameters for an active filesystem.

CYGNUM_FS_MMFS_FILE_COUNT

This option defines the maximum number of open files supported by the filesystem. This depends on the expected number of data streams, plus any random access files, that may be open simultaneously.

Default value: 4

CYGNUM_FS_MMFS_DIRNODE_COUNT

This option defines the maximum number of cached directory entries. At least one is required for each open file, plus a few for handling other filesystem operations such as renaming or deleting.

Default value: CYGNUM_FS_MMFS_FILE_COUNT+4

CYGNUM_FS_MMFS_MULTI_BUFFER

This defines the level of per-file multi-buffering. During streaming the filesystem will read ahead and write behind by this number of data blocks.

Default value: 2

CYGNUM_FS_MMFS_DATA_CACHE_SIZE

This defines the amount of memory occupied by the data cache. The default value is calculated from the multi-buffering level, and the number of files.

Default value: (CYGNUM_FS_MMFS_MULTI_BUFFER+2) * CYGNUM_FS_MMFS_FILE_COUNT * CYGNUM_FS_MMFS_BLOCK_SIZE

CYGNUM_FS_MMFS_META_CACHE_SIZE

This defines the amount of memory occupied by the metadata cache. The default value is calculated from the number of files plus an overhead to support the freelist and directory scanning.

Default value: (CYGNUM_FS_MMFS_FILE_COUNT+6) * CYGNUM_FS_MMFS_META_BLOCK_SIZE

CYGNUM_FS_MMFS_META_BLOCK_SIZE

This defines the size of a metadata cache block. These are used to contain portions of the the directory, freelist and BATs.

Default value: 4

CYGNUM_FS_MMFS_DISKIO_PRIORITY

This defines the priority of the disk IO thread. This thread should generally run at a high priority since it does very little but it is vital to the performance of the filesystem.

Default value: 4

CYGNUM_FS_MMFS_FLUSH_INTERVAL

This defines the interval at which metadata cache blocks are flushed. Each time this interval expires the oldest dirty block in the cache is written to disk. This allows dirty data to be trickled out to disk without severely impacting streaming transfers.

Default value: 10

CYGNUM_FS_MMFS_FLUSH_PERIOD

This defines the cache flush period in multiples of the cache flush interval. Each time this period expires, the entire metadata cache will be flushed to disk. The action of the flush interval will generally cause this operation to do nothing.

Default value: 6

Configuration Guidelines

This section attempts to give some guidelines about how to configure MMFS and the various tradeoffs that can be made.

Block Size

The choice of block size is the most important configuration option. The filesystem uses the large block size to amortize access time across large data transfers. The blocks also provide high locality for the data they contain, avoiding the need to implement complex localizing allocation and access mechanisms in the filesystem. The choice of block size depends on several factors: the access time and data transfer rate of the disk, the number and rate of the streams to be sustained.

The important disk performance factors to consider are the worst-case access time and the minimum sustained transfer rate. Disk manufacturers generally quote the average access time for disks and keep the worst case figures under wraps since they are often considerably higher than the average. Access time generally consists of seek time plus settling time plus rotational delay plus command submission overhead. The worst case seek time is generally a move from one edge of the disk to the other. Worst case rotational delay occurs when the target sector has just passed the head when it reached the destination cylinder; for a 7200RPM disk, this is 8.3ms. Settling and command time tend to be constant, although if the access includes a head switch then there may be a small contribution from that. As a rule of thumb, worst case access time can be taken to be about 3 times the manufacturers quoted average access time.

The sustained transfer rate for a disk varies across the disk with the differences in recording density due to zoning. Most current disks have 10 or more zones. The best data rate comes from the outer zones, and the worst from the inner zones and may differ by several MiB/s. Transfer of data to or from the disk will also incur head change and single cylinder seek delays for large multi-sector transfers. Another factor that contributes to the transfer rate is the speed with which data can be transferred across the disk interface. This will depend on things like the DMA modes supported by the disk and the host interface, cable design, cache and MMU factors. Embedded systems often do not have the kind of high performance interfaces that are common on data-centre servers.

A standard definition TV stream uses a data rate of 4-10Mb/s. An HDTV stream can run up to 27Mb/s, although current systems only run at 14 to 17 Mb/s. These are encoded using MPEG-2, which provides a highly variable data rate depending on source and contents between 2 and 14Mb/s.

To see what effect different block sizes have on throughput, let us consider an 8.2Mb/s stream, which conveniently approximates to 1MiB/s. The disk is assumed to spin at 7200 RPM, have a worst case access time of 30ms and a worst case sustained transfer rate of 20MiB/s. If this disk is formatted with 256KiB blocks, then the time to fetch one block is 42.5 ms (30ms worst case access time plus 12.5ms worst case transfer time). One second's worth of data is four blocks, taking 170ms. If the disk is formatted with 64KiB blocks, then the time to fetch one block is 33.125ms (30ms worst case access time plus 3.125ms worst case transfer time). One second's worth of data is sixteen blocks, taking 530ms.

From this we can see that using 256KiB blocks, we have enough throughput on this disk to run five or six 1MiB/s streams, but with 64KiB blocks there is barely the capacity for running two streams. The figures used here are worst case times, and on average the disk will be able to sustain more streams and higher data rates. However, if guarantees are to be met for glitch-free recording and playback, it is necessary to calculate for the most demanding scenario where seek distance, rotational delay and stream data rate conspire to make things difficult, even if such situations are rare and transient in real life.

BAT Size

The size of the Block Allocation Tables determines the amount of data that can be recorded in a single file. If the disk is formatted with a 256KiB block size a single block will contain 64Ki block addresses, which, at 1MiB/s, will record 16Ki seconds of data, or about 4.5 hours. This is sufficient for most PVR applications where most recordings are 30 minutes or an hour. It even accommodates most movies and sporting events. Increasing the BAT size to two or more blocks will allow longer recordings to be made in a single file, but at the expense of wasting space in the common case. An alternative approach would be to record a single stream in multiple files at the application level.

The number of BATs is also an important factor to consider, and is linked to the directory size. This relationship will be described in the next section. However, an important factor in choosing the size and number of BATs is the time taken to format the disk and perform filesystem startup. During formatting all the BATs must be zeroed, something that can take a long time if they are large an numerous. During filesystem startup, all BATs allocated to current files are scanned to detect orphaned blocks. The time taken to do this is proportional to the size of the BATs and the number of files.

Directory Size

The size of the directory provides one of the limits on how many files may be stored in the filesystem. The directory occupies a whole number of blocks, and with 256KiB blocks and 256 byte directory entries, each directory block can contain 1024 entries. This may be more than enough for most purposes: on a 160GB disk this averages to about 160MB per file, or 2m40s at 1MiB/s. Another way of looking at this is that a 160GB disk can contain about 40 hours of recorded TV, or about 80 30 minute programs. In this context, 1024 entries is more than adequate.

The other limit on the number of files is the number of BATs. These are allocated dynamically to files as they are created. Running out of BATs will cause file creation to fail, even if there are directory entries free. Having more BATs that directory entries is wasteful. Even having the same number, given the calculation above, can be seen as excessive. For a 160GB disk, about 200 BATs would be a more suitable figure.

Cache Sizes

The filesystem contains two caches: a metadata cache for the directory, freelist and BATs; and a data cache for file contents. The number of blocks in each cache is important to the correct functioning of the filesystem. Too many blocks and the filesystem occupies too much RAM. Too few blocks and data may be evicted from the cache too soon and result in performance problems.

The size of the metadata cache depends on the free list, the number of open files and any directory searches that are being made. The free list requires two cache blocks, one for the head and one for the tail. Each open file needs a block to contain the current read or write position in the BAT and, occasionally, an extra block to handle the prefetch of the next block in the BAT. Concurrent directory searches also consume metadata cache blocks. The default size of the metadata cache is therefore set to use two blocks for the free list, plus one for each possible open file, plus four to take up the prefetches and searches.

The size of the data cache depends only on the maximum number of open files. For each file we need a buffer for each level of multi-buffering, plus two to support the read-ahead or write-behind.

Chapter 43. Usage

MMFS is accessed through the FILEIO package which presents a standard POSIX compatible IO interface through which applications use standard `open()`, `read()`, `write()` and `close()` calls. Streaming support is provided through a small library, mmfslib, that presents a more application-friendly interface.

FILEIO Interface

MMFS supplies most of the standard file IO functionality. However, since it is optimized for supporting streamed data, it has a number of restrictions that mean that it does not always behave like a general-purpose filesystem.

- Files may not be resized after creation and are essentially write-once/read-many. Between the initial `open()` and `close()` that creates a file it will be extended as requires. On subsequent opens, even those that specify `O_WRITE`, data may only be written to the existing file extent.
- If an attempt is made to create a file that already exists, the `open()` will fail. Instead the file must be deleted first and may then be created anew.
- Creating a file with `O_EXCL` will always fail.
- If an attempt is made to rename a file to a filename that already exists, the `rename()` will fail, rather than overwriting the destination file. This includes attempting to rename the file to its own name. Instead the destination file must be deleted first.

MMFSLib

MMFS provides a simple library for handling streamed data. This comprises a small set of API function. The following sections describe the API, followed by a simple example.

MMFSLib API

The following functions are supported.

`int mmfs_stream_open( const char *path, int flags);`

Open an MMFS file for streaming. The *`flags`* argument is either `MMFS_FLAGS_READ` to open an existing file for reading or `MMFS_FLAGS_WRITE` to create a new file for writing. If the file doesn't exist (when opening for reading) or it does exist (when opening for writing) -1 will be returned and `errno` will be set to a suitable error code. On success a file descriptor is returned which may be used in other mmfslib calls, or in normal FILEIO calls.

The stream starts in `RANDOM` mode and must be set to streaming mode with a call to `mmfs_stream_set_mode()`.

`int mmfs_stream_info( int fd, mmfs_file_info *info );`

This function returns information about the file. The mmfs_file_info structure contains the following fields:

`buffer_size`

The size of data buffers that will be exchanged using `mmfs_stream_next_buffer()`.

`multi_buffers`

The number of buffers that the application may have in hand between calls to `mmfs_stream_next_buffer()`.

`file_size`

The current size of the file.

`max_size`

The maximum size the file may grow to.

`int mmfs_stream_set_mode( int fd, int mode, int stride );`

Set the file mode. The mode may be one of the following:

`MMFS_MODE_RANDOM`

This is the default mode. A file in this mode should be accessed using the standard filesystem API.

`MMFS_MODE_READ_FORWARD`

In this mode the file is being read forward. The *`stride`* argument defines the number of buffers skipped between each call to mmfs_stream_next_buffer(). A stride of 1 will read the whole file sequentially. A stride of 2 will read every other buffer; a stride of 3 will read every third buffer, and so on.

`MMFS_MODE_READ_BACKWARD`

This is similar to `MMFS_MODE_READ_FORWARD` except that the file is read backwards. The stride applies in exactly the same way except, obviously, the buffers supplied move progressively backwards through the file.

`MMFS_MODE_WRITE`

This sets the file up for streamed writing. The *`stride`* argument is not used and is forced to 1.

Mode changes take effect immediately and apply from the file's current location. A file only becomes capable of streaming after `mmfs_stream_set_mode()` has been called for the first time. Changing file mode during streaming may incur a performance penalty as new data blocks are fetched. A file may not be switched from a read mode to a write mode or vice versa.

`int mmfs_stream_get_mode( int fd, int *mode, int *speed );`

This function returns the mode and speed previously set by a call to `mmfs_stream_set_mode()`.

`int mmfs_stream_next_buffer( int fd, void **buffer );`

This function fetches the next stream buffer. The exact semantics of this function depend on the mode and the level of multi-buffering.

If the file has been set to one of the read modes, then each call returns the next buffer full of data from the file according to the direction and stride. The level of multi-buffering determines how many buffers the application may have in hand at any one time. For example, with a multi-buffering level of 2, the first two calls to this routine will return the first two buffers from the stream. The third call will return the third buffer, but will also cause the first buffer to become invalid and be returned to the filesystem for reuse. The fourth call will return the fourth buffer but will also invalidate the second buffer, and so on through the stream.

If the file has been set to the write mode, then each call returns an empty buffer for the application to fill with data. The multi-buffering level determines when the buffers will be written to the file. For example, with a multi-buffering level of 2, the first two calls will return an empty buffer each. The third call will cause the first buffer to be written to the file and will return a new empty buffer to replace it. The fourth call will cause the second buffer to be written to the file and a new buffer to be returned, and so on.

`int mmfs_stream_set_data( int fd, void *buffer );`

This function sets the per-directory entry data on the file. The `buffer` argument must point to `MMFS_DATASIZE` bytes of data that will be written into the directory entry.

`int mmfs_stream_get_data( int fd, void *buffer );`

This function reads the per-directory entry data on the file. The `buffer` argument must point to `MMFS_DATASIZE` bytes of memory that will be set to the data read from the directory entry.

`int mmfs_stream_close( int fd );`

This function closes the file. Any buffers still in possession of the application will be invalidated. If the file was open for writing the contents of these buffers will be written to the file.

Example

The following code provides a very simple example of how MMFSLib should be used. The code presented here is somewhat simplified and for clarity does not contain any error checking and recovery. It is assumed that the IO devices are accessed via a simple DMA interface; clearly real devices might be more complex than this.

First, a simple routine to stream data from a device to a file for a given duration:

```
static void write_stream( char *name, int duration )
{
    int i;
    int fd;
    int result;
    void *buffer;
    int bufno = 0;
    int buffer_size;
    mmfs_file_info info;
    cyg_tick_count end;

    // Open the stream for writing.
    fd = mmfs_stream_open( name, MMFS_OPEN_WRITE );

    // Get stream information, we are only interested in the buffer
    // size.
    result = mmfs_stream_info( fd, &info );

    buffer_size = info.buffer_size;

    // Set the stream into streamed write mode. The filesystem in now
    // ready to stream data to this file.
    result = mmfs_stream_set_mode( fd, MMFS_MODE_WRITE, 1 );

    // Convert duration from seconds to an absolute end time in system
    // ticks.
    end = cyg_current_time() + duration*ticks_per_second;

    // Prime the device with the first set of buffers, this will start
    // the DMA transfers going.
    for( i = 0; i < CYGNUM_FS_MMFS_MULTI_BUFFER; i++ )
    {
        result = mmfs_stream_next_buffer( fd, &buffer );

        dma_start( &input, bufno, DMA_READ, buffer, buffer_size );

        bufno++;
        if( bufno >= CYGNUM_FS_MMFS_MULTI_BUFFER ) bufno = 0;
    }
    // Wait for the first buffer to fill.
    dma_wait( &input, bufno );

    // Now stream to the file for the given duration.
    while( cyg_current_time() < end )
    {
        // Fetch a new buffer from MMFS. As a side effect this also
        // invalidates the oldest buffer, which will be the one that
        // has just finished its DMA transfer.
        result = mmfs_stream_next_buffer( fd, &buffer );

        // Set up a DMA transfer from the device
        dma_start( &input, bufno, DMA_READ, buffer, buffer_size );

        bufno++;
        if( bufno >= CYGNUM_FS_MMFS_MULTI_BUFFER ) bufno = 0;

        // Wait for the next device buffer to complete.
        dma_wait( &input, bufno );
    }

    // Wait for remaining buffers to finish
    for( i = 0; i < CYGNUM_FS_MMFS_MULTI_BUFFER; i++ )
    {
        bufno++;
        if( bufno >= CYGNUM_FS_MMFS_MULTI_BUFFER ) bufno = 0;

        dma_wait( &input, bufno );
    }

    // Finally close the stream.
    result = mmfs_stream_close( fd );
}
```

The code to read a stream is very similar, although this time it is parameterized by the required stride rather than the duration:

```
static void read_stream( char *name, int stride )
{
    int i;
    int fd;
    int result;
    void *buffer;
    int bufno = 0;
    int buffer_size;
    mmfs_file_info info;

    // Open the stream for reading.
    fd = mmfs_stream_open( name, MMFS_OPEN_READ );

    // Get stream information, we are only interested in the buffer
    // size.
    result = mmfs_stream_info( fd, &info );

    buffer_size = info.buffer_size;

    // Set the stream into streamed read mode using the given
    // stride. The filesystem will start preparation for streaming by
    // prefetching the first data blocks up to the multi-buffer limit.
    result = mmfs_stream_set_mode( fd, MMFS_MODE_READ_FORWARD, stride );

    // Prime the device with the first set of buffers, this will start
    // the DMA transfers going.
    for( i = 0; i < CYGNUM_FS_MMFS_MULTI_BUFFER; i++ )
    {
        result = mmfs_stream_next_buffer( fd, &buffer );

        dma_start( &output, bufno, DMA_WRITE, buffer, buffer_size );
        bufno++;
        if( bufno >= CYGNUM_FS_MMFS_MULTI_BUFFER ) bufno = 0;
    }

    // Wait for the first buffer to empty.
    dma_wait( &input, bufno );

    // Now stream from the file to the device until we reach the end
    // of the file.
    for(;;)
    {
        // Fetch a new buffer full of data from MMFS. As a side effect
        // this also invalidates the oldest buffer, which will be
        // the one that has just finished its DMA transfer.
        result = mmfs_stream_next_buffer( fd, &buffer );
        if( result < 0 && errno == EEOF )
            break;

        // Set up a DMA transfer to the device
        dma_start( &output, bufno, DMA_WRITE, buffer, buffer_size );

        bufno++;
        if( bufno >= CYGNUM_FS_MMFS_MULTI_BUFFER ) bufno = 0;

        // Wait for the next device buffer to complete.
        dma_wait( &output, bufno );
    }

    // Wait for remaining buffers to finish
    for( i = 0; i < CYGNUM_FS_MMFS_MULTI_BUFFER; i++ )
    {
        bufno++;
        if( bufno >= CYGNUM_FS_MMFS_MULTI_BUFFER ) bufno = 0;

        dma_wait( &output, bufno );
    }

    // Finally close the stream.
    result = mmfs_stream_close( fd );
}
```

The `example.c` test program contains versions of both of these routines.

Chapter 44. Testing

The MMFS package contains a number of test programs:

mmfs1
This program just tests the standard FILEIO interface of the filesystem. It is a simplified version of the filesystem functionality tests used by FATFS and RAMFS.

stream1
This program is a simple test of the streaming support. It writes and reads streams at defined data rates and checks that the rate is maintained and that data integrity is preserved.

pvr1
A basic emulation of a Personal Video Recorder. Two streams are written and one of them read back, after a delay. This simulates a PVR recording one channel while using a pause-live feature on a second channel.

pvr2
This program records a large number of short streams on the disk. This checks directory handling.

pvr3
This is a variant on pvr1, which records 3 streams while replaying one.

format
A simple test that uses the "mmfs.format" filesystem instead of "mmfs", thus reformatting the disk.

example
This contains versions of the `write_stream()` and `read_stream()` example functions described earlier, together with sufficient infrastructure to allow them to be run.

Part X. Disk IO Package

Table of Contents

Chapter 45. Introduction

This document describes the Disk I/O subsystem provided in eCos. This is implemented by the DISKIO package. This package presents a disk driver API to clients, interprets partition tables and provides the infrastructure in which hardware-specific disk device drivers operate.

Chapter 46. Configuring the DISK I/O Package

This chapter shows how to include the DISK I/O package an eCos configuration and how to configure it once installed.

Including DISK I/O in a Configuration

The DISK I/O subsystem is contained in a single eCos package, CYGPKG_IO_DISK. However, it depends on the services of the following other packages for complete functionality:

CYGPKG_IO

Device IO package. Disk devices operate within the generic device infrastructure.

CYGPKG_ERROR

The error package. Disk devices need to return standard error codes when operations fail.

The DISK I/O package can be added to any configuration just by adding its package during configuration. However, it is usually added as part of a group which also includes a filesystem implementation and hardware device drivers.

Configuring the DISK I/O Package

The option "Detect FAT boot sector" (`CYGSEM_IO_DISK_DETECT_FAT_BOOT`) can be used with certain types of removable media which are treated undeterministically by Windows PCs, such as USB keys. These usually contain a partition table, but if completely wiped, Windows will not recreate the partition table, and instead place a FAT filesystem directly on the device with no partition table. Enabling this option detects this and fabricates a partition table in memory instead. This option is usually only needed on systems which use removable media likely to be shared with Windows PCs, as indicated from low level drivers with the `CYGINT_IO_DISK_DETECT_FAT_BOOT_DEFAULT CDL` interface.

The CDL option `CYGSEM_IO_DISK_EFI_GPT` is used to support media formatted with an Extensible Firmware Interface (EFI) GUID Partition Table (GPT). This is limited to media presenting a single \"protective\" MBR partition entry covering the GPT managed space. Currently the feature is limited to providing the number of partitions supported by the parent filesystem package, and only those partitions accessible using 32-bit LBA values.

The CDL interface `CYGINT_IO_DISK_ALIGN_BUFS_TO_CACHELINE` indicates to the disk I/O package, and to its users, that data transfer buffers need to be aligned to data cache line boundaries.

The CDL interface `CYGINT_IO_DISK_REMOVABLE_MEDIA_SUPPORT` indicates that the hardware disk driver implements removable media support. This will cause the disk I/O package to implement the `CYG_IO_SET_CONFIG_DISK_EVENT` and `CYG_IO_GET_CONFIG_DISK_EVENT` configuration option keys.

Chapter 47. Usage

The user API for disk devices is the same as that for serial devices except that `cyg_io_bread()` and `cyg_io_bwrite()` are used for data transfers instead of `cyg_io_read()` and `cyg_io_write()`.

```
// Write data to a block device
Cyg_ErrNo cyg_io_bwrite(
    cyg_io_handle_t handle,
    const void *buf,
    cyg_uint32 *len,
    cyg_uint32 pos )
```

This function sends data to a device. The size of data to send is contained in `*len` and the actual size sent will be returned in the same place. This value must be a count of 512 byte sectors. The `pos` specifies the position on the disk to which the data will be written. It is a linear sector number.

```
// Read data from a block device
Cyg_ErrNo cyg_io_bread(
    cyg_io_handle_t handle,
    void *buf,
    cyg_uint32 *len,
    cyg_uint32 pos )
```

This function receives data from a device. The desired size of data to receive is contained in `*len` and the actual size obtained will be returned in the same place. This value must be a count of 512 byte sectors. The `pos` specifies the position on the disk from which the data will be read. It is a linear sector number.

Disk devices are named in the same way as other devices, thus "/dev/hd0" would name the first hard disk. The exact names used for any disk are usually part of the configuration for the target-specific device driver.

Disk devices may be partitioned using a standard DOS partition table. If this is the case then an additional element to the device name specifies the partition to be used. Thus "/dev/hd0/1" specifies partition 1, "/dev/hd0/2" partition 2, "/dev/hd0/3" partition 3 and "/dev/hd0/4" partition 4. The special name "/dev/hd0/0" specifies the entire disk without honoring the partition table. This is only really useful for accessing the master boot record in sector zero, to change the partitioning. Any other kind of access may corrupt the disk.

Application code may also install a disk event callback function. It does this using the `CYG_IO_SET_CONFIG_DISK_EVENT` configuration option using the `cyg_io_set_config()`. The buffer should point to an instance of the following structure:

```
typedef void disk_channel_event_t( cyg_uint32 event, cyg_uint32 devno, CYG_ADDRWORD data );

struct  cyg_disk_event_t
{
    disk_channel_event_t        *event;         // Event callback function
    CYG_ADDRWORD                event_data;     // Event callback user data
};

// Codes for disk_channel_event_t event argument.
#define CYG_DISK_EVENT_CONNECT          0x01
#define CYG_DISK_EVENT_DISCONNECT       0x02
```

The function should be installed on the base disk device driver (i.e. "/dev/hd0" rather than "/dev/hd0/0") and will be called when certain events occur. At present these are restricted to CONNECT and DISCONNECT events when a new disk is attached to, or detached from, the disk controller. Support for this depends on the ability of the underlying hardware device driver being able to detect these events.

A successful lookup of the base disk device driver does not necessarily imply that removeable media is present at that time. Hardware drivers supporting removeable media will typically indicate a successful lookup, irrespective of the presence of a physical disk.

The reason for this is that the call to `cyg_io_set_config()` for the `CYG_IO_SET_CONFIG_DISK_EVENT` operation may quite reasonably occur when no physical media is present, so the lookup must succeed in order to obtain a valid I/O handle. That handle is, however, unusable for operations other than `CYG_IO_SET_CONFIG_DISK_EVENT`.

The context in which the callback is made depends on the implementation of the disk driver. It cannot be assumed that it will occur in a context in which it is safe to make complex calls. It should be assumed that the call is being made from DSR context, where blocking kernel calls may not be made. In general the function should record the details of the call and pass off control to a worker thread. See the automounter in the FILEIO package for an example of how this can be done.

When hardware drivers notice the `CYG_IO_SET_CONFIG_DISK_EVENT` call, they should immediately check for the presence of a disk, in case one is already connected at the time of event registration. The event callback should be made for any connected disk devices (and not for unconnected disks).

Chapter 48. Hardware Driver Interface

While the DISK I/O package provides the top level, hardware independent, part of each disk driver, the actual hardware interface is handled by a hardware dependent interface module. To add support for a new disk device, the user should be able to use the existing hardware independent portion and just add their own interface driver which handles the details of the actual device. The user should have no need to change the hardware independent portion.

The interfaces used by the disk driver and disk implementation modules are contained in the file `<cyg/io/disk.h>`.

Note

In the sections below we use the notation <<xx>> to mean a module specific value, referred to as “xx” below.

DevTab Entry

The interface module contains the devtab entry (or entries if a single module supports more than one interface). This entry should have the form:

```
BLOCK_DEVTAB_ENTRY(<<module_name>>,
                   <<device_name>>,
                   0,
                   &cyg_io_disk_devio,
                   <<module_init>>,
                   <<module_lookup>>,
                   &<<disk_channel>>
                  );
```

Arguments

`module_name` The "C" label for this devtab entry

`device_name` The "C" string for the device. E.g. `/dev/serial0`.

`cyg_io_disk_devio` The table of I/O functions. This set is defined in the hardware independent disk driver and should be used exactly as shown here.

`module_init` The module initialization function.

`module_lookup` The device lookup function. This function typically sets up the device for actual use, turning on interrupts, configuring the controller, etc.

`disk_channel` This table (defined below) contains the interface between the interface module and the disk driver proper.

Disk Controller Structure

The arrangement of disk hardware usually has a number of physical disks connected to a common controller. For example, each IDE interface connects to just two disk devices, a SCSI controller may be connected to several disks. The important feature to consider here is that any current data transfer for any one disk on a controller prevents transfers being started on any other disks on that controller until it is finished. Disk controllers are therefore the level at which concurrency and interrupt controls must be implemented.

Each disk controller is created by the macro:

```
DISK_CONTROLLER(l, dev_priv)
```

Arguments

l
The "C" label for this structure.

dev_priv
A placeholder for any device specific data for this controller.

Disk Channel Structure

Each physical disk connected to a controller is represented by a disk channel. Each channel is defined with the following macro:

```
DISK_CHANNEL(l, funs, dev_priv, controller, mbr_supp, max_part_num )
```

Arguments

l
The "C" label for this structure.

funs
The set of interface functions (see below).

dev_priv
A placeholder for any device specific data for this channel.

controller
Pointer to controller to which this disk channel is attached.

mbr_supp
Does this disk support partitioning.

max_part_num
The maximum number of partitions to be supported.

The interface from the hardware independent driver into the hardware interface module is contained in the *funs* table. This is defined by the DISK_FUNS macro.

If the space for the channel has been allocated elsewhere, the following macro may be used to initialise it:

```
DISK_CHANNEL_INIT(dc, funs, dev_priv, controller, disk_info, part_dev_tab,
                  part_chan_tab, part_tab, mbr_supp, max_part_num )
```

The arguments are as for `DISK_CHANNEL()` except for the following:

Arguments

dc
The name of an object of type disk_channel. This object will be initialised by the macro.

disk_info
The name of an object of type disk_info.

part_dev_tab
The name of an array of objects of type struct cyg_devtab_entry. The number of array members must equal max_part_num, plus one.

part_chan_tab
The name of an array of objects of type disk_channel. The number of array members must equal max_part_num.

part_tab
The name of an array of objects of type cyg_disk_partition_t. The number of array members must equal max_part_num.

Disk Functions Structure

```
DISK_FUNS(l, read, write, get_config, set_config)
```

Arguments

l

The "C" label for this structure.

read

```
Cyg_ErrNo (*read)(disk_channel *priv,
                  void         *buf,
                  cyg_uint32    len,
                  cyg_uint32    block_num)
```

This function reads *len* sectors of data from the disk at the sector number given by *block_num*. The actual quantity of data transferred depends on the disk's sector size, which can be obtained using the `CYG_IO_GET_CONFIG_DISK_INFO` key.

If the read completes immediately, or the low level driver is configured to do all IO synchronously, this function will return `ENOERR`, and if it fails will return a negative error code, for example `-EIO`. If the function returns `-EWOULDBLOCK` then it has only started the transfer and will indicate its completion by calling the `transfer_done` callback.

write

```
Cyg_ErrNo (*write)(disk_channel *priv,
                   void         *buf,
                   cyg_uint32    len,
                   cyg_uint32    block_num)
```

This function writes *len* sectors of data to the disk at the block given by *block_num*. The actual quantity of data transferred depends on the disk's sector size, which can be obtained using the `CYG_IO_GET_CONFIG_DISK_INFO` key.

If the write completes immediately, or the low level driver is configured to do all IO synchronously, this function will return `ENOERR`, and if it fails will return a negative error code, for example `-EIO`. If the function returns `-EWOULDBLOCK` then it has only started the transfer and will indicate its completion by calling the `transfer_done` callback.

get_config

```
bool (*get_config)(serial_channel *priv,
                   cyg_uint32 key, const void *xbuf, cyg_uint32 *len);
      )
```

This function is used to get configuration data from the device. The *key* argument defines the configuration data to be fetched. The *xbuf* and `*len` arguments describe a buffer into which the data will be put. The function should return `true` if the key type is supported and the buffer of sufficient length to contain the data. The value of **len* should be updated to actual length of the data returned. The function should return `false` if the driver cannot support the key value or the buffer is of insufficient length.

The following keys may be used to get information from a disk device.

`CYG_IO_GET_CONFIG_DISK_INFO`

This key causes a cyg_disk_info_t structure, as defined in `diskio.h` to be returned.

`CYG_IO_GET_CONFIG_DISK_EVENT`

This key returns a copy of the cyg_disk_event_t previously set by `CYG_IO_SET_CONFIG_DISK_EVENT`.

set_config

```
bool (*set_config)(serial_channel *priv,
                   cyg_uint32 key, const void *xbuf, cyg_uint32 *len);
```

```
      )
```

This function is used to change the configuration of the device. The *key* argument defines the kind of configuration data to be set. The *xbuf* and `*len` arguments describe a buffer in which the data is supplied. The function should return `true` if the key type is supported and the buffer of the correct length and the data appears valid. The function should return `false` if the driver cannot support the key value or the buffer is the wrong length, or the data is invalid in some other way.

The following keys can be sent to a driver:

`CYG_IO_SET_CONFIG_DISK_MOUNT`

This is invoked from the filesystem after locating the device driver to record that the device has been mounted. The generic device layer records the mount against both the partition and physical disk and passes the call on down to the driver. The *xbuf* and **len* arguments are unused.

`CYG_IO_SET_CONFIG_DISK_UMOUNT`

This is invoked from the filesystem to record that the device has been unmounted. The generic device layer records the unmount against both the partition and physical disk and passes the call on down to the driver. If the `chan->info->mounts` counter is zero, the driver should call the `disk_disconnected()` callback to prepare the generic layer for a potential media change. The *xbuf* and **len* arguments are unused.

`CYG_IO_SET_CONFIG_DISK_EVENT`

This may be invoked by the application to set a disk event callback function. The generic disk layer is mostly responsible for handling this by recording the event function in the disk channel structure. The call is additionally passed down to the hardware driver so that it may prepare the hardware, if necessary. The *xbuf* should point to a cyg_disk_event_t structure.

Callbacks

The interface from the hardware specific driver to the hardware independent driver is contained in a disk_callbacks_t structure. A pointer to this is automatically included into the disk channel structure *callbacks* field by the `DISK_CHANNEL()` macro. The disk_callbacks_t structure contains the following function pointers:

disk_init

```
cyg_bool (*disk_init)(struct cyg_devtab_entry *tab);
```

Initialize the disk. This must be called from the disk driver's init routine to initialize the device independent driver's data structures for this disk.

disk_connected

```
Cyg_ErrNo (*disk_connected)(struct cyg_devtab_entry *tab,
                            cyg_disk_identify_t     *ident);
```

This is called when a valid disk device has been recognised on the given disk channel. At this point, if the disk supports partitioning the disk's partition table will be read and the partitions determined. This may be called either from the driver's init routine, for fixed disks, or alternatively from the driver's lookup routine. It may also be called from other places when, for example, disk insertion is detected. All the fields of the `ident` structure must be filled in by the driver before this call is made.

disk_disconnected

```
Cyg_ErrNo (*disk_disconnected)(struct disk_channel *chan);
```

This is called when, for example, disk removal is detected. It invalidates all the existing partition and driver information and renders the channel ready for a new disk device to be inserted.

disk_lookup

```
Cyg_ErrNo (*disk_lookup)(struct cyg_devtab_entry **tab,
                         struct cyg_devtab_entry  *sub_tab,
                         const char               *name);
```

This must be called from the driver's lookup function to complete the lookup process. It is here that the interpretation of the partition number element of the device name is done and a new devtab entry created for the partition if necessary.

disk_transfer_done

```
void (*disk_transfer_done)(struct disk_channel  *chan,
                           Cyg_ErrNo            res);
```

When the call to the `read()` or `write()` disk function returns `-EWOULDBLOCK` then the driver must indicate completion of the actual transfer by calling this function. This function should not be called from an ISR, but it may be called from the DSR.

In addition to these functions in disk_callbacks_t, the hardware driver is also responsible for calling the disk event callback. The calls should be made as follows:

```
    disk_channel *chan = <get pointer to disk channel>;

    …

    chan->event( CYG_DISK_EVENT_CONNECT, devno, chan->event_data );
```

The first argument should be the event being notified: `CYG_DISK_EVENT_CONNECT` as shown here, or `CYG_DISK_EVENT_DISCONNECT`. The second argument is a device number; this is needed for devices that dynamically instantiate disk devices, such as USB. If the driver does not do this, then this argument should be -1. The third argument is the user data value passed in when the callback was registered.

The driver may call this function at any time and from any context other than an ISR. Normally it will be called either from a DSR or from a thread context. By default, the generic disk layer will install a dummy function in the disk channel structure, so the driver can always make the call without needing to test for a NULL pointer. A CONNECT event call should be made when the driver detects that a new device has been inserted into the drive, and an DISCONNECT event call should be made when the device is removed.

A CONNECT event call should also be made if a disk device is already connected when the driver observes the application registering for notification of disk events by use of the `CYG_IO_SET_CONFIG_DISK_EVENT` `cyg_io_set_config()` operation. However, this only applies to connected disks - the driver does not indicate DISCONNECT events for unconnected disks.

Putting It All Together

The above descriptions, while strictly useful as documentation, do not really show how it all gets put together to make a device driver. The following example of how to create the data structures for a device driver, for a standard PC target, are derived from the eCosPro IDE disk driver.

The first thing to do is to define the disk controllers:

```
static ide_controller_info_t ide_controller_info_0 = {
    ctlr:       0,
    vector:     HAL_IDE_INTERRUPT_PRI
};

DISK_CONTROLLER( ide_disk_controller_0, ide_controller_info_0 );

static ide_controller_info_t ide_controller_info_1 = {
    ctlr:       1,
    vector:     HAL_IDE_INTERRUPT_SEC
};
```

```
DISK_CONTROLLER( ide_disk_controller_1, ide_controller_info_1 );
```

A typical PC target has two IDE controllers, so we define two controllers. The ide_controller_info_t structure is defined by the driver and contains information needed to access the controller. In this case this is the controller number, zero or one, and the interrupt vector it uses. The `DISK_CONTROLLER()` macro generates a system defined controller structure and populates it with a pointer to the matching controller info structure.

The next step is to define the disk functions that will be called to perform data transfers on this driver. These functions the main part of the driver, together with the init and lookup functions and any ISR and DSR functions.

```
DISK_FUNS(ide_disk_funs,
          ide_disk_read,
          ide_disk_write,
          ide_disk_get_config,
          ide_disk_set_config
);
```

We can now start generating per-disk-channel data structures. To make this easier we define a macro, `IDE_DISK_INSTANCE()` to make this easier.

```
#define IDE_DISK_INSTANCE(_number_,_ctlr_,_dev_,_mbr_supp_)     \
static ide_disk_info_t ide_disk_info##_number_ = {              \
    num:           _number_,                                    \
    ctlr:          &ide_controller_info_##_ctlr_,               \
    dev:           _dev_,                                       \
};                                                              \
DISK_CHANNEL(ide_disk_channel##_number_,                        \
             ide_disk_funs,                                     \
             ide_disk_info##_number_,                           \
             ide_disk_controller_##_ctlr_,                      \
             _mbr_supp_,                                        \
             4                                                  \
);                                                              \
BLOCK_DEVTAB_ENTRY(ide_disk_io##_number_,                       \
             CYGDAT_IO_DISK_IDE_DISK##_number_##_NAME,          \
             0,                                                 \
             &cyg_io_disk_devio,                                \
             ide_disk_init,                                     \
             ide_disk_lookup,                                   \
             &ide_disk_channel##_number_                        \
);
```

The first thing this macro does is generate an instance of the ide_disk_info_t. This is a driver-defined structure to contain any info that does not fit in the system defined structures. In this case the important things are the number of the device on the controller, zero or one mapping to master or slave, and a pointer to the driver-defined controller structure. The `DISK_CHANNEL()` macro creates a disk channel object and populates it with the function list defined earlier, a pointer to the matching local info structure just defined, and a pointer to the controller it is attached to. Finally, a device table entry is created. This uses linker features to install an entry into the device table that allows the IO subsystem to locate this device.

Finally we need to instantiate all the channels that this driver will support.

```
IDE_DISK_INSTANCE(0, 0, 0, true);
IDE_DISK_INSTANCE(1, 0, 1, true);
IDE_DISK_INSTANCE(2, 1, 0, true);
IDE_DISK_INSTANCE(3, 1, 1, true);
```

Each invocation of `IDE_DISK_INSTANCE()` generates all the data structures needed to access each possible physical disk that may be present.

Part XI. USB Mass Storage Support

Name

CYGPKG_DEVS_DISK_USBMS — eCosPro Support for USB Mass Storage

Description

This document describes the eCosPro USB Mass Storage class driver. This driver provides support for USB memory sticks, Hard disks and any other devices that supports the same protocol.

Protocol support is limited to Bulk transport only, and only the SCSI transparent command set is supported. This covers most modern devices, however very old devices may support other protocols.

Configuration Options

The `CYGPKG_DEVS_DISK_USBMS` package needs to be loaded in order to use the driver. In addition the `CYGPKG_IO_USB` USB package must be loaded to provide generic USB functionality and the board target entry in `ecos.db` must contain a Host Controller Driver package and a platform configuration package in order to access the USB hardware. This package also depends on support from the generic disk package `CYGPKG_IO_DISK`. If file system support is needed, then packages like `CYGPKG_FS_FAT`, `CYGPKG_IO_FILEIO` and `CYGPKG_LINUX_COMPAT` will need to be loaded along with any packages that they may depend upon. Depending on the template used to create the initial configuration some of these may be loaded already.

For more information on the USB subsystem and supported classes, consult the general USB documentation.

cdl_component CYGPKG_IO_USB_HOST

> Ensure that the host USB package has been loaded and enabled for your target so that USB mass storage can function.

cdl_option CYGDAT_DEVS_DISK_USBMS_DISK_NAME

> This is the base device name used to access the raw disk devices in eCos, for example for mount operations. Individual mass storage devices will be named using a trailing number and partitions with a yet further trailing partition number. For example disk 0, partition 1 would be named /dev/usbms/0/1. This is the default mount point for a standard USB memory stick.

cdl_option CYGNUM_DEVS_DISK_USBMS_MAX_TRANSFER

> This defines the maximum transfer size submitted to the device. Larger disk transfer requests will be split into smaller transfers of this size. If the USB stack or host device drivers have reduced resources, this value should be reduced to consume fewer resources for each transfer.

cdl_option CYGNUM_DEVS_DISK_USBMS_CONTROLLER_COUNT

> This defines the number of disk controllers the USBMS driver can handle simultaneously. There is a one-to-one correspondence between controllers and USB devices, so this defines the number of USB mass storage devices that can be accessed at one time.

cdl_option CYGNUM_DEVS_DISK_USBMS_CHANNEL_COUNT

> This defines the number of disk channels the USBMS driver can handle simultaneously. Each channel corresponds to a Logical Unit Number within a controller or device. Most USB mass storage devices contain a single LUN, so the default is to set this to the same value as the controller count. If devices with more LUNs are expected to be used regularly, then this value should be increased.

Part XII. MMC, SD, SDHC and SDIO Media Card Disk Driver

Name

CYGPKG_DEVS_DISK_MMC — eCos Support for MMC, SD, SDHC and SDIO media Cards

Description

This package provides a disk device driver for two commercial flash memory card standards: MultiMedia Cards (MMC), and Secure Digital (SD) cards, including the high-capacity SDHC variant. The package also provides some (non-disk) basic SD I/O (SDIO) card support.

The MMC card implementation is intended to allow operation with memory cards compliant with the MultiMediaCard Standard version 2, as published by the MultiMediaCard Association. The SD implementation is intended to allow operation with cards compliant with the SD Physical Layer Specification version 2, as published by the SD Card Association.

This package evolved from an MMC-only implementation and as such the naming of certain aspects such as the CDL package name reflects that heritage. Any identifiers which reference MMC usually refer to either MMC or SD cards unless otherwise noted. Similarly, the package provides (limited) support for SDIO cards which do *NOT* require the presence of the CYGPKG_IO_DISK infrastructure and do not present as disk (memory) devices.

An MMC/SD card provides non-volatile storage in a small footprint (24mm * 32mm * 1.4mm), and weighing less than 2 grams. Typical card sizes are 128MB to 2GB, with an upper limit of 4GB for MMC and SDv1; and 32GB for SDHC cards in SDv2. It should be noted that these sizes are measured in millions of bytes, not 2^20. This driver provides support for 4GB MMC and SDv1 cards, although in practice, the FAT16 filesystem layout on such cards is unusual and may not be supported by a filesystem implementation using this driver. This problem should not occur with cards of size 2GB and less, or with SDHC cards.

At the hardware level there are two ways of accessing an MMC card. The first it to use a custom interface frequently known as either an an MCI (Multimedia Card Interface, although this allows supports for SD as well) or an MMC/SD bus. The second interface is via connection to an SPI bus. A card will detect the interface in use at run-time. The custom MCI interface allows for better performance but requires additional hardware. SPI peripheral support is more readily available on many existing CPUs. At this time, the SPI bus mode of interface does not support SD or SDIO cards in this driver.

Theoretically an MMC/SD memory card can be used with any file system. In practice all cards are formatted for PC compatibility, with a partition table in the first block and a single FAT file system on the rest of the card. The SPI mode driver always checks the format of the MMC card and will only allow access to a card if it is formatted this way. The MCI card bus driver can adapt to a card with no partition table as long as it contains a FAT filesystem starting from the first block. This non-standard format can sometimes be created by Windows when reformatting a corrupted card. This ability is controlled by the CYGSEM_IO_DISK_DETECT_FAT_BOOT CDL configuration option in the generic disk device driver package CYGPKG_IO_DISK.

Card Insertion and Removal

An MMC or SD socket allows cards to be removed and inserted at any time. It is a common feature for such sockets to contain a contact allowing the presence of cards to be detected. On some hardware that signal is routed to the processor allowing it to be sampled, usually connected as a GPIO signal or to an interrupt line (or to a GPIO interrupt if available).

In such cases, the MMC/SD bus driver layer in this package is able to be informed by the hardware MMC/SD bus driver of whether cards are present or not, and if possible, can be informed by an event callback that a card has just been inserted or removed. The SPI mode driver in this package does not yet support this feature.

If using the MMC/SD bus driver with appropriate hardware and driver support, the MMC/SD bus driver layer in this package can plug into the removeable media support offered by the generic disk driver layer (CYGPKG_IO_DISK) if the configuration option CYGFUN_DEVS_DISK_MMCSD_BUS_REMOVABLE_MEDIA_SUPPORT is enabled. This option may only be enabled if a hardware driver indicates that support is available. This facility allows for event notification when a card is inserted or removed from the socket. This information can be used directly by the application using the disk package APIs (see that package's documentation), or to allow use of, for example, the automounter support provided in the File I/O package (CYGPKG_IO_FILEIO).

If card detection by an interrupt is not possible, or if using the SPI bus driver, then the only time the device driver will detect removal events is when the next I/O operation happens. At that point, the operation will fail, typically with an error code such as ENODEV, ETIMEDOUT or possible EIO. It is left to higher-level code to recover from this error - the MMC/SD driver is unable to do anything since the card has gone. In the case of the eCosPro implementation of the FAT filesystem, it has been made robust to such events such that it will always be able to force an unmount using the `umount_force` function instead of the standard `umount` function.

Without card detection by interrupt, use of the automounter is not possible, therefore expected usage is that application code will explicitly `mount` the card before attempting any file I/O.

Irrespective of card detection abilities, it is expected that the application will `umount` the card before it is removed. Until unmounted, the system is likely to keep some disk blocks cached, for performance reasons. If the card is removed before the `umount` then it may end up with a corrupted file system. Application design to inform users of when it is safe to remove card media, and regular uses of the standard `sync` function will reduce the risk of file system corruption.

If card detection support is available, but is only pollable, rather than being connected to an interrupt, then this has limited benefits other than to accelerate the process of determining whether a card has been removed, which otherwise necessitate attempting operations and waiting for potential timeouts. In a future revision of this driver it may become possible to use a polling thread to check periodically for whether cards have been inserted or removed.

Write Protection and Security

The MMC and SD specifications allow cards to be write-protected in software. The current device driver does not yet make it possible to mark a card as write-protected, however it does respect the setting, and on mounting such a card will mark it internally as read-only. Any attempt to write to the card will fail with the error EROFS.

SD cards additionally feature a write-protect or 'lock' switch to indicate that cards must not be written to. This is not a physical protection however - instead it is expected that the lock switch position is detected by a contact in the socket, and it is for software to sample the state of that contact to determine whether the card is write-protected. Therefore the lock switch may not be respected if either the hardware or hardware driver does not support sampling the lock switch position from the socket. If sampling is supported however, the MMC/SD bus driver will respect that and mark the card internally as read-only.

SD (and to a lesser extent MMC) support other security features such as password protection and encryption. This driver does not yet support these features.

Configuration Options

`CYGPKG_DEVS_DISK_MMC` is a hardware package which should get loaded automatically when you configure for a suitable eCos target platform. In this case suitable means that the hardware either:

a. has an MMC/SD socket connected to an SPI bus, that an SPI bus driver package exists and is also automatically loaded, and that the platform HAL provides information on how the card is connected to the SPI bus; or

b. has an MMC/SD socket connected to a custom MCI interface's card bus and a driver package for the MCI exists and is also automatically loaded, or exists in the HAL.

For memory card support the package depends on support from the generic disk package `CYGPKG_IO_DISK`. That will not be loaded automatically: the presence of an MMC/SD socket on the board does not mean that the application has any need for a file system. Hence by default `CYGPKG_DEVS_DISK_MMC` will be inactive and will not contribute any code or data to the application's memory footprint. To activate the driver it will be necessary to add one or more packages to the configuration using **ecosconfig add** or the graphical configuration tool: the generic disk support `CYGPKG_IO_DISK`; usually a file system, `CYGPKG_FS_FAT`; support for the file I/O API `CYGPKG_IO_FILEIO`; and possibly additional support packages that may be needed by the file system, for example `CYGPKG_LINUX_COMPAT` for FAT. Depending on the template used to create the initial configuration some of these may be loaded already.

For non-memory SDIO cards it is possible for the package to be used without the disk I/O infrastructure. This is controlled by the `CYGFUN_DEVS_DISK_MMCSD_SDIO` option, which is available when the target platform indicates that it implements the relevant SDIO support. This allows for embedded (non-removable) SDIO device support on platforms without incurring the cost of including the unnecessary disk I/O code.

SPI mode operation configuration

The package provides two main configuration options when using the SPI mode of operation. CYGDAT_DEVS_DISK_MMC_SPI_DISK0_NAME specifies the name of the raw disk device, for example /dev/mmcdisk0. Allowing for partition tables that makes /dev/mmcdisk0/1 the first argument that shoul be passed to a mount call. If the hardware has multiple disk devices then each one will need a unique name. CYGIMP_DEVS_DISK_MMC_SPI_POLLED controls whether the SPI bus will be accessed in interrupt-driven or polled mode. It will default to interrupt-driven if the application is multi-threaded, which is assumed to be the case if the kernel is present. If the kernel is absent, for example in a RedBoot configuration, then the driver will default to polled mode. With some hardware polled mode may significantly increase disk throughput even in a multi-threaded application, but will consume cpu cycles that could be used by other threads.

MMC/SD card bus mode operation configuration

When using an MMC/SD card bus, there a number of CDL configuration settings to be aware of within this driver.

Number of sockets on the MMC/SD bus (CYGINT_DEVS_DISK_MMCSD_BUS_CONNECTORS)

> This CDL interface indicates the number of sockets capable of being supported by the MMC/SD card bus driver. It is usually implemented by either a hardware device driver or the platform HAL. At the present time there can only be 1 socket supported. This limitation is intended to be lifted in the future.

SD card support (CYGFUN_DEVS_DISK_MMCSD_SD)

> This option is present to allow SD card support to be disabled. SD card support is considered a superset of MMC support, and therefore it is not possible to disable MMC card support. If SD cards are not to be used, this option can be disabled to reduce code and memory footprints, along with slightly faster execution.

SDIO card support (CYGFUN_DEVS_DISK_MMCSD_SDIO)

> This option is present to allow SDIO card support to be enabled for targets that do not require memory MMC/SD card disk support. It is enabled by default when the target platform/variant indicates the requirement, and is not normally an option the user should need to manually configure.

Device name for the MMC/SD disk 0 device (CYGDAT_DEVS_DISK_MMCSD_BUS_DISK0_NAME)

> This is the name of the raw disk or SDIO device. For disks it provides the prefix used for the separate disk device strings which are passed to the mount call. For example, a setting of /dev/mmcsd0/ would allow the first partition on the card to be accessed as /dev/mmcsd0/1, the second as /dev/mmcsd0/2, etc. /dev/mmcsd0/0 is a special device name used to access the entire device (including the partition table if present. Furthermore, the /dev/mmcsd0 device can be used for registering disk insertion/removal events with the disk layer. Consult the disk package documentation for details. The setting of this configuration option must end with a slash character ('/').

Hardware drivers support card detection (CYGINT_DEVS_DISK_MMCSD_BUS_CARD_DETECTION)

> This CDL interface is implemented by a hardware device driver or platform HAL to indicate that it is able to report the presence or absence of cards.

Removable MMC/SD media support (CYGFUN_DEVS_DISK_MMCSD_BUS_REMOVABLE_MEDIA_SUPPORT)

> This option is used to determine whether the MMC/SD bus layer will plug into the generic disk package's removeable media support, i.e. allowing notification of insertion or removal of cards. There is no point enabling this option without hardware and

driver support, so it is not possible to enable it if CYGINT_DEVS_DISK_MMCSD_BUS_CARD_DETECTION has not been implemented. Some code can be saved if this option is disabled.

MMC/SD debug output (CYGDBG_DEVS_DISK_MMCSD_BUS_DEBUG)

Detailed debugging output is possible via the diagnostic console. By default there is no debugging output, but setting this option to 1 or 2 will provide increased verbosity of debugging output.

Certain MMC/SD bus device drivers may provide support for multi-sector I/O. But if you are using the FAT filesystem, it will not take advantage of this facility unless you make a configuration change within the FAT filesystem package (CYGPKG_FS_FAT). You may increase the value of the "FAT block cache block size" (CYGNUM_FS_FAT_BLOCK_CACHE_BLOCKSIZE) to a higher power of two, in order to increase the number of sectors read or written in a chunk by the filesystem. This will cause multi-sector I/O to be employed within this driver. It has been noticed that certain models of SD cards (including some made by brand-name manufacturers like Sandisk and Kingston) perform disproportionately poorly if only using single block I/O; therefore we recommend that where possible you do adjust this option to a higher value (e.g. 16384). Note that memory usage will go up proportionately unless you also reduce the "FAT block cache memory size" (CYGNUM_FS_FAT_BLOCK_CACHE_MEMSIZE), which you may wish to do depending on your memory requirements.

Additional SPI Mode Functionality

When using the SPI mode to access MMC cards, the disk driver package exports a variable cyg_mmc_spi_polled. This defaults to true or false depending on the configuration option CYGIMP_DEVS_DISK_MMC_SPI_POLLED. If the default mode is interrupt-driven then file I/O, including mount operations, are only allowed when the scheduler has started and interrupts have been enabled. Any attempts at file I/O earlier during system initialization, for example inside a C++ static constructor, will lock up. If it is necessary to perform file I/O at this time then the driver can be temporarily switched to polling mode before the I/O operation by setting cyg_mmc_spi_polled, and clearing it again after the I/O. Alternatively the default mode can be changed to polling by editing the configuration, and then the main() thread can change the mode to interrupt-driven once the scheduler has started.

Porting to New Hardware

SPI mode

Assuming that the MMC connector is hooked up to a standard SPI bus and that there is already an eCos SPI bus driver, porting the MMC disk driver package should be straightforward. Some other package, usually the platform HAL, should provide a cyg_spi_device structure cyg_spi_mmc_dev0. That structure contains the information needed by this package to interact with the MMC card via the usual SPI interface, for example how to activate the appropriate chip select. The platform HAL should also implement the CDL interface CYGINT_DEVS_DISK_MMC_SPI_CONNECTORS.

When defining cyg_spi_mmc_dev0 special care must be taken with the chip select. The MMC protocol is transaction-oriented. For example a read operation involves an initial command sent to the card, then a reply, then the actual data, and finally a checksum. The card's chip select must be kept asserted for the entire operation, and there can be no interactions with other devices on the same SPI bus during this time.

Optionally the platform HAL may define a macro HAL_MMC_SPI_INIT which will be invoked during a mount operation. This can take any hardware-specific actions that may be necessary, for example manipulating GPIO pins. Usually no such macro is needed because the hardware is set up during platform initialization.

On some targets there may be additional hardware to detect events such as card insertion or removal, but there is no support for exploiting such hardware at present.

Only a single MMC socket is supported. Given the nature of SPI buses there is a problem if the MMC socket is hooked up via an expansion connector rather than being attached to the main board. The platform HAL would not know about the socket so would not implement the CDL interface CYGINT_DEVS_DISK_MMC_SPI_CONNECTORS, and the ecos.db target entry would not include

CYGPKG_DEVS_DISK_MMC. Because this is a hardware package it cannot easily be added by hand. Instead this scenario would require some editing of the existing platform HAL and target entry.

Card bus mode

Creating a hardware driver for accessing a card connected via a card bus requires a large amount of detailed description closely related to the specific code definitions. Therefore comprehensive descriptions of functionality has been provided in the mmcsd_bus.h header file in the include directory of this package. Drivers should include this file, although before doing so they must define the C preprocessor macro __MMCSD_DRIVER_PRIVATE in order to obtain definitions private to card bus drivers.

It is appropriate to provide a high-level overview of the porting process however. A driver package must implement the CDL interface CYGINT_DEVS_DISK_MMCSD_BUS_CONNECTORS to indicate the presence of a socket driven as a card bus. It may also implement CYGINT_DEVS_DISK_MMCSD_BUS_CARD_DETECTION if appropriate.

The driver in this package accesses the hardware driver through the abstraction of the card bus. This is done by instantiating a bus object using the CYG_MMCSD_BUS macro. This takes as arguments an opaque word of private data which may be useful to the hardware driver for identifying this bus or for any relevant bus state, and it also takes a function callback list. The CYG_MMCSD_BUS instantiation must exist in a module which is always included in the program image. This is usually performed when building the package by including it in the libextras.a library (which is converted to extras.o in the eCos build process and forcibly included in the program image that way).

This function callback list must be instantiated using the CYG_MMCSD_BUS_FUNS macro. This provides a table identifying driver functions to: initialise the bus at system startup time; (re-)initialise the socket when attempting to access a card in it for the first time; shutting down a socket to conserve power; doing specialised configuration options; preparing to select a card in a socket; sending a command to a card; and transferring data blocks to or from a card. At this point the byte and stream operations may be left as NULL and are only present for potential future expansion. Details on the purpose and arguments to these functions can be found in mmcsd_bus.h.

If the hardware and driver is capable of reporting card insertion/removal events, then notification of insertion or removal can be performed by calling the MMCSD_CARD_DETECT_EVENT() macro to register this with the MMC/SD layer, which will perform any further processing required. It must be called in DSR or thread context, not ISR context.

SDIO Support

Due to the undefined nature of SDIO card features, the package (currently) provides basic initialisation and device access support. Custom drivers will be needed to support specific SDIO cards or embedded devices. A simple API is exposed to allow the underlying SD commands to be passed to the SDIO card compliant with the SD Specifications Part E1 SDIO Simplified Specification Version 3.00 document as published by the SD Card Association.

A custom driver will reference the SDIO card via an I/O handle obtained via a call to the cyg_io_lookup() function. This handle can be used to perform MMC/SD bus driver “config” calls as well as perform SD operations via the SDIO specific functions exposed by this package. Currently two SDIO specific functions are available.

```
Cyg_ErrNo cyg_sdio_transaction_direct(cyg_io_handle_t handle,
                                      cyg_uint32      cmd,
                                      cyg_uint32      arg,
                                      cyg_uint32 *response);
```

The function above can be used to send card control commands (e.g. CMD0, CMD5, etc.) or the SDIO single register read/write CMD52 whereas the function below is an interface to the specific SDIO block data transfer CMD53 support.

```
Cyg_ErrNo cyg_sdio_transaction_extended(cyg_io_handle_t handle,
                                        cyg_uint32      arg,
                                        cyg_uint32      *response,
                                        cyg_bool        read,
                                        cyg_uint32      block_length,
                                        cyg_uint32      block_count,
                                                  cyg_uint8 *buf);
```

Notes

1. The current SDIO implementation is limited to platforms that define the `HAL_MMCSD_PLF_SDIO_INIT_EARLY_EXIT` macro since the detection of MMC/SD-vs-SDIO (and combo) cards during card specific initialisation has not yet been implemented.
2. It is currently the responsibility for the custom SDIO device driver to perform card initialisation (CMD0, CMD5, et-al) via the exposed `cyg_sdio_transaction_direct()` API.

Part XIII. MMC/SD Card Device Drivers

Table of Contents

Chapter 49. Atmel SAM series Multimedia Card Interface (MCI) driver

Name

Atmel SAM series Multimedia Card Interface (MCI) driver — Using MMC/SD cards with block drivers and filesystems

Overview

The MultiMedia Card Interface (MCI) driver in the SAM MCI device driver package allows use of MultiMedia Cards (MMC cards) and Secure Digital (SD) flash storage cards within eCos, exported as block devices. This makes them suitable for use as the underlying devices for filesystems such as FAT.

This driver can support boards based on either the SAM9 or SAMA5 processors, where underlying platform HAL support exists.

Configuration

This driver provides the necessary support for the generic MMC bus layer within the `CYGPKG_DEVS_DISK_MMC` package to export a disk block device. The disk block device is only available if the generic disk I/O layer found in the package `CYGPKG_IO_DISK` is included in the configuration.

The block device may then be used as the device layer for a filesystem such as FAT. Example devices are "`/dev/mmc0/1`" to refer to the first partition on the card, or "`/dev/mmc0/0`" to address the whole device including potentially the partition table at the start.

Typically, platform HALs provide an option to permit enabling or disabling MCI support.

If the driver is enabled, there are three CDL configuration options:

`CYGIMP_DEVS_MMCSD_ATMEL_SAM_MCI_INTMODE`

This indicates that the driver should operate in interrupt-driven mode if possible. This is enabled by default if the eCos kernel is enabled. Note though that if the driver finds that global interrupts are off when running, then it will fall back to polled mode even if this option is enabled. This allows for use of the MCI driver in an initialisation context.

`CYGNUM_DEVS_MMCSD_ATMEL_SAM_MCI_POWERSAVE_DIVIDER`

The SAM MCI peripheral allows the MCI clock to be divided down if told to enter power saving mode. This option specifies the divider to use. The driver itself does not implement any power saving - it is up to the application to enable power saving in the MCI control register if it is required.

`CYGHWR_DEVS_MMCSD_ATMEL_SAM_MCI_DEVICE`

Some SAM processors have two or even three MCI interfaces. This option selects which of these will be used by the MMC driver. The default for the SAM9263 is to select interface 1, since the PIO lines for interface 0 are shared with SPI0, which will usually be occupied by a dataflash device or card. On the SAM9G45 the pins are not shared, so we select MCI0 by default. The SAMA5D3 permits three MCI devices, and these can be selected here.

Usage notes

MMC/SD cards may only be used in a MMC/SD card slot, and not a dataflash slot. The driver will detect the appropriate card sizes. Hotswapping of cards is supported by the driver, and in the case of eCosPro, the FAT filesystem. Although any cards removed before explicit unmounting or a `sync()` call to flush filesystem buffers will likely result in a corrupted filesystem on the removed card.

The MMC/SD bus layer will parse partition tables, although it can be configured to allow handling of cards with no partition table.

This driver implements multi-sector I/O operations. If you are using the FAT filesystem, see the generic MMC/SD driver documentation which describes how to exploit this feature when using FAT.

Part XIV. The Yaffs filesystem

Important

The Yaffs filesystem package is distributed with eCosPro under the GNU Public License (GPL). The viral nature of the GPL license is incompatible with both the the eCosPro License, making this package suitable for internal evaluation and testing purposes only. NO PART OF ECOSPRO IN ANY FORMAT MAY BE REDISTRIBUTED WHEN LINKED WITH THIS PACKAGE OR ANY OTHER GPL CODE. Shipment of prototypes, hardware or products containing eCosPro licensed code in any format that has been linked with this package are therefore STRICTLY PROHIBITED.

A separate COMMERCIAL LICENSE for Yaffs from eCosCentric is therefore required to permit distribution of binary forms of eCosPro with this package.

Some releases of eCosPro may not include this package. In this case, please contact eCosCentric for licensing and availability.

Table of Contents

Chapter 50. What is Yaffs?

Yaffs is a filesystem for NAND flash chips.

Yaffs is accessed through the FILEIO package which presents a standard POSIX compatible IO interface through which applications use standard open(), read(), write() and close() calls.

Yaffs is a *journalling* filesystem with *wear-levelling*. It is particularly suited to NAND flash parts, having been designed with their unique properties in mind. The use of traditional filesystems (FAT, ext2, etc) which do not have these features is not recommended on such chips because their design requires the use of fixed address on the underlying hardware. Such behaviour causes flash sectors to wear out, the consequence of which would typically be to cause the whole device to become unbootable.

Yaffs also provides a high degree of robustness, which is usually a requirement of embedded devices. A power failure or other crash can leave a traditional filesystem in an inconsistent state which is often difficult to repair, especially in the field.

Yaffs can also be built into RedBoot, which allows you to store application images on NAND flash and boot them with RedBoot's usual flexible scripting system.

For more information about NAND flash chips, how they differ from NOR flash parts and other ways to access them, refer to the documentation for the eCos NAND Flash Library.

For more information about Yaffs itself, refer to yaffs.net.

Chapter 51. Getting started with Yaffs

Licensing considerations

Before you can use Yaffs, you must accept its license. *Yaffs is not covered by the standard eCos license.* You will be reminded of your license to use Yaffs when you install it.

Most users will only have access to Yaffs under the GNU GPL. This costs nothing to license. However this usually means that if you ever distribute your application, you must do so under the GPL. This requires you to publish or otherwise make all of your application, eCos and everything else you link with it available as source code. For full details refer to the text of the GPL (v2).

If you cannot accept the restrictions and obligations of the GPL, Yaffs for eCos is available under a proprietary license, for a fee. Details are available on request from eCosCentric or Aleph One.

Installation

Yaffs is included within the standard eCosPro distribution and no additional installation of the GPL-licensed version is required. The proprietary licensed version is supplied as an EPK (eCos Package) file which may be installed alongside the GPL-licensed version. The remainder of this section deals with the installation of the proprietary licensed version.

Installation via the eCos Configuration Tool

1. Open up the eCos Configuration Tool.
2. Open up the *Administration* dialog, from the *Tools* menu.
3. Press the *Add* button.
4. A file browser windows opens. Navigate to the Yaffs EPK file.
5. The License screen shows. You must accept the license in order to install the package. Press Yes if you do.

Installing from the command-line

Advanced users may alternatively use the `ecosadmin.tcl` tool from the command line. You will be prompted to accept the license at the appropriate time during the procedure.

```
tclsh $ECOS_REPOSITORY/ecosadmin.tcl add yaffs-v1_2_3.epk
```

Configuration and Building

After installing the EPK, Yaffs is added to your eCos repository and is configured and built in the normal way.

Package dependencies

To link Yaffs into your application, add `CYGPKG_FS_YAFFS` to your eCos configuration in the normal way, either using the eCos Configuration Tool (*Packages* dialog on the *Build* menu), or the `ecosconfig` command-line tool.

You will also need to add `CYGPKG_IO_NAND` and `CYGPKG_IO_FILEIO` to your configuration if they are not already present. Your platform HAL should supply packages for all NAND device(s) present.

If you started with a smaller template than *default*, you may also need to add some of the following:

- `CYGPKG_LIBC_STDLIB`
- `CYGPKG_LIBC_STRING`
- `CYGPKG_MEMALLOC` or something else which provides `CYGINT_ISO_MALLOC`
- `CYGPKG_LIBC_I18N` or something else which provides `CYGINT_ISO_CTYPE`

Configuration options

Yaffs provides a number of package options, including tuning parameters.

`CYGPKG_FS_YAFFS_CFLAGS_ADD`
`CYGPKG_FS_YAFFS_CFLAGS_REMOVE`

These settings allow specific build options to be added to or removed from the CFLAGS list when building Yaffs.

`CYGSEM_FS_YAFFS_CACHE_SHORT_NAMES`

If set, caches files' short names in RAM. This consumes more RAM but improves performance.

`CYGPKG_FS_YAFFS_RET_DIRENT_DTYPE`

Controls whether Yaffs supports setting the *`d_type`* field in a struct dirent. If you don't need this, leave it switched off to save a little code size.

`CYGNUM_FS_YAFFS_RESERVED_BLOCKS`

The number of blocks to keep in reserve to allow for garbage collection and block failures. The recommended value is 5, but you can tune it for performance. *This setting is a global default and may be changed by a mount-time option.*

`CYGNUM_FS_YAFFS_SHORTOP_CACHES`

The number of page cache entries to use. Values of 10 to 20 are recommended; increasing the number consumes more RAM, and 0 disables it altogether. *This setting is a global default and may be changed by a mount-time option.*

`CYGNUM_FS_YAFFS_TRACEMASK`

This is a 32-bit bitfield which controls diagnostic output. The bit definitions are found in `yportenv.h`; they are only useful if you are debugging Yaffs itself.

`CYGNUM_FS_YAFFS_TEMP_BUFFERS`

Yaffs requires temporary buffers in many places throughout the code. To avoid the overhead of a dynamic malloc every time, a number of buffers are preallocated at mount time. This setting controls how many; should it not prove enough, Yaffs will call malloc on demand as required. The default setting is 6; most users will not need to change it.

`CYGSEM_FS_YAFFS_SMALLPAGE_MODE`

This option only affects behaviour on so-called "small page" NAND devices (those whose pages are 512 bytes long). Such devices do not have enough space in their Out Of Band area to store a full set of Yaffs metadata tags. There are two ways to work around this:

- `YAFFS2` mode - the default - uses regular tags, but at a price: it steals 16 bytes from the available space per page to store them. *This reduces the apparent available size of your filesystem by 1/32!*

- YAFFS1 mode places a smaller tagset in the OOB area, but with a different side-effect: whenever a page is deleted, one byte of the tags area has to be rewritten. Some devices forbid rewrite-without-erase in this way, so it may not be safe for you to use this option. *You must refer to the spec sheet for the chip on your board before selecting this option!*

CYGSEM_FS_YAFFS_OMIT_YAFFS2_CODE

This causes all YAFFS2 code to be omitted from the build. This option only makes sense when all the devices on which Yaffs is to be used are small-page and operating in YAFFS1 mode.

Note

There is no corresponding option to omit YAFFS1 code, because that code is only compiled when CYGSEM_FS_YAFFS_SMALLPAGE_MODE is set to YAFFS1.

CYGMEM_FS_YAFFS_REDBOOT_HEAP_REQUIRED

RedBoot carefully controls the amount of memory available for its heap, allocating it from a fixed-size workspace. If Yaffs is being used with RedBoot, the heap space required is likely to go up substantially. The exact amount depends on properties of the filesystem being mounted. Consult the eCosPro Yaffs documentation for more details of Yaffs' memory requirements. This option ensures RedBoot's heap is increased to a more reasonable size, but it has been made an option in order to allow developers to decrease it, if they are sure the filesystem will not require as much memory as this.

Note

However, note that even this larger amount may not be adequate for some filesystems.

Using Yaffs

Yaffs appears in the eCos filesystem table. This means that you can mount a filesystem in the standard Unix-like way, then interact with it with calls to open, read, etc.

Mounting a filesystem

Before you can use a filesystem, it must be *mounted*.

A NAND device is logically organised as one or more *partitions*, which are usually set up by the relevant platform HAL. You need to tell the mount command which device and partition you wish to access. In the following example, we are mounting partition 0 of the *onboard* NAND device.

```
rv = mount("onboard/0", "/nand", "yaffs");
```

Note

The *device* argument to the mount call is a NAND-specific device name, not an entry in /dev. Refer to the documentation for your platform HAL for details of how the NAND device(s) are named, and to the NAND library documentation for details of how partitions are addressed.

You can, if you wish, make the filesystem mounting automatic at static constructor time with the MTAB_ENTRY macro. (Your platform HAL may already do this; check it carefully.)

```
MTAB_ENTRY(my_nand, "/nand", "yaffs", "onboard/0", "", 0);
```

Note

This example is for eCosPro. In eCos, the MTAB_ENTRY macro takes only four arguments.

Mount-time options

eCosPro allows various options to be passed to a filesystem at mount time, by combining them with the filesystem argument in a particular format. Yaffs understands the following options:

- `reserved`=<int> The number of physical NAND blocks to reserve for garbage collection and block failures (minimum 2). The default is set in CDL as `CYGNUM_FS_YAFFS_RESERVED_BLOCKS`.
- `caches`=<int> The number of page cache entries to use. Values of 10 to 20 are recommended. The default is set in CDL as `CYGNUM_FS_YAFFS_SHORTOP_CACHES`.
- `skip-checkpoint-read` Instructs Yaffs to not attempt to reload the filesystem from a checkpoint, if one exists. In other words, this option forces a full filesystem scan whether or not one is necessary.
- `format` Instructs Yaffs to format the filesystem before it mounts it. This deletes its entire contents.

Data flushing

Yaffs operates a cacheing layer in order to save undue wear on the NAND chip if many small writes are performed. Because of this, if you wish to ensure that any data written to a still-open file has been fully flushed, you must make a synchronisation request. This is done with the `fsync` function, which takes as its argument the file descriptor of the file you wish to synchronise.

Checkpointing

When mounting a filesystem, Yaffs has to scan the NAND chip to recreate its internal state. This can be a slow process, but is made much faster if there is a valid *checkpoint*.

A checkpoint is written out automatically when you unmount the filesystem. At any other time, you can manually force a checkpoint to be written with one of the following functions:

- `cyg_fs_fssync(mountpoint)` synchronises a filesystem (automatically called on umount)
- `sync` synchronises all mounted filesystems.

Note

A checkpoint becomes invalid as soon as there have been any other writes to the filesystem. Finding a good place to sync is necessarily dependent on your application logic.

Limitations

Although Yaffs is a Unix-compatible filesystem, the eCos port does not provide support for the full range of Unix attributes.

- eCos does not check file or directory permissions; everything it creates is given fixed user and group IDs of zero and standard permissions (files rw-r--r--, directories rwxr-xr-x).
- It is not currently possible to change file ownership or permissions.
- It is not currently possible to create symbolic links, FIFOs (named pipes), sockets or device nodes.
- Hard links to files work in the expected way. Hard links to directories are forbidden.
- It is not possible to unlink the '.', '..' or 'lost+found' special directories.

Note

If you will be sharing a Yaffs filesystem between eCos and some other operating system, you are advised to carefully check the other system's definitions of mode (permission) bits and whether any translation may be required.

Memory requirements

The amount of RAM required by Yaffs to hold its in-memory data structures grows with the number of objects (files and directories) in your filesystem. You are recommended to test your application thoroughly to ensure that sufficient memory exists for Yaffs to operate with the most complicated filesystem it is likely to encounter.

If you wish to estimate your RAM usage, the Yaffs author provides the following calculation:

- The partition itself requires a yaffs_DeviceStruct of 3608 bytes.
- If CYGNUM_FS_YAFFS_SHORTOP_CACHES is enabled, each is the size of a NAND page plus 28 bytes.
- Every object (file, directory or hardlink) in the filesystem takes a yaffs_Object struct, which is 124 bytes.
- Every page of every file requires a Tnode entry, but they are always allocated in groups of 16 at a time.
  - The size of a single Tnode entry is the number of *bits* required to number all the pages in the NAND partition Yaffs is using, numbering from *one*; this is rounded up to a multiple of 2, and has an absolute minimum of sixteen bits.
  - For example: on a partition with 65536 pages, seventeen bits are required for the numbering, which round up to 18. Therefore each file takes 288 bits (36 bytes) per group of Tnodes, and one group of Tnodes will cover up to sixteen pages of data.

Note

Actual memory consumption will be slightly higher than suggested by the above. This arises from the tree structure holding the Tnodes, overheads from the heap itself, and so on.

Yaffs calls the standard `malloc` function to allocate memory and `free` to release it. Normally, the eCos heap occupies all spare RAM not needed for the program, its static data or the stacks. Therefore, most applications will not need to do anything special beyond ensuring there is enough spare RAM available on the platform.

Tip

If you wish to experiment with restricted-size heaps to determine much memory your application actually uses under Yaffs, you may find the option `CYGSEM_MEMALLOC_INVOKE_OUT_OF_MEMORY` of use.

Worked example

Consider a Yaffs filesystem hosted by a NAND partition with 65536 pages, each of size 2k, using the default setting of ten short-op caches. On this filesystem we shall store 10000 files each of size 10240 bytes, hence each requires a single group of Tnodes.

Table 51.1. Yaffs RAM use worked example

Consumer	**RAM used (bytes)**
yaffs_DeviceStruct	3,608
Short-op caches @ 10 x (2048+28)	20,760
Total	**1,624,368**

Consumer	**RAM used (bytes)**
yaffs_Objects @ 10,000 x 124	1,240,000
Tnode groups @ 10,000 x 36 *(see above)*	360,000
Total	**1,624,368**

This example is a close match to the actual consumption measured by eCosCentric during testing. (The measured consumption as reported by `mallinfo` was 1,681,112 bytes, which includes the heap's own overheads.)

Testing

Yaffs is supplied with a number of test programs, some of which are have been adapted from tests for other filesystems in eCos.

fops

This was the first basic test created for the port of the filesystem. It is believed to exercise all of the code paths (filesystem operations, file operations and directory operations) within the eCos-Yaffs adaptation layer.

This test was originally intended to run on a synthetic NAND filesystem. On real NAND chips, it deliberately omits the more stressful routines to avoid undue wear on the hardware.

yaffs1

A number of filesystem edge-case semantic tests, including file and directory creation and deletion, invalid open and rename operations, and removing nonexistent files and directories.

yaffs2

Concurrent multi-threaded filesystem access and consistency checks.

yaffs4

Semantic and edge-case testing - like yaffs1 - but with long file names.

yaffs5

Tests that file reading and writing works over reasonably large files (up to 1Mbyte) with different I/O chunk sizes. Some operation timings are collected and reported, as is the data rate on large files.

yaffs6

Semantic and edge-case testing - like yaffs1 - but with Cyrillic filenames in order to test UTF-8 correctness.

mounttime

A simple benchmark which repeatedly mounts and unmounts the filesystem and measures how long this takes. You can optionally use the `mkfiles` routine - also present in the tests directory - to create many short files so you can test performance on a loaded filesystem.

hammer [*]

A stress test designed to shake out corner cases. Repeatedly creates many files of varying sizes from multiple threads until the filesystem fills up, then verifies their contents and removes them. From time to time, all threads pause and the filesystem is unmounted and remounted.

This test is particularly useful when combined with the bad block injection functionality provided by the synthetic NAND device. It has been used in this way by eCosCentric to thoroughly test this package's stability under error conditions.

[*] This test runs forever, until interrupted.

Chapter 52. Using Yaffs with RedBoot

It is possible to link Yaffs into RedBoot and use it to boot an executable image stored on a NAND array.

This is done by configuring and building RedBoot largely in the normal way. You will need to add `CYGPKG_FS_YAFFS` and `CYGPKG_IO_FILEIO` to your configuration, plus their attendant dependencies.

The presence of CYGPKG_IO_FILEIO activates the `fs` series of RedBoot commands. The following (edited) transcript illustrates how they might be used in concert with other RedBoot commands to store an ELF image on a NAND partition, load it back and execute:

```
RedBoot> fs mount -d onboard/0 -t yaffs /nand
yaffs: restored from checkpoint
RedBoot> load -r -h my.tftp.ip.address -b %{freememlo} my.image
Using default protocol (TFTP)
Raw file loaded 0xa013f000-0xa01554b3, assumed entry at 0xa013f000
RedBoot> fs write /nand/myimg.elf
RedBoot> fs list /nand
   1 drwxr-xr-x  0 size      0 .
   1 drwxr-xr-x  0 size      0 ..
 262 -rw-r--r--  0 size  91316 myimg.elf
   2 drwxr-xr-x  0 size      0 lost+found
RedBoot> load -m file /nand/myimg.elf
RedBoot> go
Hello, NAND world!
```

Note

When you command RedBoot to execute an image, it first synchronises all mounted filesystems. Therefore, provided these filesystems support the synchronisation operation (which Yaffs does), it is not always necessary to unmount them before invoking an image.

Memory considerations under RedBoot

RedBoot traditionally has very limited requirements for memory management; the main need is for there to be free space in RAM at the correct (physical) address to load an image before jumping to it.

Introducing Yaffs brings with it not just the need to have dynamically allocatable RAM (`CYGPKG_MEMALLOC`), but enough to replay the filesystem journal. This must be balanced against the need for RAM to load images into.

When the `CYGPKG_MEMALLOC` package is present in RedBoot, by default a small (64k) heap is set up so that the maximum RAM possible is available for loading images. This is not enough to support Yaffs in any circumstances, so the following definition has been included in the `yaffs.cdl` file:

```
requires { CYGPKG_REDBOOT implies (CYGMEM_REDBOOT_WORKSPACE_HEAP_SIZE >= 0x00014000) }
```

Caution

This declaration only provideds the bare minimum heap required to mount a trivial Yaffs filesystem. More will be required for all but the simplest of cases and it is recommended that you test for typical use in your environment. Refer also to the section called “Memory requirements”.

It is recommended that, should you wish to make a filesystem usable by RedBoot, your platform HAL should make a similar declaration in its CDL to establish an appropriate heap size. For example, the platform HAL for the EA LPC2468 OEM board - which has a 128MB NAND chip on-board - contains the following declaration:

```
requires { (CYGPKG_REDBOOT && CYGPKG_FS_YAFFS) implies (CYGMEM_REDBOOT_WORKSPACE_HEAP_SIZE >= 0x20000) }
```

Tip

If you wish to experiment with restricted heaps to determine much memory your application actually uses under Yaffs, you may find the option `CYGSEM_MEMALLOC_INVOKE_OUT_OF_MEMORY` of use.

Part XV. eCos NAND I/O

Table of Contents

Chapter 53. The eCos NAND Flash Library

Description

This is a library which allows NAND flash devices to be accessed by the eCos kernel and applications. It is analogous to the eCos FLASH library, but for NAND devices. It exists as a separate library because of the fundamental differences between the two types of flash memory.

This library provides the following functionality:

- Interrogation to confirm that the expected device is present
- Reading from and writing to flash pages
- Erasing flash blocks
- The ability to divide a single device into multiple partitions, like those of a hard drive
- Creation and maintenance of a Bad Block Table
- Use of an Error Correcting Code to detect and correct single-bit errors, and to detect multiple-bit errors
- Packing of the ECC and application out-of-band data into the spare area on the device

Note

The spare area, ECC and bad block table have been deliberately created with the intention of compatibility with current versions of the Linux MTD layer. For example, this would allow a single NAND device to be accessed by RedBoot to load a Linux kernel, which could then go on to use another partition as its root filesystem.

Tip

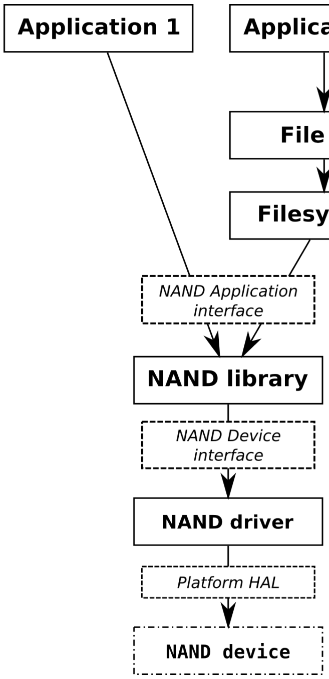
This library is also used as glue to allow appropriate filesystems to use NAND devices. This allows more useful higher-level access by applications and RedBoot via the File I/O and POSIX interfaces. In other words, your application may not need to invoke this library directly, though of course you may still have to write a driver for your chip and/or board.

Structure of the library

This library has two principal interfaces: one for *applications* to call into it, and another to call out to the chip-specific *drivers*. (The chip drivers themselves then require support from the relevant platform HAL to allow them to access the physical chip in an appropriate manner for the board - such as the memory-mapped I/O range to use.)

The following diagram illustrates the calls from two applications all the way to an underlying NAND device. Application 1 uses the NAND library directly, whereas application 2 is using a filesystem and the eCos File I/O layer.

Figure 53.1. Library layout diagram



Device support

Before this library can be used on a given board, an appropriate device driver must be created. Each driver is for a particular NAND part or family of parts; the HAL for each board then instantiates the relevant driver(s) appropriately with board-specific glue such as the memory-mapped I/O range to use. Full details on creating a driver are presented in Chapter 55, *Writing NAND device drivers*.

There is also a Synthetic Target NAND Flash Device for testing purposes, which is present on the *synth* target.

Danger, Will Robinson! Danger!

Unlike nearly every other aspect of embedded system programming, getting it wrong with FLASH devices can render your target system useless. Most targets have a boot loader in the FLASH. Without this boot loader the target will obviously not boot. So before starting to play with this library its worth investigating a few things. How do you recover your target if you delete the boot loader? Do you have the necessary JTAG cable? Or is specialist hardware needed? Is it even possible to recover the target boards or must it be thrown into the rubbish bin? How does killing the board affect your project schedule?

Differences between NAND and NOR flash

Most flash devices supported by the eCos Flash library are categorised as NOR flash. These are fundamentally different from NAND flash devices, both in terms of the storage cells deep within the chip, and how they are addressed and used by applications.

Attribute	NOR	NAND
Addressing of data	By byte address within the device. Usually expressed as memory-mapped addresses.	By row (page) number. Pages are a power of two; commonly 512 or 2048 bytes. Optimised for reading and writing a page at a time. Sometimes supports column (byte) addressing, but this library does not expose such functionality.

Attribute	NOR	NAND
Are direct reads and writes possible? [a]	Usually	Not in general, though a few special-case exceptions exist such as OneNAND devices.
Erase block size	May vary across the chip	A fixed number of pages, typically 64
Out-of-band data	Not supported	A small number of bytes per page - typically 16 "spare" per 512 "data" bytes - are usable by the application. They are read, written and erased at the same time as the "real" page data.
May factory-bad regions [b] exist on the chip?	No	Typically up to 20 eraseblocks are marked as factory-bad in their OOB area. The OS is expected to scan these to create a Bad Block Table. [c]
May data be rewritten without being erased first?	Usually (but only by resetting 1-bits to 0)	Usually, on SLC NAND chips; not on MLC chips.
Error detection and correction	Not present	Usually automatic. Typically this involves an Error Correcting Code, automatically calculated and stored in the OOB area, then checked on read.

[a] In other words, can the application read flash directly as if it was RAM, or does it have to invoke the driver to copy data in and out?

[b] Regions which were found during manufacture to be bad and marked in some way - usually by placing a special code in the Out Of Band area.

[c] Once a BBT exists it can then be used to keep track of any blocks which fail through wear during the lifetime of the device.

Since a NAND chip can in general only be read indirectly, its contents must be copied to RAM before they can be executed. This means that the caveats in the eCos FLASH library about disabling interrupts whilst programming do not apply here, except in special cases such as OneNAND devices.

Preparing for deployment

It is generally not recommended to hard-code physical on-NAND locations in case of factory bad blocks or block failures in the field. [1] Instead it is preferable to set up *partitions* on the chip with a generous safety margin and to store data in a location-independent way. This is commonly achieved by placing logical tags in the spare area of each page, or using a log-structured filesystem such as YAFFS. Such strategies remove the dependence on physical addressing, at the cost of increased complexity.

The upshot of this is that you cannot reliably create a simple binary image to bulk-program in the factory. A more complicated programming operation is required to take account of your chip partitions, logical addressing strategy and any bad blocks which may be encountered during write.

[1] Usually the first block is guaranteed to be defect free for a certain number of erase cycles. This tends to be necessary if bootstrapping the CPU off NAND, and is an obvious exception to this rule.

Chapter 54. Using the NAND library

The eCos NAND library exposes two principal APIs: one for applications to use and the other to communicate with device drivers.

Configuring the NAND library

The following configuration options are provided. They affect the library globally, i.e. across all drivers.

`CYGPKG_IO_NAND_CFLAGS_ADD`
`CYGPKG_IO_NAND_CFLAGS_REMOVE`

Allows specific build options to be added to or removed from the CFLAGS list when building this library.

`CYGSEM_IO_NAND_DEBUG`

This is the master switch for all debug reporting from the library.

`CYGSEM_IO_NAND_DEBUG_FN_DEFAULT`

This is the default function that the library will use when sending debugging output. It must behave like `printf`. The default - `cyg_nand_defaultprintf` - is a wrapper to `diag_printf`.

Note

Individual drivers may override this setting in their `devinit` routines by overwriting the pointer in the device struct.

`CYGSEM_IO_NAND_DEBUG_LEVEL`

Specifies the verbosity of the NAND library and device drivers. Ranges from 0 (off) to 9 (incredibly verbose); the default setting is 1. (Higher values are only likely to be of use during driver development, if ever.) When enabled, messages are printed using the per-device printf-like function (see above).

Note

Should a serious problem be encountered it will always be reported the printf-like function, regardless of this setting. Such messages may be suppressed altogether by turning off `CYGSEM_IO_NAND_DEBUG`.

`CYGSEM_IO_NAND_READONLY`

Globally disables all code which writes to NAND devices. This may be useful during driver development.

`CYGNUM_NAND_MAX_PARTITIONS`

Sets a compile-time limit on the number of partitions any NAND device may have. The default is 4, which should be enough for most purposes; unnecessarily setting this higher wastes RAM.

`CYGSEM_IO_NAND_USE_BBT`

Globally enables and disables the use of Bad Block Table.

Warning

This setting should not be disabled lightly! It is strongly recommended that you leave this setting enabled unless you have a very good reason to not use it. It is provided really as a convenience for allowing developers to recover their NAND from a confused state.

The NAND Application API

All of the functions described here are declared in the header file `<cyg/nand/nand.h>`, which should be included by all users of the NAND library.

Note

Most of the functions in the library are declared as returning int. *Unless otherwise stated, all functions return 0 for success, or a negative eCos error code if something went wrong.*

Device initialisation and lookup

NAND devices are identified to the library by name. In many cases there will be only one, commonly named *onboard*, but this flexibility allows for easy expansion later without cross-device confusion.

Note

The naming of NAND devices is set up by the code that instantiates their drivers. Normally this is done by the platform HAL port.

```
 __externC int cyg_nand_lookup(const char *devname, cyg_nand_device **dev_o);
```

On success, *dev_o will be set up to point to a cyg_nand_device struct. On failure, it will not; a return code of `-ENOENT` signifies that the requested device name was not found.

Applications will hardly, if ever, need to access the cyg_nand_device structs directly. The following members and convenience macros are most likely to be of relevance:

```
struct _cyg_nand_device_t {
…
cyg_nand_printf pf; // Diagnostic printf-like function for this device to use. May be changed at runtime.
…
size_t page_bits; // log2 of no of regular bytes per page
size_t spare_per_page; // OOB area size in bytes
size_t block_page_bits; // log2 of no of pages per eraseblock
size_t blockcount_bits; // log2 of number of blocks
size_t chipsize_log; // log2 of total chip size in BYTES.
…
};

#define CYG_NAND_BYTES_PER_PAGE(dev) (1<<(dev)->page_bits)
#define CYG_NAND_SPARE_PER_PAGE(dev) ((dev)->spare_per_page)
#define CYG_NAND_PAGES_PER_BLOCK(dev) (1<<(dev)->block_page_bits)
#define CYG_NAND_BLOCKCOUNT(dev) (1<<(dev)->blockcount_bits)
#define CYG_NAND_PAGECOUNT(dev) (NAND_BLOCKCOUNT(dev) * NAND_PAGES_PER_BLOCK(dev))
#define CYG_NAND_CHIPSIZE(dev) (1<<(dev)->chipsize_log)
#define CYG_NAND_APPSPARE_PER_PAGE(dev) ((dev)->oob->app_size)
#define CYG_NAND_BYTES_PER_BLOCK(dev)   (1<<( (dev)->block_page_bits + (dev)->page_bits ))
```

NAND device addressing

NAND devices are arranged as a series of *pages* and *eraseblocks*. The eCos NAND library numbers pages and eraseblocks sequentially, both starting at 0 and continuing until the end of the chip. For example, eraseblock 0 might contain pages 0 through 63; eraseblock 1, pages 64 through 127; and so on.

Caution

This numbering scheme is independent of the device's addressing scheme. Take care, particularly when erasing blocks; some devices and some applications effectively express the location to erase as a page number (or, in NAND-speak, as the *row address* to erase from).

Warning

Most NAND chip manufacturers document restrictions on the order in which pages may be written to their device. Typically, individual pages within an eraseblock must be written in sequential order starting from the first, and random-order writes are prohibited or unspecified. The eCos NAND library does not attempt to police such restrictions; if at all unsure, check the spec sheet for the part. You have been warned!

NAND devices are widely considered to be arranged as one or more *partitions*, and the eCos NAND library supports this. However, there is no universal scheme for partition sizes to be supplied to the driver, unlike hard drives which encode a partition table into their first sector. Partition arrangements are often implicitly hardcoded, such as by byte address within the device, though they could be encoded in a "partition table", user-set, or even variable under software control by some esoteric rules. Therefore, every device driver is responsible for configuring its partition information as appropriate for the device, and this might for example appear as CDL options.

Tip

Be sure to read the notes associated with the device driver to understand how partitions are set up; if no notes are provided, look in its `devinit` code.

NAND device partitions

After a NAND device has been initialised, its device struct contains a list of partitions. These are numbered from 0 and may go up to `CYGNUM_NAND_MAX_PARTITIONS`-1. Before an application can use the NAND device, it must obtain a partition context (pointer) with the following call:

```
__externC cyg_nand_partition* cyg_nand_get_partition(cyg_nand_device *dev, unsigned partno);
```

Note

This call returns a pointer to the partition struct, not an error code. If the given partition number is inactive or invalid, it returns NULL.

About the spare area

Every page on the NAND array has a small number of "spare" bytes associated with it. These are used by the NAND library to store the page's ECC; whatever is left over may be used by the application for whatever purposes may suit it.

Every page has `CYG_NAND_APPSPARE_PER_PAGE(dev)` bytes of spare area available to the application. (This amount is implicit from the driver configuration and cannot change during the lifetime of a device.)

Note

Application spare bytes are not subject to the ECC. When reading the spare area data, you must be prepared to cope with the consequences of the (unlikely) event of a bit drop-out or other failure.

Manipulating the NAND array

Now, finally, given a cyg_nand_partition*, your application can make use of the NAND array with the following functions:

Reading data

```
__externC int cyg_nand_read_page(cyg_nand_partition  *ctx,
                                 cyg_nand_page_addr  page,
                                 void *              dest,
                                 size_t              size,
                                 void *              spare,
                                 size_t              spare_size);
```

Reads a single page and its spare area. The data read from the chip will be automatically ECC-checked and repaired if necessary. Parameters are as follows:

ctx
: The partition that data is to be read from.

page [1]
: The page to be read, *numbered from the start of the partition*. As a double-check, the library will refuse the operation with `-ENOENT` if this address is not within partition *ctx*.

dest
: Where to put the data. May be NULL, in which case the page data is not read.

size
: The maximum amount of data to read. (In any event, no more than a single page will be read, but if your application knows it doesn't need the whole page, you can place a cap here.)

spare
: Where to store the application data read from the spare area. This may be NULL if spare data is not required.

spare_size
: The maximum number of bytes to read from the spare area. This will not be more than `CYG_NAND_APPSPARE_PER_PAGE(dev)` bytes.

An error response of `-EIO` means that a multiple-bit I/O error has occurred in the page data, which the ECC could not repair. The library stores the data read from the device in `*dest` and `*spare` on a best-effort basis; it should not be relied upon. The application should take steps to salvage what it can and erase the block as soon as possible.

Writing data

```
__externC int cyg_nand_write_page(cyg_nand_partition  *ctx,
                                  cyg_nand_page_addr  page,
                                  const void *        src,
                                  size_t              size,
                                  const void *        spare,
                                  size_t              spare_size);
```

Writes a single page and its spare area. The ECC will be computed and stored automatically. Parameters are as follows:

ctx
: The partition that data is to be written to.

page
: The page to be written, *numbered from the start of the partition*. As a double-check, the library will refuse the operation with `-ENOENT` if this address is not within partition *ctx*.

src
: Where to read the data from. May be NULL, in which case the page data is not written.

size
: The amount of data to write. (In any event, no more than a single page will be written.)

[1] This was changed in application interface v2; earlier page and block addresses were device-relative.

spare
: Where to read the data to go into the spare area; it will automatically be packed around the ECC as necessary. Again, this may be NULL if spare data is not required.

spare_size
: The number of bytes to write to the spare area. This should not be larger than `CYG_NAND_APPSPARE_PER_PAGE(dev)`; if it is, only that many bytes will be stored.

An error response of `-EIO` means that the page write failed. The application should copy out any data it wishes to keep from the rest of the eraseblock, then call `cyg_nand_bbt_markbad()` to put the block beyond use.

Erasing blocks

```
__externC int cyg_nand_erase_block(cyg_nand_partition *ctx, cyg_nand_block_addr blk);
```

ctx
: The partition that data is to be erased from.

blk
: The block to be erased, *numbered from the start of the partition*. As a double-check, the library will refuse the operation with `-ENOENT` if this address is not within partition *ctx*.

An error response of `-EIO` means that the block erase failed. In this case, the library automatically marks the block as bad, and the application need take no further action.

Common error returns

The following common error returns may be encountered when manipulating the NAND array using the above functions:

`-EIO`
: The operation could not be completed due to an I/O error. This may require the application to take further action; check the details provided above for the call you have just made.

`-ENOENT`
: The page or block address was not valid for the given partition.

`-EINVAL`
: The page (block) address was (within) a block that is marked bad.

Ancillary NAND functions

The following functions are provided to allow applications to interact with the Bad Block Table:

```
typedef enum {
    CYG_NAND_BBT_OK=0,
    CYG_NAND_BBT_WORNBAD=1,
    CYG_NAND_BBT_RESERVED=2,
    CYG_NAND_BBT_FACTORY_BAD=3
} cyg_nand_bbt_status_t;

__externC int cyg_nand_bbt_query(cyg_nand_partition *ctx, cyg_nand_block_addr blk);

__externC int cyg_nand_bbt_markbad(cyg_nand_partition *ctx, cyg_nand_block_addr blk);
```

To determine the status of an eraseblock, use `cyg_nand_bbt_query`; this returns an enum from cyg_nand_bbt_status_t or a negative eCos error code. All blocks which return a non-0 enum value are considered inaccessible by applications.

Occasionally, it is necessary for applications to mark a block as bad. This most commonly happens when a write operation fails (see the section called “Writing data” above). To do this, call `cyg_nand_bbt_markbad`; the return is 0 for success, or a negative eCos error code. *As with other calls, blocks are numbered from 0 at the start of the partition, and internally translated for the device as appropriate.*

Both of these calls may foreseeably return `-ENOENT` if the given block address was not valid, or `-EIO` if something awful happened with the on-chip bad block table.

Chapter 55. Writing NAND device drivers

Planning a port

Before you start, you will need to have sight of appropriate spec sheets for both the NAND chip and the board into which it is connected, and you need to know how the chip is to be partitioned.

Driver structure and layout

A typical NAND device driver falls into two parts:

- high-level operations specific to the NAND chip (page reads and writes); and
- board-specific plumbing (sending commands and data to the chip; reading data back from the chip).

This distinction is important in the interests of code reuse; the same part may appear on different boards, or indeed multiple times, but connected differently. It need not be maintained if there are good reasons not to.

The *NAND library device interface* consists of a C struct, cyg_nand_device, comprising a number of data fields and function pointers. Each NAND chip to be made available to the library requires exactly one instance of this struct.

Tip

The cyg_nand_device structure includes a *`void* priv`* member which is treated as opaque. The driver may use this member as it sees fit; it is intended to provide an easy means to identify the NAND array, MMIO addresses or function pointers to use and so on. Typically this is used by the chip driver for its own purposes, and includes a further opaque member for the use of the HAL port.

The function pointers in the struct form the driver's high-level functions; they make use of the low-level functions to talk to the chip. We present the high-level functions first, although there is no intrinsic reason to prefer either ordering during driver development.

The high-level chip-specific functions are traditionally laid out as an *inline file* in an appropriate package in `devs/nand/`*`CHIP`*. The board-specific functions should normally appear in the platform HAL and #include the inline.

Chip partitions

Before embarking on the port, you should determine how the NAND array will be partitioned. This is necessarily a board-specific question, and your layout must accommodate any other software users of the array. You will need to know either the fixed layout - converted to eraseblock addresses - or how to determine the layout at initialisation time.

Tip

It may be worthwhile to set up partitioning by way of some parameters in your platform's CDL, with sensible defaults, instead of outright hard-coding the partition layout.

Locking against concurrent access

The eCos NAND library provides per-device locking, to guard against concurrent access during high-level operations. This support is fully automatic; drivers need take no action to make use of it.

This strategy may not be sufficient on all target boards: sometimes, accessing a NAND chip requires mediation by CPLD or other device, which must be shared with other NAND chips or even other peripherals. *If this applies, it is the responsibility of the driver and platform port to provide further locking as appropriate!*

Tip

When using mutexes in a driver, one should use the *driver API* as defined in `<cyg/hal/drv_api.h>` instead of the full kernel API. This has the useful property that mutex operations are very cheaply implemented when the eCos kernel is not present, such as when operating in RedBoot.

Required CDL declarations

An individual NAND chip driver must declare the largest page size it supports by means of CDL. This is done with a statement like the following in its cdl_package stanza:

```
requires ( CYGNUM_NAND_PAGEBUFFER >= 2048 )
```

Note

This requirement is due to the internal workings of the eCos NAND library: a buffer is required for certain operations which manipulate up to a NAND page worth of data, internally to the library. This is declared once as a global buffer for safety under low-memory conditions; a page may be too big to use temporary storage on the C stack, and the NAND library deliberately avoids the use of `malloc`.

By convention, a driver package would declare `CYGPKG_IO_NAND` as its `parent` and use `cyg/devs/nand` as its `include_dir`, but there is no intrinsic reason why this should be so.

High-level (chip) functions

The high-level functions provided by the chip driver are typically created as an *inline file* providing a fully-populated cyg_nand_dev_fns_v1 struct, instantiated by the CYG_NAND_FUNS macro. The high-level driver should not directly read or write to the hardware itself, but instead call into functions in the low-level driver.

The form the low-level functions should take is not prescribed; typically functions will be required to write commands to the device, to read and write data, and to query any status line which may be present. The high-level driver should normally provide a header file containing prototypes for the functions it requires from the low-level driver. (The low-level source file would provide the low-level functions required, include the high-level include, then instantiate the combined driver using the CYG_NAND_DEVICE macro.)

This source code layout is not intended as a prescription. It would for example be entirely in order to store pointers to the low-level functions in a struct and set *`priv`* to point to that struct, which could be useful in some cases.

Note

The device driver must not call `malloc` or otherwise allocate memory; all data should be in the stack or set as globals. This is because the driver may be required to run within a minimal eCos configuration.

These functions should all return 0 on success, or a negative eCos error code. In the event of an error, do *not* call back into the NAND library; use the NAND_CHATTER macro to report, in case a human is watching, and return an error code. The library will take care of ensuring the correct response to the application and updating the BBT as necessary.

Device initialisation

```
static int my_devinit (cyg_nand_device *dev);
```

The `devinit` function is the most complex, and logically one to write first. It is responsible for:

- initialising the device, typically by sending a reset command;

- interrogating the device to confirm its presence and properties;
- setting up the partition table list (see "Planning a port" above);
- setting up mutexes as necessary (see "Locking against concurrent access" above);
- populating the other members of the cyg_nand_device struct (see below).

Interrogating the device is normally performed by sending a *Read ID* command and examining the result, which typically encodes some or all of the chip parameters.

Given the similarity between many NAND parts, it may be possible to write a generic driver to cover all of one or more manufacturer's parts, or indeed for all ONFI-compliant parts. At the time of writing, this has not yet been attempted.

The `devinit` function must set up the following struct members:

`page_bits`
The size of the regular (non-spare) part of a page, expressed as the logarithm in base 2 of the number of bytes. For example, if pages are 2048 bytes long, *`page_bits`* would be 11. Obviously, the size of a page must be an exact power of two.

`spare_per_page`
The number of bytes of spare area available in each page.

`block_page_bits`
The base-2 log of the number of pages per eraseblock.

`blockcount_bits`
The total number of erase blocks in the device, expressed as a base-2 log.

`chipsize_log`
The total size of the chip, not counting the spare areas. This is required so that the library can double-check that the given parameters make sense by comparing with the preceding fields. Again, this field is itself a base-2 logarithm.

`bbt.data`
Space for the in-memory Bad Block Table for this device.

`bbt.datasize`
This is the size of *`bbt.data`*, in bytes. At present, this should be two bits times the number of blocks in the device; in other words, `1<<(blockcount_bits-2)` bytes.

The cyg_nand_device struct has two further members *`ecc`* and *`oob`* which must be set up to point to the ECC and OOB descriptors to use for the device. This is normally done by the CYG_NAND_DEVICE low-level instantiation macro, so will be better described in that section, but at this level you should be aware that it is also safe to set up the descriptor block during `devinit`. for example if multiple semantics might be you had included logic to detect what semantics to use.

The Bad Block Table itself is implemented in a way which intends to be compatible with the Linux MTD layer. A full parameter struct is not currently provided, though one may be in future.

Reading, writing and erasing data

The read and write operations are divided into three phases, with the following flow:

- Begin. This is called once; the driver should lock any platform-level mutex and send the command and address.
- Stride. This is called one or more times to read the page data from the device.

Note

The reason for this is if the platform provides a NAND controller with hardware ECC: it is often necessary to read out the ECC registers every so often.

- Finish. This is called once; it should read or write the spare area, (on programming) send a "program confirm" command and check its status, and unlock any platform-level mutex.

Erasing is a single-shot call which should lock any platform-specific mutex, send the command, check its status and unlock the mutex.

```
static int my_read_begin(   cyg_nand_device *dev, cyg_nand_page_addr   page);
static int my_read_stride(  cyg_nand_device *dev, void * dest,  size_t size);
static int my_read_finish(  cyg_nand_device *dev, void * spare, size_t spare_size);

static int my_write_begin(  cyg_nand_device *dev, cyg_nand_page_addr  page);
static int my_write_stride( cyg_nand_device *dev, const void * src,   size_t size);
static int my_write_finish( cyg_nand_device *dev, const void * spare, size_t spare_size);

static int my_erase_block(  cyg_nand_device *dev, cyg_nand_block_addr blk);
```

Searching for factory-bad blocks

```
static int my_is_factory_bad(cyg_nand_device *dev, cyg_nand_block_addr blk);
```

The very first time a NAND chip is used, the library has to scan it to check for factory-bad eraseblocks and build up the Bad Block Table. This function is called repeatedly to do so, one block at a time; it should return 1 if the block is marked bad, or 0 if the block appears to be OK.

Typically this function will invoke `read_page`; blocks are usually marked factory-bad by the presence of a particular signature in the out-of-band area of the first or second page of that block.

Warning

It is extremely important that you get this function right; after an eraseblock has been written to, it is no longer possible to reliably determine whether the block was factory-bad. It is never safe to assume that the factory-bad signature for a chip is the same as that of a similarly-sized chip or another by the same manufacturer; *always* check the correct spec sheet for the actual part or part-family in use!

Tip

Because this function is critical and a subtle error could cripple your application some time later in the field when it runs across undetected factory-bad blocks, you might find it handy to have a double-check before proceeding. If you enable CYGSEM_IO_NAND_READONLY in your eCos configuration during early development, you can safely fire up a test application (which calls `cyg_nand_lookup`) whilst watching the chatter output: the scan will be performed, but no BBT will be written. You can then compare the number of bad blocks reported against the manufacturer's specification of the maximum. Double-check that your `is_factory_bad` function is correct before enabling read-write mode!

Declaring the function set

```
CYG_NAND_FUNS_V2(mydev_funs, my_devinit,
        my_read_begin, my_read_stride, my_read_finish,
        my_write_begin, my_write_stride, my_write_finish,
        my_erase_block, my_is_factory_bad);
```

This macro ties the above functions together into a struct whose name is given as its first argument. The name of the resulting struct must be quoted when the driver is formally instantiated, which is normally done by the low-level functions.

Note

Earlier versions of this library used a slightly different device interface, keyed off the macro CYG_NAND_FUNS. This interface has been retired.

Low-level (board) functions

The set and prototypes of the functions required here will necessarily depend on the board and to a lesser extent on the NAND part itself. The following functionality is typically required:

- Very low-level hardware initialisation - for example, GPIO pin direction and interrupt config - if this has not already been done by the platform HAL
- Set up the chip partition table (see below)
- Runtime hardware config as required, such as commanding an FPGA or CPLD to route lines to the NAND part
- Write a command (byte)
- Write an address (handful of bytes)
- Write data, usually at the chip's full bus width (typically 8 or 16 bits)
- Read data at full bus width
- Read data at 8-bit width (if the chip has a 16 bit data bus, some commands - commonly ReadID - may return 8-bit data)
- Poll any status lines required or - if supported - set them up as interrupts to allow sleeping-wait

Talking to the chip

It is impossible to prescribe how to achieve this, as it depends entirely on how the NAND part is wired up on the board.

The ideal situation is that the NAND part is wired in via the CPU's memory controller and that the controller is set up to do most of the hard work for you. In that case, reading and writing the device is as simple as accessing the correct memory-mapped I/O address; usually different address ranges connect to the device's command, address and data registers respectively.

Tip

The HAL provides a number of macros in `<cyg/hal/hal_io.h>` to read and write memory-mapped I/O.

Note

On platforms with an MMU, MMIO may be rerouted to different addresses to those on the board spec sheet. Check the MMU setup in the platform HAL.

On some platforms, you may have to invoke an FPGA or CPLD to be able to talk to the NAND chip. This might typically take the form of a handful of MMIO accesses, but should hopefully be fairly straightforward once you've figured out how the components interrelate.

The worst case is where you have no support from any sort of controller hardware and have to bit-bang GPIO lines to talk to the chip. This is a much more involved process; you have to take great care to get the timings right with carefully tuned delays. The result is usually quite CPU intensive, and could be clock speed sensitive too; you should check for and take account of any CDL settings in the architecture and variant HAL which allow the CPU clock frequency to be changed.

Tip

If your low-level functions take a cyg_nand_device pointer as an argument, you can use its *`priv`* member to hold or point to some relevant data like the MMIO addresses to use, which is preferable to hard-coding them. Indeed, if you wish your board port to support more than one chip, you should use the *`priv`* member to distinguish between them.

Setting up the chip partition table

It is the responsibility of the high-level `devinit` function to set up the device's partition table. (It may be appropriate for it to invoke a low-level function to do this.)

The partition definition is an array of cyg_nand_partition entries in the cyg_nand_device.

```
struct _cyg_nand_partition_t {
    cyg_nand_device *dev;
    cyg_nand_block_addr first;
    cyg_nand_block_addr last;
};
typedef struct _cyg_nand_partition_t cyg_nand_partition;

struct _cyg_nand_device_t {
    …
    cyg_nand_partition partition[CYGNUM_NAND_MAX_PARTITIONS];
    …
};
```

Application-visible partition numbers are simply indexes into this array.

- On a live partition, *`dev`* must point back to the cyg_nand_device containing it. If `NULL`, the partition is inactive.
- *`first`* is the number of the first block of the partition.
- *`last`* is the number of the last block of the partition (*not* the number of blocks, unless the partition starts at block 0).

Putting it all together…

Finally, with everything else in place, we turn to the CYG_NAND_DEVICE macro to instantiate it.

```
CYG_NAND_DEVICE(my_nand, "onboard", &mydev_funs, &my_priv_struct, &linux_mtd_ecc, &nand_mtd_oob_64);
```

In order, the arguments to this macro are:

- The name to give the resultant cyg_nand_device struct;
- the device identifier string, application-visible to be used in `cyg_nand_lookup()` ;
- a pointer to the device high-level function set to use, normally set up by the CYG_NAND_FUNS macro;
- the *`priv`* member to include in the struct;
- a pointer to the ECC semantics block to use. `linux_mtd_ecc` provides software ECC compatible with the Linux MTD layer, but it is strongly recommended to use onboard hardware ecc support if this is present as it gives a huge speed boost. See the section called “ECC implementation” for more details.
- a pointer to the OOB-area layout descriptor to use (see `nand_oob.h` : nand_mtd_oob_16 and nand_mtd_oob_64 are Linux-compatible layouts for devices with 16 and 64 bytes of spare area per page respectively).

The macro invokes the appropriate linker magic to pull all the compiled NAND device structs into one section so the NAND library can find them.

ECC implementation

The use of ECC is strongly recommended with NAND flash parts owing to their tendency to occasionally bit-flip. This is usually done with a variant of a Hamming code which calculates column and line parity. The computed ECC is stored in the spare area of the page to which it relates.

The NAND library automatically computes and stores the ECC of data as it is written to the chip. On read, the code is calculated for the data actually read; this is compared with the stored code and the data repaired if necessary.

The NAND library comes with a software ECC implementation named `linux_mtd_ecc`. This is compatible with the ECC used in the Linux MTD layer, hence its name. It calculates a 3-byte ECC on a 256-byte data block. This algorithm is adequate for most circumstances, but it is strongly recommended to use any hardware ECC support which may be available because of the performance gains it yields. (In testing, we observed that up to two thirds of the time taken by every page read and program call was used in computing ECC in software.)

The ECC interface

This library draws a semantic distinction between *hardware* and *software* ECC implementations.

- A software ECC implementation will typically not require an initialisation step. The calculation function will always be called with a pointer to the data bytes to compute.
- A hardware implementation is assumed to read and act upon the data *as it goes past*. Therefore, it will not be passed a pointer to the data when its `calculate` step is invoked.

An ECC is defined by the following parameters:

- The size of data block it handles, in bytes.
- The size of ECC it calculates on those blocks, in bytes.
- Whether the algorithm is hardware or software.

An ECC algorithm must provide the following functions:

```
/* Initialises an ECC computation. May be NULL if not required. */
void my_ecc_init(struct _cyg_nand_device_t *dev);

/* Returns the ECC for the given data block.
 * If IS_HARDWARE:
 *  - dat and nbytes are ignored
 * If ! IS_HARDWARE:
 *  - dat and nbytes are required
 *  - if nbytes is less than the chunk size, the remainder are
 *    assumed to be 0xff.
 */
void my_ecc_calc(struct _cyg_nand_device_t *dev,
                 const CYG_BYTE *dat, size_t nbytes, CYG_BYTE *ecc);

/* Repairs the ECC for the given data block, if needed.
 * Call this if your read-from-chip ECC doesn't match what you computed
 * over the data block. Both *dat and *ecc_read may be corrected.
 *
 * `nbytes' is the number of bytes we're interested in; if a correction
 * is indicated outside of that range, it will be ignored.
 *
 * Returns:
 *       0 for no errors
 *       1 for a corrected single bit error in the data
 *       2 for a corrected single bit error in the ECC
 *      -1 for an uncorrectable error (more than one bit)
 */
int my_ecc_repair(struct _cyg_nand_device_t *dev,
                  CYG_BYTE *dat, size_t nbytes,
                  CYG_BYTE *ecc_read, const CYG_BYTE *ecc_calc);
```

In some cases - particularly where hardware assistance is in use - it is necessary to specify different functions for calculating the ECC depending on whether the operation at hand is a page read or a page write. In that case, two *init* and *calc* functions may be supplied, each taking the same prototype.

The algorithm parameters and functions are then tied together with one of the following macros:

```
CYG_NAND_ECC_ALG_SW(my_ecc,  _datasize, _eccsize, my_ecc_init, my_ecc_calc, my_ecc_repair);

CYG_NAND_ECC_ALG_HW(my_ecc,  _datasize, _eccsize, my_ecc_init, my_ecc_calc, my_ecc_repair);

CYG_NAND_ECC_ALG_HW2(my_ecc, _datasize, _eccsize, my_ecc_init, my_ecc_calc_read,
                     my_ecc_calc_write, my_ecc_repair);

CYG_NAND_ECC_ALG_HW3(my_ecc, _datasize, _eccsize, my_ecc_init_read, my_ecc_init_write,
                     my_ecc_calc_read,  my_ecc_calc_write,    my_ecc_repair);
```

Tip

It's OK to use software ECC while getting things going, but if you do then switch to a hardware implementation, you probably need to erase your entire NAND chip including its Bad Block Table. The `nanderase` utility may come in handy for this.)

Warning

You must be sure that your ECC repair algorithm is correct. This can be quite tricky to test. However, it is often possible to hoodwink the controller into computing ECCs for you even if the data is not going to affect the data stored on the NAND chip, for example if you send it data but haven't told it to program a page. A variant of the `sweccwalk` test may come in handy for this purpose.

An example implementation, including an ECC calculation and repair test named `eccwalk`, may be found in the STM3210E evaluation board platform HAL, `packages/hal/cortexm/stm32/stm3210e_eval`. The chip NAND controller has on-board ECC calculation, but does not undertake to repair data; a repair function was written specially.

Chapter 56. Tests and utilities

Unit and functional tests

The NAND library includes a number of tests. The most useful to driver writers are `readwrite`, `rwbenchmark` and `sweccwalk`; the others are only likely to be of interest to library maintainers.

readwrite

Performs a read-write-erase cycle on the first NAND device it finds, checking that its operations have had the expected effect on the device contents. This is a potentially destructive test; do not run it on a device containing data you care about!

rwbenchmark

A more involved version of `readwrite`, this is a timing test which performs multiple reads, writes and erases and applies statistical techniques to the results in the same way that `tm_basic` instruments the speed of various eCos kernel functions. *This is a potentially destructive test; do not run it on a device containing data you care about!*

sweccwalk

Repeatedly makes single-bit changes to a data buffer and checks that the software ECC implementation correctly repairs them.

Tip

This test can be adapted to test out hardware ECC implementations. The test outputs the raw ECC codes as it goes, which is useful in confirming that the bits in the computed ECC are what you think they are.

nandunit

Some unit tests which do not require any NAND device: ECC known answer vectors, and OOB area packing/unpacking correctness.

readlimits

Attempts to read a block outside of a partition, confirming that it doesn't work.

There are some further tests of the library which require the synthetic NAND device.

Ancillary NAND utilities

The following utilities are included with the NAND library. They are standalone eCos applications; for convenience, you can set `CYGBLD_IO_NAND_BUILD_UTILS` in your eCos configuration and they will be built and placed into `install/tests/io/nand/current/utils`.

Warning

It is particularly dangerous to run the utility `erase_bbt_dangerous.c` on a production device, as it is generally not possible to later reconstruct the list of factory-bad blocks. It is intended only as an aid to driver authors.

erasenand.c

Loops over all the blocks of a partition, erasing all the blocks [1] which are not marked as bad. The device and partition to erase are set by #define.

erase_bbt_dangerous.c[2]

Erases the NAND blocks comprising the primary and mirror bad-block tables of a device. The device to erase is set by #define. (The tables are detected by the library in the usual way. If

[1] This will not normally erase the Bad Block Table. This is because the BBT reports its own blocks as "Reserved" when queried via `cyg_nand_bbt_query`, which makes them inaccessible to applications. However, if `CYGSEM_IO_NAND_USE_BBT` is turned off, then any BBT present will not be detected and hence will be erased.

[2] Note the warning regarding running this on a production device

none are present, the library will scan the device for factory-bad blocks to create such a table, then this code will immediately erase it.)

Chapter 57. The eCos configuration store

Overview

The eCos configuration store is a simple typed key/value store which uses NAND flash for its persistent storage.

The library is aimed at applications that wish to store simple configuration data without the overhead of a fully NAND-aware filesystem. It is also used by RedBoot to store persistent configuration data.

The following functionality is provided:

- Write data
- Read data
- Erase individual data items
- List and dump out store keys and contents (for debugging)

Design limitations

- The data which may be stored is limited to a total of one NAND block, including the store's internal metadata.
- The store is designed to be robust but simple. It is not expected to scale well; if there are a great many items in the store, read access will be slow.
- The entire store is rewritten on every write; this means that write access to a busy store will similarly be slow.
- The store is NAND-aware and incorporates simple wear-levelling logic but excessive numbers of writes will still risk burning out the NAND array. If the store is allocated only a small number of NAND blocks, this will exacerbate the effect. It is recommended to allow a reasonable number of blocks (5-10) to allow for blocks wearing out over the lifetime of the device.
- Only simple locking is used to prevent corruption; all config store operations block until they are able to secure the protecting mutex.

Using the config store

The main entry points to the config store logic are as follows:

```
/* From <cyg/configstore/write.h>.
 * These functions write out a key, overwriting it if it is already there.
 * They return 0 for success or a negative errno value; see the header
 * file for details.
 */
externC
int cyg_configstore_write_int(const char *key, cyg_uint32 i);
externC
int cyg_configstore_write_bool(const char *key, cyg_bool b);
externC
int cyg_configstore_write_bytes(const char *key, void *src, cyg_uint32 len);
externC
int cyg_configstore_write_string(const char *key, const char *data);

/* Erases a single key */
externC
int cyg_configstore_erase_keystr(const char *key);
```

```
/* From <cyg/configstore/read.h>.
 * These functions read out a key or header.
 * They return 0 for success or a negative errno value; see the header
 * file for details. */

externC
int cyg_configstore_read_int(const char *key, cyg_uint32 *i);
externC
int cyg_configstore_read_bool(const char *key, cyg_bool *b);

/* Note:
* For bytes and strings, check *len_io after read to see the actual number
* of bytes read, INCLUDING the trailing NUL. */
externC
int cyg_configstore_read_bytes(const char *key, CYG_BYTE *buf, unsigned *len_io);
externC
int cyg_configstore_read_string(const char *key, char *buf, unsigned *len_io);

/* Reading out only the header allows you to check a key's type and size. */
externC
int cyg_configstore_read_header(const char *key, cyg_configstore_header_t *hdr);
```

```
/* From <cyg/configstore/util.h>. */

/* Lists all keys in the store (to diag_printf).
 * Not really machine-readable; intended for human-read debugging. */
externC
void cyg_configstore_list(void);

/* Dumps out everything in the store (to diag_printf).
 * Intended for human-read debugging.
 * NOTE: This may emit large amounts of output, which may
 * take an excessive length of time over a slow debug channel. */
externC
void cyg_configstore_dump(void);
```

For more details of the types and structures used, refer to `<cyg/configstore/serialise.h>` and `<cyg/configstore/record.h>` .

Note

Both store keys, and strings in the store, should not contain the ASCII NUL (0x00) character. Behaviour in this case is undefined.

Locking

The config store uses mutexes in order to prevent corruption by concurrent access. If `CYGPKG_KERNEL` is loaded in your eCos configuration, the config store automatically inherits the configured mutex behaviour.

Configuration

If the NAND array reports an error when writing or erasing a block, the config store will automatically retry the operation, up to `CYGNUM_CONFIG_STORE_RETRIES` times. The default setting is 3 retries.

The config store is allocated a single NAND partition. The device and partition are configured by the CDL options `CYGDAT_CONFIG_STORE_DEVICE` and `CYGNUM_CONFIG_STORE_PARTITION.` Normally `CYGDAT_CONFIG_STORE_DEVICE` is set by the platform HAL; `CYGNUM_CONFIG_STORE_PARTITION` may also be hard-wired, if RedBoot or other boot loader needs it.

To configure partition sizes, refer to the eCos HAL documents for your platform. It is recommended to allow a reasonable number of blocks (5-10) for the config store, in order to allow for blocks wearing out over the lifetime of the device.

Caution

1. If the config store is to be shared between multiple clients - for example, RedBoot and an application - the partition geometry must be configured identically to both of them. Be aware that changing the geometry in CDL will not update RedBoot unless you also reconfigure, rebuild and reflash it!
2. If other applications write other data to the NAND array, care should be taken to not overwrite the config store. It is recommended to give them their own partition.

Storage details

The config store uses a single NAND block, conceptually contiguous from its component NAND pages but of course read and written a single page at a time.

The data block has the following contents:

- Magic number `CYG_CONFIGSTORE_MAGIC_HEADER` .
- Block serial number. These allow us to detect old versions and automatically clean them up. Serial Number Arithmetic (RFC1982) is used to compare.
- Zero or more records, each introduced by the magic number `CYG_CONFIGSTORE_MAGIC_RECORD.`
- Magic number `CYG_CONFIGSTORE_MAGIC_FOOTER` . This allows us to detect an incompletely-written block.

Every page written by the config store also contains magic numbers `CYG_CONFIGSTORE_ECOS_TAG` and `CYG_CONFIGSTORE_MAGIC_TAG` in the out-of-band (spare) area identifying it as belonging to the store. This allows us to attempt to be a tolerant neighbour and not erase data that appears to belong to another (possibly misconfigured) client of the NAND array.

Each record has the following contents:

- The key. This is a null-terminated string to the user, though the null is *not* stored on NAND. This is stored in the same way as a string (see below).
- The record type. This is one of Integer, Boolean, String or Bytes.
- The length of the data.
- The length of the data including padding.
- The data itself.
- Any padding required (see below).

Padding

Everything written is padded to the nearest 4-octet boundary.

- Integers are always stored unsigned as 4 octets in host byte order.
- Booleans are stored as integers with 1 mapping to True and 0 to False.
- Strings and Bytes are stored as a tuple (data length, data, padding). The difference is that strings are null-terminated in RAM; the trailing null is stripped on write and restored on read.

Scanning

On every access, both read and write, the config block is scanned for consistency. Any obsoleted or incompletely-written blocks are automatically erased. When writing, the old block is only erased once the new block has been completely written.

Part XVI. NAND Device Drivers

Table of Contents

Chapter 58. Samsung K9 family NAND chips

Overview

The `CYGPKG_DEVS_NAND_SAMSUNG_K9` driver package currently provides support for the Samsung K9F1G08, K9F2G08 and K9F1208 series of NAND flash chips, and is intended to be expanded to provide support for more of the K9 family.

Most users will not need to interact with this package; it should be included as a hardware dependency on all appropriate targets. This package provides only an inline code fragment which is intended to be instantiated by the target platform HAL and provided with appropriate board-specific low-level functions allowing it to access the hardware.

Notes

1. The large-page parts in this family are not quite ONFI-compliant, but this code could probably be extended to a much wider set of chips - or indeed to the ONFI specification - without too much trouble. Appropriate definitions will be required for the chip identifier, decoding of the Read ID response, and the chip's blockcount-bits and device-size fields.
2. At the present time, this driver has the limitation that it only supports 8-bit parts. This is an area of probable future expansion.

Using this driver in a board port

This driver's top-level chip support is currently provided as two files:

`cyg/devs/nand/k9_generic.h`
: Prototypes the low-level chip access functions required by the chip driver and declares a private struct for use by the driver.

`cyg/devs/nand/k9_generic.inl`
: Implements high-level chip functions and exposes them via the `CYG_NAND_FUNS` macro. This file is not intended to be compiled on its own, but to be included by the source file in a platform HAL which implements the low-level functions.

A platform HAL would typically make use of this driver in a single source file with the following steps:

- Declare a local private struct with contents as appropriate,
- `#include <cyg/devs/nand/k9_generic.h>`
- implement the required low-level functions,
- `#include <cyg/devs/nand/k9_generic.inl>`
- declare a list of the supported `k9_subtype` which may appear on the board, terminated by `K9_SUBTYPE_SENTINEL`
- declare a static instance of the `k9_priv` struct containing pointers to that list and to an instance of the local-private struct
- finally, instantiate the chip with the `CYG_NAND_DEVICE` macro, selecting the ECC and OOB semantics to use.

Note

If there is more than one chip on the board, each needs its own CYG_NAND_DEVICE with a distinct name and device name, its own instance of the k9_priv struct.

For more details about the infrastructure provided by the NAND layer and the semantics it expects of the chip driver, refer to Chapter 53, *eCos NAND Flash Library*. An example driver instantiation can be found in the NAND driver for the EA LPC2468 platform.

Memory usage

As discussed in the section called “High-level (chip) functions”, the chip initialisation function must set up the `bbt.data` pointer in the cyg_nand_device struct. This driver does so by including a large byte array in the k9_priv struct whose size is controlled by CDL depending on the enabled chip support. That struct is intended to be allocated as a static struct in the data or BSS segment (one per chip), which avoids adding a dependency on `malloc`.

Low-level functions required from the platform HAL

These functions are prototyped in `k9_generic.h`. They have no return value ("void"), except for `read_data_1` which returns the byte it has read.

`write_cmd(device, command)`
: Writes a single command byte to the chip's command latch.

`write_addrbytes(device, pointer to bytes, number of bytes)`
: Writes a number of address bytes in turn to the chip's address latch.

`CYG_BYTE read_data_1(device)`, `read_data_bulk(device, output pointer, number of bytes)`
: Reads data from the device, respectively a single byte and in bulk.

`write_data_1(device, byte)`, `write_data_bulk(device, data pointer, number of bytes)`
: Writes data to the device, respectively a single byte and in bulk.

`wait_ready_or_time(device, initial delay, fallback time)`
: Wait for the chip to signal READY line or, if this line is not available, fall back to a worst-case time delay (measured in microseconds).

`wait_ready_or_status(device, mask)`
: Wait for the chip to signal READY line or, if this line is not available, enter a loop waiting for its Status register (ANDed with the given mask) to be non-zero.

`k9_devlock(device)`, `k9_devunlock(device)`
: Hooks for any board-specific locking which may be required in addition to the NAND library's chip-level locking. (This would be useful if, for example, access to multiple chips was mediated by a single set of GPIO lines which ought not to be invoked concurrently.)

`k9_plf_init(device)`
: Board-level platform initialisation hook. This is called very early on in the chip initialisation routine; it should set up any locking required by the devlock and devunlock functions, interrupts for the driver and any further lines required to access the chip as approprate. *Once this has returned, the chip driver assumes that the platform is fully prepared for it to call the other chip access functions.*

`k9_plf_partition_setup(device)`
: Board-level partition initialisation hook. This should set up the `partition` array of the device struct in a way which is appropriate to the platform. For example, the partitions may be set as fixed ranges of blocks, or by CDL. This is called at the end of the chip initialisation routine and may, for example, call into the chip to read out a "partition table" if one is present on the board. *If you do not set up partitions, applications will not be able to use the high-level chip access functions provided the NAND library.*

Chapter 59. ST Microelectronics NANDxxxx3a chips

Overview

The CYGPKG_DEVS_NAND_ST_NANDXXXX3A driver package provides support for the NANDxxxx3A chip family by ST Microelectronics.

Most users will only need to add this package to their eCos configuration and not need to interact with it further. This package provides only an inline code fragment which is intended to be instantiated by the target platform HAL and provided with appropriate board-specific low-level functions allowing it to access the hardware.

Using this driver in a board port

This driver's chip support is currently provided as two files:

cyg/devs/nand/nandxxxx3a.h
: Prototypes the low-level chip access functions required by the chip driver, declares a private struct for use by the driver and provides a NANDXXXX3A_DEVICE macro for convenience.

cyg/devs/nand/nandxxxx3a.inl
: Implements high-level chip functions and exposes them via the CYG_NAND_FUNS macro. This file is not intended to be compiled on its own.

A platform HAL would typically make use of this driver in a single source file with the following steps:

- Declare a private struct and one or more static instances of it as appropriate,
- #include <cyg/devs/nand/nandxxxx3a.h>
- implement the required low-level functions,
- #include <cyg/devs/nand/nandxxxx3a.inl>
- finally, instantiate the chip with the NANDXXXX3A_DEVICE macro the appropriate number of times, giving each chip an appropriate name and its own private struct if need be, declaring its size, and selecting the ECC and OOB semantics to use.

For more details about the infrastructure provided by the NAND layer and the semantics it expects of the chip driver, refer to Chapter 53, *eCos NAND Flash Library*. An example driver instantiation can be found in the platform HAL for the STM3210E-EVAL board.

Memory usage note

As discussed in the section called “High-level (chip) functions”, the chip initialisation function must set up the bbt.data pointer in the cyg_nand_device struct. This driver does so by including pointer to a sufficiently large byte array in the nandxxx3a_priv struct. That struct is intended to be allocated as a static struct in the data or BSS segment (one per chip), which avoids adding a dependency on malloc.

Low-level functions required from the platform HAL

These functions are prototyped in nandxxxx3a.h. They have no return value ("void"), except where indicated.

`write_cmd(device,command)`
: Writes a single command byte to the chip's command latch.

`write_addrbytes(device, pointer to bytes, number of bytes)`
: Writes a number of address bytes in turn to the chip's address latch.

CYG_BYTE`read_data_1(device)`, `read_data_bulk(device, output pointer, number of bytes)`
: Reads data from the device, respectively a single byte and in bulk.

`write_data_1(device, byte)`, `write_data_bulk(device, data pointer, number of bytes)`
: Writes data to the device, respectively a single byte and in bulk.

`wait_ready_or_time(device, initial delay, fallback time)`
: Wait for the chip to signal READY or, if this line is not available, fall back to a worst-case time delay (measured in microseconds).

`wait_ready_or_status(device, mask)`
: Wait for the chip to signal READY or, if this line is not available, enter a loop waiting for its Status register (ANDed with the given mask) to be non-zero.

`nandxxxx3a_devlock(device)`, `nandxxxx3a_devunlock(device)`
: Hooks for any board-specific locking which may be required in addition to the NAND library's chip-level locking. (This would be useful if, for example, access to multiple chips was mediated by a single set of GPIO lines which ought not to be invoked concurrently.)

int `nandxxxx3a_plf_init(device)`
: Board-level platform initialisation hook. This is called very early on in the chip initialisation routine; it should set up any locking required by the devlock and devunlock functions, interrupts for the driver and any further lines required to access the chip as approprate. *Once this has returned, the chip driver assumes that the platform is fully prepared for it to call the other chip access functions.*

int `nandxxxx3a_plf_partition_setup(device)`
: Board-level partition initialisation hook. This should set up the `partition` array of the device struct in a way which is appropriate to the platform. For example, the partitions may be set as fixed ranges of blocks, or by CDL. This is called at the end of the chip initialisation routine and may, for example, call into the chip to read out a "partition table" if one is present on the board. *If you do not set up partitions, applications will not be able to use the high-level chip access functions provided the NAND library.*

Chapter 60. Micron MT29F family NAND chips

Overview

The CYGPKG_DEVS_NAND_MICRON_MT29F driver package currently provides support for the Micron MT29F2G08 NAND flash chip, and is intended to be expanded to provide support for more of the MT29F family.

Most users will not need to interact with this package; it should be included as a hardware dependency on all appropriate targets. This package provides only inline code fragments which are intended to be included and instantiated by the target platform HAL and provided with appropriate board-specific low-level functions allowing it to access the hardware.

Notes

1. The large-page parts in this family are not quite ONFI-compliant, but this code could probably be extended to a much wider set of chips - or indeed to the ONFI specification - without too much trouble. Appropriate definitions will be required for the chip identifier, decoding of the Read ID response, and the chip's blockcount-bits and device-size fields.

2. At the present time, this driver has the limitation that it only supports 8-bit parts. This is an area of probable future expansion.

Using this driver in a board port

This driver's top-level chip support is currently provided as three files:

`cyg/devs/nand/mt29f_generic.h`
: Prototypes the low-level chip access functions required by the chip driver and declares a private struct for use by the driver.

`cyg/devs/nand/mt29f_generic.inl`
: Implements high-level chip functions and includes mt29f_generic_lp.inl. This file is not intended to be compiled on its own, but to be included by the source file in a platform HAL which implements the low-level functions.

`cyg/devs/nand/mt29f_generic_lp.inl`
: Implements those high-level chip functions which are specific to large-page chips, completing the driver and exposing it via the CYG_NAND_FUNS macro. This file is not intended to be compiled or included directly by platform code.

A platform HAL would typically make use of this driver in a single source file with the following steps:

- Declare a local private struct with contents as appropriate,
- `#include <cyg/devs/nand/mt29f_generic.h>`
- implement the required low-level functions,
- `#include <cyg/devs/nand/mt29f_generic.inl>`
- declare a list of the supported `mt29f_subtype` which may appear on the board, terminated by `MT29F_SUBTYPE_SENTINEL`
- declare a static instance of the `mt29f_priv` struct containing pointers to that list and to an instance of the local-private struct
- finally, instantiate the chip with the `CYG_NAND_DEVICE` macro, selecting the ECC and OOB semantics to use.

Note

If there is more than one chip available on the board, each needs its own CYG_NAND_DEVICE with a distinct name and device name, its own instance of the mt29f_priv struct.

For more details about the infrastructure provided by the NAND layer and the semantics it expects of the chip driver, refer to Chapter 53, *eCos NAND Flash Library*.

Memory usage

As discussed in the section called “High-level (chip) functions”, the chip initialisation function must set up the `bbt.data` pointer in the cyg_nand_device struct. This driver does so by including a large byte array in the mt29f_priv struct whose size is controlled by CDL depending on the enabled chip support. That struct is intended to be allocated as a static struct in the data or BSS segment (one per chip), which avoids adding a dependency on `malloc`.

Low-level functions required from the platform HAL

These functions are prototyped in `mt29f_generic.h`. They have no return value ("void"), except for `read_data_1` which returns the byte it has read.

`write_cmd(device, command)`
: Writes a single command byte to the chip's command latch.

`write_addrbytes(device, pointer to bytes, number of bytes)`
: Writes a number of address bytes in turn to the chip's address latch.

`CYG_BYTE read_data_1(device)`, `read_data_bulk(device, output pointer, number of bytes)`
: Reads data from the device, respectively a single byte and in bulk.

`write_data_1(device, byte)`, `write_data_bulk(device, data pointer, number of bytes)`
: Writes data to the device, respectively a single byte and in bulk.

`wait_ready_or_time(device, initial delay, fallback time)`
: Wait for the chip to signal READY line or, if this line is not available, fall back to a worst-case time delay (measured in microseconds).

`wait_ready_or_status(device, mask)`
: Wait for the chip to signal READY line or, if this line is not available, enter a loop waiting for its Status register (ANDed with the given mask) to be non-zero.

`mt29f_devlock(device)`, `mt29f_devunlock(device)`
: Hooks for any board-specific locking which may be required in addition to the NAND library's chip-level locking. (This would be useful if, for example, access to multiple chips was mediated by a single set of GPIO lines which ought not to be invoked concurrently.)

`mt29f_plf_init(device)`
: Board-level platform initialisation hook. This is called very early on in the chip initialisation routine; it should set up any locking required by the devlock and devunlock functions, interrupts for the driver and any further lines required to access the chip as appropriate. *Once this has returned, the chip driver assumes that the platform is fully prepared for it to call the other chip access functions.*

`mt29f_plf_partition_setup(device)`
: Board-level partition initialisation hook. This should set up the `partition` array of the device struct in a way which is appropriate to the platform. For example, the partitions may be set as fixed ranges of blocks, or by CDL. This is called at the

end of the chip initialisation routine and may, for example, call into the chip to read out a "partition table" if one is present on the board. *If you do not set up partitions, applications will not be able to use the high-level chip access functions provided the NAND library*.

Name

Synthetic Target NAND Flash Device — Emulate NAND flash hardware in the synthetic target

Overview

The device driver `CYGPKG_DEVS_NAND_SYNTH` emulates NAND flash hardware inside the eCos synthetic target. In addition it provides a number of debug facilities which cannot readily be implemented on real embedded hardware, including:

1. The emulated NAND contents are held on a file in the Linux host. This makes it easy to archive and restore NAND images, allowing test runs to be repeated with the exact same state each time.
2. The device driver can log details of all NAND I/O to a separate logfile in the Linux host. This makes it easier to work out exactly what is happening in the application, and more importantly it can help with figuring out what went wrong when. For extended runs it is possible to limit the disk space used for logging. It is also possible to generate checkpoints, where the current NAND image is saved to a separate file.
3. It is possible to inject bad blocks at run-time, to check how the application would cope on real hardware if and when a NAND erase block developed a fault. These can be made to affect random blocks or specific blocks, for example ones holding filesystem metadata.

Some of the functionality is always available and uses compile-time configuration via CDL. This allows applications to be run stand-alone. The more advanced functionality such as logging and bad block injection is only available when running in conjunction with the synthetic target I/O auxiliary, when *`--io`* is used on the command line. The settings for logging and bad block injection usually come from the `default.tdf` target definition file. These can be changed on a per-run basis by adding *`--nanddebug`* to the command line, which will cause a suitable dialog box to pop up during NAND driver initialization.

Compile-time Configuration

This package `CYGPKG_DEVS_NAND_SYNTH` will automatically be loaded when creating a new eCos configuration for the Linux synthetic target. However the package will be inactive until the generic NAND support is added to the configuration.

The synthetic target NAND driver has been designed to be functional both when running stand-alone and when used with the I/O auxiliary. Hence some of the basic parameters of the emulated NAND device must be specified at compile-time, and this is handled via CDL configuration options.

`CYGDAT_NAND_SYNTH_FILENAME` specifies the host-side file that will be used to hold the NAND data. The default is `synth_nand.dat` in the current directory. If the file does not exist then the driver will create it during initialization. All data in a newly-created image file will be set to 0xFF, corresponding to an erased device. Hence deleting the current image file makes it possible to start a test run with a blank NAND device.

A NAND device consists of some number of erase blocks: erase operations affect all data in an erase block. Erase blocks are made up of some number of pages, and write operations typically affect a page at a time. Each page consists of a main data block plus some spare bytes, also known as out of band or OOB data. There are four CDL configuration options controlling the size and layout of the emulated flash device: `CYGNUM_NAND_SYNTH_BLOCK_COUNT`, `CYGNUM_NAND_SYNTH_PAGES_PER_BLOCK`, `CYGNUM_NAND_SYNTH_PAGESIZE`, and `CYGNUM_NAND_SYNTH_SPARE_PER_PAGE`. The default settings are 1024 erase blocks, 32 pages per block, 2K of data per page, and 64 bytes of OOB data per page. This gives an emulated device size of 64MB plus 2M OOB.

The size and layout parameters are encoded in each NAND image file. If these configuration options are changed then existing image files will be incompatible and the device driver will report a fatal error at run-time. This avoids compatibility problems with higher-level code: if a file system has formatted the NAND device for a 2K page size then it is likely to get very confused if the page size suddenly changes to 512 bytes.

The NAND device can be partitioned manually by enabling the component `CYGSEM_DEVS_NAND_SYNTH_PARTITION_MANUAL_CONFIG` and manipulating the options below this. The default is for a single partition occupying the entire NAND device.

Option CYGSEM_NAND_SYNTH_RANDOMLY_LOSE activates code in the driver which triggers frequent bit errors during read operations. These should be handled by error correcting codes within the generic NAND layer so should be transparent to higher-level code. The option exists mainly as an easy way of testing the automatic error correction support.

Run-time Customization

Logging and bad block injection are controlled by run-time customization via the synthetic target I/O auxiliary, not by compile-time CDL options. This allows the same test executable to be run with and without logging or with different sequences of injected bad blocks. If the executable is run without the I/O auxiliary, without the *--io* command line option, then both logging and bad block injection will be disabled.

The main way of customizing both logging and bad block injection is via the target definition file, usually default.tdf. The driver comes with a file nand.tdf holding the various options and explanatory text. This file should be incorporated into default.tdf and edited as appropriate. Note that all NAND-related settings should be inside a synth_device nand section.

Logging

The target definition file settings related to logging are as follows:

```
logfile             "/tmp/synthnand.log"
log                 read write erase error
max_logfile_size    16M
number_of_logfiles  4
generate_checkpoint_images
```

The logfile setting controls the location of the logfile. The default is to add a suffix .log to the CYGDAT_NAND_SYNTH_FILENAME setting, thus creating logfiles in the same directory as the NAND image file.

The log setting specifies which events should be logged. It is followed by a list of some or all of the following: read, READ, write, WRITE, erase, and error. read logs all calls to the driver's page read function, but not the data actually read. READ is like read but logs the actual data as well as the event. Similarly write and WRITE log calls to the driver's page write function, without or with the data being written. erase logs calls to the driver's block erase function. error logs any bad block injection events.

Logging can quickly generate very large files, especially when READ or WRITE debugging is enabled. This can have unfortunate side effects, for example an overnight stress test can fail because the logfile has filled all available disk space. To avoid this it is possible to limit the size of each logfile using the max_logfile_size setting. This is simply a number followed by a unit K, M or G.

When max_logfile_size is exceeded the NAND driver takes appropriate action. The default behaviour is just to delete the current logfile and create a new one, with the same name as before. This can be unfortunate if some particularly interesting event happened just before the maximum logfile size was exceeded because all logging information related to that event will have been lost. To avoid this it is possible to have multiple logfiles, limited by the number_of_logfiles setting. Assume a logfile name of /tmp/synthnand.log, a maximum logfile size of 16M and four logfiles. After the first 16MB of logging data has been written to /tmp/synthnand.log that file will be renamed to /tmp/synthnand.log.0 and a new current logfile /tmp/synthnand.log will be created. After another 16MB the current logfile will be renamed to /tmp/synthnand.log.1, and so on. After 64MB the maximum allowed number of logfiles has been created, so /tmp/synthnand.log.0 will be deleted and then /tmp/synthnand.log will be renamed to /tmp/synthnand.log.3. Hence the maximum disk space used will be between 48MB and 64MB, plus a small amount of overflow for each logfile. All logfiles are in plain text, one event per line, and a single event will not be spread over multiple logfiles.

In addition to the logfiles the NAND driver will generate image checkpoint files if generate_checkpoint_images is enabled. At the start of the test run the driver will copy the current NAND image to a new file /tmp/synthnand.log.checkpoint, using the same base filename as for logfiles. If support for multiple logfiles is enabled then the current checkpoint file will be renamed in the same way and at the same time as the current logfile, and a new checkpoint file will be created using the current image data. Hence for any logfile it is possible to examine both the starting image and the final image (which may be the current one).

Bad Block Injection

There are two settings related to bad block injection: `factory_bad` and `inject`. The former is straightforward:

```
factory_bad 17 42 256 1019
```

This setting is used only when the NAND image file does not yet exist and the driver has to create a new one. The specified erase blocks are marked as factory-bad and hence unusable. The setting consists simply of one or more numbers, each in the range 0 to `CYGNUM_NAND_SYNTH_BLOCK_COUNT-1`. A maximum of 32 blocks can be marked factory bad.

Bad block injection is rather more complicated, in an attempt to make it sufficiently flexible for a variety of uses. The target definition file can contain one or more `inject` settings. There is a limit of eight erase definitions and eight write definitions, giving a maximum of sixteen bad block injection definitions. However some of these can use `repeat`, so the number of bad blocks injected during a test run is limited only by the size of the emulated device. Example settings are:

```
inject erase current after rand% 1024 erases
inject write current after rand% 100000 calls repeat
inject erase block 1 after 3 block_erases
inject write page 9860 after 1000 writes
```

The `inject` keyword should be followed by either `erase` or `write`. If `erase` then the bad block injection happens during a call to the driver's erase function, otherwise it happens during a call to write. This is followed by a block or page definition, the keyword `after`, an event counter, and a couple of optional flags.

The simplest block or page definition is the keyword `current`. This simply means that whichever block is being erased, or whichever block contains the page being written, will be marked bad. Typically this will be used for injecting random faults. If a given block is the subject of an above-average number of erase or write operations then it is more likely to be the current block in one of these definitions, so heavily-used blocks are more likely to fail.

The alternative to `current` is to list a specific block for an erase definition, or a specific page for a write definition. Blocks go from 0 to `CYGNUM_NAND_SYNTH_BLOCK_COUNT` - 1. Pages go from 0 to (`CYGNUM_NAND_SYNTH_BLOCK_COUNT * CYGNUM_NAND_SYNTH_PAGES_PER_BLOCK`) - 1. This can be particularly useful when testing higher-level code that uses certain blocks specially, for example for storing filesystem metadata. It can also be useful when attempting to repeat a test run using information from a logfile.

The fields immediately following the `after` keyword specify when the bad block injection should trigger. They consist of the optional keyword `rand%`, a count, and an event identifier. If `rand%` is not specified then exactly the specified number of events must occur before the bad block injection triggers. Otherwise some number between 0 and count-1 events must occur. The event identifier can be one of `erases`, `writes`, `calls`, `block_erases`, or `page_writes`. `erases` means the number of calls to the driver's block erase function. `writes` means the number of calls to the page write function. `calls` means the total number of read, write or erase calls. `block_erases` means erase calls for a specific block. Similarly `page_writes` means write calls for a specific page. `block_erases` and `page_writes` cannot be used together with `current`, only with a specific block or page.

So, consider the first example again:

```
inject erase current after rand% 1024 erases
```

The driver will calculate a random number between 0 and 1023, say 427. Once there have been at least 427 erase calls the bad block injection will trigger. Since the definition is for erase current, the injection can happen immediately. Hence whichever block is specified during the 427th erase call will be marked bad and that erase call will fail with error code `EIO`.

Suppose that the definition used `write current` instead of `erase current`. The definition will still trigger during erase call 427, but it will not take effect immediately. Instead whichever page is the subject of the next write operation will be marked bad. Alternatively, suppose that the definition was for `erase block 42` but call 427 was for block 512 instead. If some time after call 427 there was another erase call for block 42, that later erase call will fail and cause the block to be marked bad.

Now consider the next definition:

```
inject write current after rand% 100000 calls repeat
```

This event will trigger after between 0 and 99999 calls into the driver. These calls can be reads, writes, or erases. If the triggering call is a write then the block affected will be the one containing the page being written. Otherwise whichever page is the subject of the next write operation will be the one affected.

```
inject erase block 1 after 3 block_erases
```

This definition will only ever affect block 1. The first two calls to erase block 1 will succeed. The third call will fail. Erase calls for any other block have no effect on this definition.

```
inject write page 9860 after 1000 writes
```

This definition will only ever affect page 9860. The definition will trigger after 1000 writes to any page. If the thousandth write happens to be for page 9860, it will fail. Otherwise the next write for page 9860 will fail, whenever that happens. If the definition specified event type `page_writes` instead of `writes` it would trigger only after 1000 writes to page 9860 instead of 1000 writes to any page.

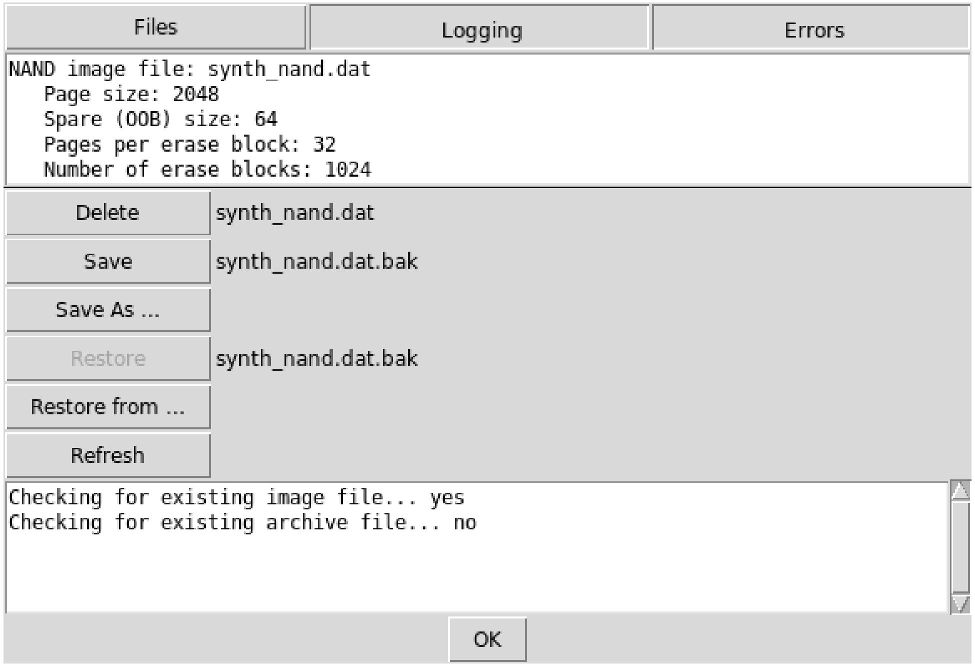
Trigger definitions can be followed by two optional keywords. The first is `repeat` and indicates that the definition should trigger multiple times, not just once. `repeat` can only be used for block or page `current`, not for a specific block or page, since any given block can only fail once. The second keyword is `disabled`. This can be used to create a bad block injection definition which is not active by default but which can be enabled in the GUI interface.

All bad block injection definitions operate in parallel, not sequentially. It is possible for multiple definitions to trigger during a single call but a given block can only fail once.

Interactive Dialog

Although it is possible to change the logging and other settings between test runs by editing the target definition file, the package also provides a way of changing these during driver initialization time. If the command line option *`--nanddebug`* is used in addition to *`--io`* then the I/O auxiliary will pop up a dialog box allowing the various settings to be edited.

Figure 2. I/O auxiliary Dialog, Files



```
NAND image file: synth_nand.dat
   Page size: 2048
   Spare (OOB) size: 64
   Pages per erase block: 32
   Number of erase blocks: 1024
```

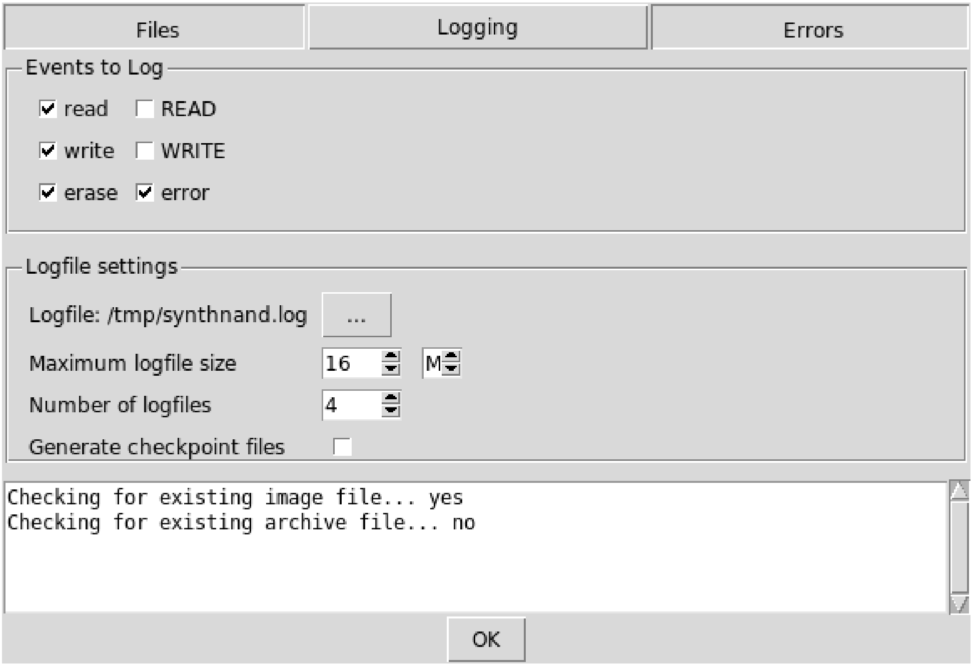
Delete: synth_nand.dat
Save: synth_nand.dat.bak
Restore: synth_nand.dat.bak

```
Checking for existing image file... yes
Checking for existing archive file... no
```

The dialog consists of a tabbed notebook with separate tabs for Files, Logging, and Errors. The default tab is Files. This shows the NAND device settings as configured via CDL options. If a current NAND image file exists then it can be deleted with a single click, allowing the test run to proceed with a new blank NAND device. The current image file can be saved away to an archive, either using a default name based on the current image name or by letting the user select a file. It is also possible to restore a previously-saved archive, again using the default name if that archive exists, or by selecting an alternative file. If any of the relevant files are changed outside this dialog then the refresh button forces the dialog to check the filesystem again. The various operations will be reported at the bottom of the dialog.

If the Logging tab is selected then the dialog changes to the following:

Figure 3. I/O auxiliary Dialog, Logging



Logfile: /tmp/synthnand.log

Maximum logfile size 16

Number of logfiles 4

Generate checkpoint files □

```
Checking for existing image file... yes
Checking for existing archive file... no
```

There are separate checkbuttons for the six types of events that can be logged. It is also possible to change the current logfile and to edit the other settings related to logfiles.

The Errors tab is not yet implemented.

The dialog can be dismissed using the OK button or by hitting the ESC key. At that point the eCos application will resume running with the selected settings.

File Formats

A NAND image is a binary file with six sections: a 64-byte header block; an array of erase counts; an array of write counts; an array of the factory-bad blocks; a bitmap of the good and bad blocks; and the actual data. The header consists of the following data structure:

```
struct header {
  cyg_uint32 magic;           // 0xEC05A11F
  cyg_uint32 page_size;       // CYGNUM_DEVS_NAND_SYNTH_PAGESIZE
  cyg_uint32 spare_size;      // CYGNUM_DEVS_NAND_SYNTH_SPARE_PER_PAGE
  cyg_uint32 pages_per_block; // CYGNUM_DEVS_NAND_SYNTH_PAGES_PER_BLOCK
  cyg_uint32 number_of_blocks;// CYGNUM_DEVS_NAND_SYNTH_BLOCK_COUNT
  cyg_uint32 tv_sec;
  cyg_uint32 tv_usec;
  cyg_uint32 spare[9];
};
```

All integers in the header and in the following three sections are stored in bigendian format. The *`magic`* field is used to check that a file really holds a NAND image. The next four fields specify the emulated device size and layout, as per the corresponding CDL options. The *`tv_sec`* and *`tv_usec`* fields are filled in with the result of a `gettimeofday()` system call during driver initialization. These fields also appear in logfiles, so code can check that a logfile and an image file correspond to the same test run.

Following the header is an array of BLOCK_COUNT integers holding the number of erase calls for each block. Next is an array of (BLOCK_COUNT * PAGES_PER_BLOCK) integers holding the number of write calls for each page. These arrays can be used to check that higher-level code is performing wear levelling.

The array of factory-bad blocks consists of 32 integers holding the settings of the target definition's file `factory_bad` setting at the time that the image file was created.

The bitmap following the factory-bad block array holds the current state of each erase block. Bit 0 of byte 0 corresponds to erase block 0, bit 0 of byte 1 corresponds to erase block 8, and so on. If a bit is set then the erase block is ok. If a bit is clear then the erase block is bad, either factory-bad or because it has failed subsequently due to a bad block injection.

The bad block bitmap is followed by the actual data. This consists of all erase blocks concatenated without padding, starting with erase block 0. Each erase block is stored starting from page 0 within that block, and again all the pages are concatenated without padding. For each page the actual data is stored first, followed by the spare (OOB) data.

A logfile is a plain text file, not a binary file. It holds one log event per line. Some of these lines can be rather long if READ or WRITE logging is enabled. The fields within each line are separated by a single space. The first field indicates the type of record. The next two fields are call counts, one for the event in question and one for the total number of calls into the driver. The remaining fields depend on the record type.

```
I 0 0 1247514233 562000 synth_nand.dat 2048 64 32 1024
```

This is an initialization record when the logfile is created. There have been no calls to the driver yet so the two counts are 0. The next two fields are the *`tv_sec`* and *`tv_usec`* timestamp values which are also written into the NAND image file. This allows logfiles and image files to be matched up. The remaining fields identify the page size, the spare size, the number of pages per erase block, and the number of erase blocks.

```
F 2 4 43 0
```

This is a call into the driver's `factorybad` function. It is the second such call, and the fourth call into the driver. The query is for erase block 42, and that block has not been marked as factory-bad.

```
 r 5 12 32736 0x0200f0c0 2048 0x0200eeb0 64
```

This is a `read` event. It is the fifth page read into the driver and the 12th call. The request is for page number 32736. 2048 bytes of data should be read into a buffer at location 0x0200f0c0, and 64 bytes of OOB data should be read into 0x0200eeb0.

```
Rd 5 12 32736 0x0200f0c0 2048 FFFFFFFFFFFF…
Ro 5 12 32736 0x0200eeb0 64   FFFFFFFFFFFF…
```

These are two `READ` log events corresponding to the previous `read`. The first line `Rd` is for the data part, and the final field consists of 4096 bytes of hexadecimal data. The second line `Ro` is for the OOB part and the final field consists of 128 bytes of hexadecimal data.

```
w 1 1030 32736 0x0200f0c0 2048 0x0200eed0 64
Wd 1 1030 32736 0x0200f0c0 2048 FFFFFFFF3FFFFFFFFFCF…
Wo 1 1030 32736 0x0200eed0 64 FFFFFFFFFFFFFFFF426274…
```

These lines show a `write` log event and a `WRITE` log event for the same call into the driver. The fields are the same as for `read` and `READ`.

```
E 2 1031 1022
```

This logs an erase call into the library for block 1022. It is the second erase call, and by this time there have been 1031 calls into the driver.

```
Bb 1 2857 631
…
Bp 2 4012 3189 99
```

These lines show bad block injections. The first is for an erase operation for block 631. That erase call is about to fail with EIO and the block will be marked bad. The second is for a write operation for page 3189, which is part of erase block 99. That write operation is about to fail and all of erase block 99 will be marked bad.

Installation

Before a synthetic target eCos application can use a NAND device it is necessary to build and install host-side support. The relevant code resides in the `host` subdirectory of the synthetic target NAND package and building it involves the standard **configure**, **make** and **make install** steps. The implementation of the NAND support does not require any executables, just a Tcl script `nand.tcl` and some support files, so the **make** step is a no-op.

There are two main ways of building the host-side software. It is possible to build both the generic host-side software and all package-specific host-side software, including the NAND support, in a single build tree. This involves using the **configure** script at the toplevel of the eCos repository. For more information on this, see the `README.host` file at the top of the repository. Note that if you have an existing build tree which does not include the synthetic target NAND support then it will be necessary to rerun the toplevel configure script: the search for appropriate packages happens at configure time.

The alternative is to build just the host-side for this package. This requires a separate build directory, building directly in the source tree is disallowed. The **configure** options are much the same as for a build from the toplevel, and the `README.host` file can be consulted for more details. It is essential that the NAND support be configured with the same `--prefix` option as other eCos host-side software, especially the I/O auxiliary provided by the synthetic target architectural HAL package, otherwise the I/O auxiliary will be unable to locate the NAND support.

Test programs

bbt

Bad Block Table unit test. Finds a readable block, then fiddles with its status in the BBT confirming expected behaviour. Requires the synthetic NAND device.

multipagebbt

As for *bbt* but insists that the device parameters mean that the BBT spans multiple pages on-chip. (This is perhaps a contrived case, but might crop up in future with larger devices, so needed to be tested.)

eccdamage

An ECC error fuzzing exercise. Requires `CYGSEM_NAND_SYNTH_RANDOMLY_LOSE`, which induces pseudo-random bit errors; after 1,000 runs, the number of errors corrected is reported.

Part XVII. Journalling Flash File System v2 (JFFS2)

Name

CYGPKG_FS_JFFS2 — Provides Journalling file system for Flash

Description

The Journalling Flash File System version 2 (JFFS2) provides a robust file system to allow reliable use of NOR Flash devices as data storage. The eCos implementation is greatly shared with the Linux kernel implementation, thus ensuring compatibility and encouraging development.

JFFS2 was designed from the outset for embedded devices. It allows recovery when the system has failed abnormally, without the file system itself being left in an unusable state, even if power is disconnected at the moment the Flash device is in the middle of being written to. It also offers features such as compression for efficient data storage, and garbage collection to improve capacity. Most importantly it is fully integrated into the eCos file I/O infrastructure as a plug-in filesystem.

External references

There are a number of external resources containing information about JFFS2 on the internet, other than the usual eCos-specific general resources. The key site is the Linux MTD website which, although clearly having a Linux focus, contains lots of useful documentation on JFFS2 as well as a mailing list with searchable archives. The mailing list welcomes questions on using JFFS2 on eCos. Note that the eCos JFFS2 port does not use the MTD layer itself.

Another useful site is the Red Hat JFFS2 website, which contains a very useful paper presented to a Linux symposium covering the internals and some of the design of JFFS2.

Name

JFFS2 usage — Description of how to use JFFS2

Mounting

A JFFS2 filesystem can be mounted just like any normal eCos filesystem, using the `mount()` function from the POSIX file I/O package (`CYGPKG_FILEIO`). You must choose an appropriate Flash I/O block device to use. Documentation on Flash I/O block devices can be found in the Generic Flash package documentation.

Example 1. Mounting and unmounting a JFFS2 filesystem

```
#include <cyg/fileio/fileio.h>
#include <stdio.h>
#include <string.h>
#include <errno.h>
    …
    int rc;
    rc = mount( "/dev/flash/fis/jffs2test", "/fs", "jffs2" );
    if (rc < 0)
       printf( "mount returned error: %s\n", strerror(errno) );
    …
    rc = umount( "/fs" );
    if (rc < 0)
       printf( "umount returned error: %s\n", strerror(errno) );
    …
```

No file system needs to be created in advance for JFFS2. A new file system image will be instantiated if JFFS2 is pointed at an erased Flash area. Similarly if JFFS2 is pointed at a non-erased Flash area that does not contain valid JFFS2 markers, it will refuse to mount it to prevent destruction of data.

If the Flash device supports locking, you should ensure that the flash region for the JFFS2 filesystem is unlocked before mounting, otherwise it will not be possible to write to the Flash. Alternatively, enabled the CDL option `CYGSEM_FS_JFFS2_UNLOCK_FLASH` to unlock Flash on mounting. This option is disabled by default for safety reasons — if Flash has been locked, it may be for an important reason.

If mounting an existing JFFS2 filesystem, the mount procedure will search for any unused blocks that have not already been erased, and erase them. This can result in an extended mount time, and so this feature can be disabled with the CDL option `CYGOPT_FS_JFFS2_ERASE_PENDING_ON_MOUNT`.

Normally it is sufficient to prepare a clean JFFS2 partition as above, and load files into it using RedBoot or an eCos application. But if you do wish to use a pregenerated file system image generated on your host PC, there is a utility named **mkfs.jffs2** which can be used to generate an image. On Ubuntu, Fedora and Red Hat-based distributions of Linux it can be found in a package named mtd-utils; in Windows with Cygwin, in the mtd package. Be sure to use the `-l` or `-b` options to select the endianness so it corresponds with your target, and you may need to set other options according to the requirements of your Flash hardware such as erase block size. The erase block size to use on the **mkfs.jffs2** command line should be the largest flash block size used by your JFFS2 partition on the flash device. Note that the `-s` or `--pagesize` options are unrelated to the flash block size, and instead control JFFS2's view of the page size - see here for information on changing the value. Use the `--help` option for a complete list of **mkfs.jffs2** parameters.

Note that JFFS2's memory requirements are not static, and so they may increase over time before stabilising. Larger Flash partitions may require non-trivial amounts of memory, especially at mount time. Memory use may be controlled by removing features such as compression, or by constraining the size of the Flash partition. Configuration options controlling optional features may be found in the JFFS2 package CDL configuration.

JFFS2 has built-in tolerance of Flash errors when erasing and should adapt and work around bit errors that arise as Flash reaches the end of its working life. Obviously this comes at the expense of device capacity.

Garbage collection

By default, JFFS2 performs garbage collection on an as-needed basis. This means that when there are insufficient spare clean flash blocks remaining, JFFS2 will perform repeated garbage collection until a block can be erased and then used for future writes.

Garbage collection involves scanning a flash block and determining which nodes are still used for valid data and which are obsolete - valid data is then relocated to a new alternative block, until only obsolete data remains, at which point the block can be erased. The algorithms which choose which block is nominated for garbage collection do so to ensure wear levelling over the life of the flash device. Nodes representing individual file fragments are able to be coalesced and merged with adjacent file fragments leading to reduced flash use overall due to eliminating some of the overhead caused by node metadata on the Flash. There will also be a consequent simplification in the internal filesystem data structures, resulting in reduced memory consumption and fewer data structures which JFFS2 needs to trawl through when locating data. It will also greatly augment the benefit of compression: when compressing, nodes are considered in isolation, and so small nodes are unlikely to compress well, whereas larger coalesced nodes are more likely to occupy less flash space.

Garbage collection thread

As a result of only performing garbage collection when needed, it can mean that individual writes to files may occasionally take a lengthy period of time to run if a new flash block is required - a whole flash block may need to be garbage collected from scratch, have its live data written to a new block, and be erased, the latter in particular being a very lengthy procedure. As such, JFFS2 offers the option of using a *garbage collection thread*, which can run in the background to advance the garbage collection process when the filesystem is not otherwise being used.

Of course if a filesystem is going to change too rapidly, or the application is CPU bound by higher priority threads, then the garbage collection thread may not be able to keep up. But for the majority of applications, it can considerably reduce or even virtually eliminate the delays caused by the requirement for occasional garbage collection.

The garbage collection thread can be enabled in the JFFS2 package's configuration using the "Garbage collection background thread" CDL option (`CYGOPT_FS_JFFS2_GC_THREAD`). The priority of that thread defaults to the lowest possible - 1 above that of the idle thread, but this can be changed with the `CYGNUM_JFFS2_GC_THREAD_PRIORITY` option. The thread of course requires a stack for execution, the value of which can be optimised with the `CYGNUM_JFFS2_GC_THREAD_STACK_SIZE` option. Note that one garbage collection thread is started for each mounted JFFS2 filesystem, and so one thread stack is allocated for each.

Usually the garbage collection thread will gradually garbage collect nodes from erase blocks until the block is completely unused by valid data. However it would not actually erase it, leaving that to the usual code path that erases blocks only at the point they are needed. This is because otherwise the Flash system may get locked for the duration of the erase process, preventing any threads, including high priority threads, access to it at that time. Yet the garbage collection thread is intended to be a low priority background thread. Nevertheless, enabling the option `CYGSEM_JFFS2_GC_THREAD_CAN_ERASE` allows the garbage collection thread to erase blocks as well, if blocks are available for erasure.

Finally, the garbage collection thread may run continuously but does not have to run constantly. By default, the thread will be inactive unless the amount of free space in the filesystem is beginning to run low. The filesystem code makes a judgement based on a myriad of factors to decide when to activate this background GC thread (although its low thread priority may result in it not running in practice, so choose its thread priority wisely in relation to the other running threads). Once active, the garbage collection thread will run until sufficient free space is now available, even if more garbage collection may be possible.

As a variation on this behaviour, it is possible to periodically wake the GC thread to advance garbage collection even when the available free space is not yet low; thus preventing it getting close to running out in the first place. This feature is controlled with the `CYGNUM_JFFS2_GC_THREAD_TICKS` configuration option, which gives the number of ticks between garbage collection passes, even when space is not low.

How ticks corresponds to real time is unspecified and depends on the HAL and kernel clock configuration (although most ports have traditionally defaulted to 10ms ticks). The value of this option can even be set to 0. Note though, that garbage collection is never considered "done" - the thread will run continuously until the filesystem is unmounted, therefore making it run too frequently may in fact cause unnecessary flash operations, increasing flash wear (even though it will be levelled wear). The value should be chosen according to the expected write pattern.

The number of ticks between garbage collection passes can also be set at runtime, by invoking a `cyg_fs_setinfo()` call on a filesystem object. There is a corresponding `cyg_fs_getinfo()` call to retrieve the current delay ticks. For example:

```
#include <cyg/fs/jffs2/jffs2.h>
    …
    {
        int err;
        cyg_tick_count_t old_delay_ticks;
        cyg_tick_count_t new_delay_ticks;

        err = cyg_fs_getinfo( "/jffs2",
                              FS_INFO_JFFS2_GET_GC_THREAD_TICKS,
                              &old_delay_ticks,
                              sizeof(cyg_tick_count));
        assert(err == 0);
        new_delay_ticks = old_delay_ticks*10; // slow down GC
        err = cyg_fs_setinfo( "/jffs2",
                              FS_INFO_JFFS2_SET_GC_THREAD_TICKS,
                              &new_delay_ticks,
                              sizeof(cyg_tick_count));
        assert(err == 0);
    }
```

One application of dynamically setting the wakeup delay for the garbage collection thread is so that the thread is more active in times of relative system activity, but operates more slowly when quiescent. This may improve flash life, while still retaining benefits of the garbage collection thread.

The value of the wakeup delay can be set to a special value of `(cyg_tick_count_t)-1`, which indicates that the thread should not wake up periodically any more, but only when space is running low (the behaviour when `CYGNUM_JFFS2_GC_THREAD_TICKS` is disabled). Similarly retrieving the current wakeup tick value with `cyg_fs_getinfo()` may return this special value.

Efficiency

Write size

JFFS2 does not guarantee 100% optimal use of Flash space due to its journalling nature, and the granularity of Flash blocks. It is possible for it to fill up even when not all file space appears to have been used, especially if files have had many small operations performed on them and the Flash partition is small compared to the size of the Flash blocks. It is strongly recommended to have at least 5 or 6 Flash blocks spare, over and above space requirements for data, in order to allow the JFFS2 garbage collector to operate.

It is certainly the case that JFFS2 will work very inefficiently if using many small writes. Unless and until garbage collected, each write will occupy its own JFFS2 node on Flash, and so will incur overhead from the node header. A filesystem is likely to "fill" quickly if written a few bytes at a time, rather than in large chunks, so caution in advised, and more space reserved if that write pattern is anticipated. A common application that can do this is logging. Small writes can also remove the benefits of compression, as there is too little data to compress effectively.

Garbage collection

Use of the garbage collection thread will provide a level of continuous garbage collection. As indicated above, garbage collection can reduce flash usage and memory consumption, and improve performance. Therefore doing so on a continuous basis is a wise idea.

Extra spare space is required in order to allow the JFFS2 garbage collector to operate, over and above space requirements for data. A rule of thumb is to use the following formula:

```
Recommended overhead == 2 + (( flashsize/50 ) + (flashsectors*100) + (sectorsize-1)) / sectorsize
```

So for example, a 16Mbyte flash with 64Kbyte blocks given over entirely to JFFS2 would actually require an overhead of 6 blocks. Or to look at it another way, trying to write data when you have used up all but 6 blocks worth may result in an ENOSPC error being reported. Due to metadata and write characteristics (e.g. lots of 1 byte writes) it's not possible to easily calculate what that actually translates to in terms of maximum file size. Even the above formula is only a rule of thumb, and it has not been proven to be guaranteed to work in all circumstances. It is recommended to be conservative if possible.

Compression

JFFS2 will default to trying to compress files. However, it may be more memory efficient to disable JFFS2 compression entirely in the CDL configuration, and instead ensure that images are stored compressed when they are downloaded, and use the standard RedBoot mechanism to decompress the files upon loading.

Maximum data node size

By default JFFS2 will operate on chunks of files up to 4 kilobytes in size, but larger chunks may be able to be compressed more efficiently, and have lower metadata overheads. To increase the size, you must change JFFS2's view of the machine page size - the eCos JFFS2 port's view of the page size does not actually need to reflect any real underlying page size of the memory management system, and the notion of the page size is a hangover from the Linux origins of JFFS2 which would be too disruptive to remove. Changing the page size can be performed by changing the page size exponent configuration option (`CYGNUM_LINUX_COMPAT_PAGE_SIZE_EXPONENT`) in the Linux compatibility layer package (`CYGPKG_LINUX_COMPAT`). A value of 12 indicates 2^{12} which is 4 kilobytes. For example this could be changed to 16, corresponding to 2^{16} which is 64 kilobytes. If using **mkfs.jffs2**, make sure that its value for the page size, using the `-s` or `--pagesize` options, is the same or lower than the page size given by `CYGNUM_LINUX_COMPAT_PAGE_SIZE_EXPONENT`.

Configuration dependencies

JFFS2 has a number of package dependencies. As such it may be helpful to use the below eCos minimal configuration (.ecm) file and import it into your configuration to satisfy most dependencies quickly without conflict. This minimal configuration file is usable for building both eCos and RedBoot with JFFS2 included. Note you may need to modify the package versions from *`current`* to the version of your release, e.g. *`v2_0_64`*.

```
cdl_configuration eCos {
    package CYGPKG_IO_FLASH current ;
    package CYGPKG_MEMALLOC current ;
    package CYGPKG_COMPRESS_ZLIB current ;
    package CYGPKG_IO_FILEIO current ;
    package CYGPKG_FS_JFFS2 current ;
    package CYGPKG_ERROR current ;
    package CYGPKG_LINUX_COMPAT current ;
    package CYGPKG_IO current ;
    package CYGPKG_CRC current ;
    package CYGPKG_LIBC_STRING current ;
};

cdl_option CYGPKG_IO_FILEIO_DEVFS_SUPPORT {
    user_value 1
};
cdl_component CYGPKG_IO_FLASH_BLOCK_DEVICE {
    user_value 1
};
```

For example:

```
$ ecosconfig new adderII
$ ecosconfig import jffs2.ecm
$ ecosconfig tree
$ make tests
```

Use with RedBoot

JFFS2 support can be built into RedBoot using the above minimal configuration file. In most cases, the configuration settings will then make all the adjustments necessary.

However note that a build of RedBoot which includes JFFS2 with RedBoot, is likely to require more Flash space for its own image, as well as much more RAM space to run. The latter is particularly important to note given that this can reduce the size of the program image which can be loaded into RAM from a JFFS2 filesystem.

Particularly large JFFS2 filesystems, or filesystems with a large number of nodes, require more RAM to be used for JFFS2's in-memory data structures. As such, the value of the configuration option controlling the size of the RedBoot heap (`CYGMEM_REDBOOT_WORKSPACE_HEAP_SIZE`) may need to be increased in such cases. JFFS2 will already make the default size of this heap occupy 192KiB of RAM.

Secure Erase

The eCosPro® port of JFFS2 includes a *Secure Erase* feature. This feature allows the application to ensure that when a file is deleted, its contents are fully erased from the flash.

Usually deleted files persist in Flash for an indeterminate period of time, marked as obsolete. The possible solution taken with other filesystems of trying to overwrite the file data before deletion does not work with JFFS2, as JFFS2 will still retain the old file data in Flash, but writes additional nodes with a higher node version number, and rendering the previous data obsolete. Therefore the Secure Erase functionality can be used to guarantee that a deleted file will have its past contents wiped from the Flash.

Methodology

Because obsolete data for a file could exist in any block, the only way to achieve this is to ensure that every block (other than bad or completely free blocks) is wiped, taking care to relocate live data. This effectively means methodically garbage collecting and erasing every flash block used by the filesystem.

Operation time

For a filesystem which almost completely consists of used flash blocks the secure erase process could take a considerable amount of time during which the filesystem cannot be used for other operations. Therefore it is strongly recommended that the garbage collection thread support is enabled with an appropriate value for `CYGNUM_JFFS2_GC_THREAD_TICKS`. With the garbage collection thread running, more blocks are likely to be completely clean, or at least partially garbage collected, thus reducing the time for secure erasure.

Usage

Support for the secure erase functionality must first be enabled with a CDL configuration option - `CYGOPT_FS_JFFS2_SECERASE`.

Then a secure erase operation can be performed on the filesystem with a `cyg_fs_setinfo()` function call using the `FS_INFO_SECURE_ERASE` config key. This call can be invoked specifying any file or directory within the filesystem including its mount point, although the operation itself will take place on the entire filesystem.

Example 2. Secure erase usage

```
#include <cyg/fileio/fileio.h>
#include <errno.h>
#include <stdio.h>
    …
    int err;
    err = cyg_fs_setinfo("/fs", FS_INFO_SECURE_ERASE, NULL, 0);
    if (ENOERR != err)
    {
      printf( "Secure erase failed: %d\n", strerror(err) );
      …
```

Testing JFFS2

JFFS2 comes with a number of tests that may be run as normal eCos test applications. If you are running the tests under the RedBoot ROM monitor, you should create a FIS partition in RedBoot named “jffs2test”.

Alternatively, for standalone applications, if the platform HAL defines the `CYG_HAL_IO_FLASH_TEST_DEVICES` macro, the code will step through the vector entries supplied by that macro using the referenced flash device entry in conjunction with the `offset` and `size` values supplied.

Without the “jffs2test” named FIS partition, or a platform supplied vector, you must set the CDL configuration options `CYGNUM_FS_JFFS2_TEST_OFFSET` and `CYGNUM_FS_JFFS2_TEST_LENGTH`. In this case the first valid flash device (“`/dev/flash/0`”) will be used.

The tests will attempt to use the region identified by the offset/length combination, but will first check if the area is blank, and will report a test failure if it is not.

When the tests run, they will erase the Flash test area (usually the “jffs2test” FIS partition) in its entirety, so do not use an existing JFFS2 partition in this space.

The tests are designed to test both general features of JFFS2, as well as do a limited stress-test JFFS2 in the presence of multiple threads.

More specifically, the `jffs2-fileio1` test checks a wide variety of file system operations including creating and removing files and directories, scanning directories, and reading and writing file contents. It also repeats to verify that unmounting and remounting works.

The `jffs2-fseek1` test verifies file seek operations on JFFS2 files, using standard I/O C library calls.

Test files with names of the form `jffs2-`*`NtNf`* verify operation with varying numbers of threads, and varying numbers of files.

The test `jffs2_3` is specifically to verify operation of the garbage collection code, and performs a small set of operations repeatedly to do so. It also gives an opportunity for the garbage collection thread to be tested, if enabled.

The test `jffs2-secerase1` is specifically to verify operation of the secure erase facility, if the `CYGOPT_FS_JFFS2_SECERASE` CDL configuration option has been enabled. It also provides further testing of the garbage collection code and the garbage collection thread.

Part XVIII. NOR Flash Support

Table of Contents

Chapter 61. The eCos NOR FLASH Library

The NOR FLASH library is an optional part of eCos, and is only applicable to some platforms.

The eCos NOR FLASH library provides the following functionality:

1. Identifying installed device of a FLASH family.

2. Read, erasing and writing to FLASH blocks.

3. Validating an address is within the FLASH.

4. Determining the number and size of FLASH blocks.

There are two APIs with the flash library. The old API is retained for backwards compatibility reasons, but should slowly be replaced with the new API which is much more flexible and does not pollute the name space as much.

Notes on using the NOR FLASH library

FLASH devices cannot be read from when an erase or write operation is active. This means it is not possible to execute code from flash while an erase or write operation is active. It is possible to use the library when the executable image is resident in FLASH. The low level drivers are written such that the linker places the functions that actually manipulate the flash into RAM. However the library may not be interrupt safe. An interrupt must not cause execution of code that is resident in FLASH. This may be the image itself, or RedBoot. In some configurations of eCos, ^C on the serial port or debugging via Ethernet may cause an interrupt handler to call RedBoot. If RedBoot is resident in FLASH this will cause a crash. Similarly, if another thread invokes a virtual vector function to access RedBoot, eg to perform a `diag_printf()` a crash could result.

Thus with a ROM based image or a ROM based Redboot it is recommended to disable interrupts while erasing or programming flash. Using both a ROMRAM or RAM images and a ROMRAM or RAM RedBoot are safe and there is no need to disable interrupts.

Danger, Will Robinson! Danger!

Unlike nearly every other aspect of embedded system programming, getting it wrong with FLASH devices can render your target system useless. Most targets have a boot loader in the FLASH. Without this boot loader the target will obviously not boot. So before starting to play with this library its worth investigating a few things. How do you recover your target if you delete the boot loader? Do you have the necessary JTAG cable? Or is specialist hardware needed? Is it even possible to recover the target boards or must it be thrown into the rubbish bin? How does killing the board affect your project schedule?

Chapter 62. The Version 2 eCos FLASH API

There are two APIs described here. The first is the application API which programs should use. The second API is that between the FLASH IO library and the device drivers.

FLASH user API

All of the functions described below are declared in the header file `<cyg/io/flash.h>` which all users of the FLASH library should include.

Initializing the FLASH library

The FLASH library needs to be initialized before other FLASH operations can be performed. This only needs to be done once. The following function will only do the initialization once so it's safe to call multiple times:

```
__externC int cyg_flash_init(cyg_flash_printf *pf);
```

The parameter *`pf`* must always be set to NULL. It exists solely for backward compatibility and other settings are deprecated and obsolete. Past use of this parameter has now been replaced with use of the `cyg_flash_set_global_printf` function.

Retrieving information about FLASH devices

The following five functions return information about the FLASH.

```
__externC int cyg_flash_get_info(cyg_uint32 devno, cyg_flash_info_t * info);
__externC int cyg_flash_get_info_addr(cyg_flashaddr_t flash_base, cyg_flash_info_t * info);
__externC int cyg_flash_verify_addr(const flashaddr_t address);
__extern size_t cyg_flash_block_size(const cyg_flashaddr_t flash_base);
typedef struct cyg_flash_block_info
{
  size_t                      block_size;
  cyg_uint32                  blocks;
} cyg_flash_block_info_t;

typedef struct {
  cyg_flashaddr_t              start;          // First address
  cyg_flashaddr_t              end;            // Last address
  cyg_uint32                   num_block_infos;// Number of entries
  const cyg_flash_block_info_t *block_info;    // Info about one block size
} cyg_flash_info_t;
```

`cyg_flash_get_info()` is the main function to get information about installed flash devices. Parameter *`devno`* is used to iterate over the available flash devices, starting from 0. If the devno'th device exists, the structure pointed to by *`info`* is filled in and `CYG_FLASH_ERR_OK` is returned, otherwise `CYG_FLASH_ERR_INVALID`. `cyg_flash_get_info_addr()` is similar, but returns the information about the flash device at the given address. `cyg_flash_block_size()` returns the size of the block at the given address. `cyg_flash_verify_addr()` tests if the target addresses is within one of the FLASH devices, returning `CYG_FLASH_ERR_OK` if so.

Reading from FLASH

There are two methods for reading from FLASH. The first is to use the following function.

```
__externC int cyg_flash_read(cyg_flashaddr_t flash_base, void *ram_base, size_t len, cyg_flashaddr_t *err_address);
```

`flash_base` is where in the flash to read from. *`ram_base`* indicates where the data read from flash should be placed into RAM. *`len`* is the number of bytes to be read from the FLASH and *`err_address`* is used to return the location in FLASH that any error occurred while reading.

The second method is to simply `memcpy()` directly from the FLASH. This is not recommended since some types of device cannot be read in this way, eg NAND FLASH. Using the FLASH library function to read the FLASH will always work so making it easy to port code from one FLASH device to another.

Erasing areas of FLASH

Blocks of FLASH can be erased using the following function:

```
__externC int cyg_flash_erase(cyg_flashaddr_t flash_base,
                              size_t          len,
                              cyg_flashaddr_t *err_address);
```

`flash_base` is where in the flash to erase from. *`len`* is the minimum number of bytes to erase in the FLASH and *`err_address`* is used to return the location in FLASH that any error occurred while erasing. It should be noted that FLASH devices are block oriented when erasing. It is not possible to erase a few bytes within a block, the whole block will be erased. *`flash_base`* may be anywhere within the first block to be erased and *`flash_base+len`* may be anywhere in the last block to be erased.

Programming the FLASH

Programming of the flash is achieved using the following function.

```
__externC int cyg_flash_program(cyg_flashaddr_t flash_base,
                                void            *ram_base,
                                size_t          len,
                                cyg_flashaddr_t *err_address);
```

`flash_base` is where in the flash to program from. *`ram_base`* indicates where the data to be programmed into FLASH should be read from in RAM. *`len`* is the number of bytes to be program into the FLASH and *`err_address`* is used to return the location in FLASH that any error occurred while programming.

Locking and unlocking blocks

Some flash devices have the ability to lock and unlock blocks. A locked block cannot be erased or programmed without it first being unlocked. For devices which support this feature and when `CYGHWR_IO_FLASH_BLOCK_LOCKING` is enabled then the following two functions are available:

```
__externC int cyg_flash_lock(   const cyg_flashaddr_t flash_base,
                                size_t                len,
                                cyg_flashaddr_t       *err_address);

__externC int cyg_flash_unlock( const cyg_flashaddr_t flash_base,
                                size_t                len,
                                cyg_flashaddr_t       *err_address);
```

For some devices the granularity will be at the whole device level, where the code will lock or unlock all of the blocks at the same time.

Locking FLASH mutexes

When the eCos kernel package is included in the eCos configuration, the FLASH IO library will perform mutex locking on FLASH operations. This makes the API defined here thread safe. However applications may wish to directly access the contents of the FLASH. In order for this to be thread safe it is necessary for the application to use the following two functions to inform the FLASH IO library that the FLASH devices are being used and other API calls should be blocked.

```
__externC int cyg_flash_mutex_lock(const cyg_flashaddr_t from, size_t len);
__externC int cyg_flash_mutex_unlock(const cyg_flashaddr_t from, size_t len);
```

Configuring diagnostic output

Each FLASH device can have an associated function which is called to perform diagnostic output. The function to be used can be configured with the following functions:

```
__externC int cyg_flash_set_printf(const cyg_flashaddr_t  flash_base,
                                   cyg_flash_printf       *pf);
__externC void cyg_flash_set_global_printf(cyg_flash_printf *pf);
typedef int cyg_flash_printf(const char *fmt, …);
```

The parameter *`pf`* is a pointer to a function which is to be used for diagnostic output. Typically the function `diag_printf()` will be passed. Normally this function is not used by the higher layer of the library unless `CYGSEM_IO_FLASH_CHATTER` is enabled. Passing a *`NULL`* causes diagnostic output from lower level drivers to be discarded.

`cyg_flash_set_printf` is used to set a diagnostic output function which will be used specifically when diagnostic output is attempted from the FLASH device driver associated with the base address of *`flash_base`*. An error will be returned if no FLASH device is found for this address, or the FLASH subsystem has not yet been initialised with `cyg_flash_init`.

`cyg_flash_set_global_printf` sets a diagnostic output function for all available FLASH devices. Any previous setting of a diagnostic output function (including with `cyg_flash_set_printf`) will be discarded. This function may be called prior to `cyg_flash_init`.

Return values and errors

All the functions above return one of the following return values.

```
CYG_FLASH_ERR_OK              No error - operation complete
CYG_FLASH_ERR_INVALID         Invalid FLASH address
CYG_FLASH_ERR_ERASE           Error trying to erase
CYG_FLASH_ERR_LOCK            Error trying to lock/unlock
CYG_FLASH_ERR_PROGRAM         Error trying to program
CYG_FLASH_ERR_PROTOCOL        Generic error
CYG_FLASH_ERR_PROTECT         Device/region is write-protected
CYG_FLASH_ERR_NOT_INIT        FLASH info not yet initialized
CYG_FLASH_ERR_HWR             Hardware (configuration?) problem
CYG_FLASH_ERR_ERASE_SUSPEND   Device is in erase suspend mode
CYG_FLASH_ERR_PROGRAM_SUSPEND Device is in program suspend mode
CYG_FLASH_ERR_DRV_VERIFY      Driver failed to verify data
CYG_FLASH_ERR_DRV_TIMEOUT     Driver timed out waiting for device
CYG_FLASH_ERR_DRV_WRONG_PART  Driver does not support device
CYG_FLASH_ERR_LOW_VOLTAGE     Not enough juice to complete job
```

To turn an error code into a human readable string the following function can be used:

```
__externC const char *cyg_flash_errmsg(const int err);
```

FLASH device API

This section describes the API between the FLASH IO library the FLASH device drivers.

The FLASH device Structure

This structure keeps all the information about a single driver.

```
struct cyg_flash_dev {
  const struct cyg_flash_dev_funs *funs;            // Function pointers
  cyg_uint32                      flags;            // Device characteristics
  cyg_flashaddr_t                 start;            // First address
  cyg_flashaddr_t                 end;              // Last address
  cyg_uint32                      num_block_infos;  // Number of entries
  const cyg_flash_block_info_t    *block_info;      // Info about one block size
  const void                      *priv;            // Devices private data
  // The following are only written to by the FLASH IO layer.
  cyg_flash_printf                *pf;              // Pointer to diagnostic printf
  bool                            init;             // Device has been initialised
#ifdef CYGPKG_KERNEL
  cyg_mutex_t                     mutex;            // Mutex for thread safeness
#endif
#if (CYGHWR_IO_FLASH_DEVICE > 1)
  struct cyg_flash_dev            *next;            // Pointer to next device
#endif
};

struct cyg_flash_dev_funs {
  int     (*flash_init) (   struct cyg_flash_dev   *dev );

  size_t  (*flash_query) (  struct cyg_flash_dev  *dev,
                            void                  *data,
                            size_t                len );

  int     (*flash_erase_block) (struct cyg_flash_dev  *dev,
                                cyg_flashaddr_t       block_base );

  int     (*flash_program) (struct cyg_flash_dev  *dev,
                            cyg_flashaddr_t       base,
                            const void            *data,
                            size_t                len );

  int     (*flash_read) (   struct cyg_flash_dev  *dev,
                            const cyg_flashaddr_t base,
                            void                  *data,
                            size_t                len );
#ifdef CYGHWR_IO_FLASH_BLOCK_LOCKING
  int     (*flash_block_lock) (   struct cyg_flash_dev  *dev,
                                  const cyg_flashaddr_t block_base );

  int     (*flash_block_unlock) ( struct cyg_flash_dev  *dev,
                                  const cyg_flashaddr_t block_base);
#endif
};
```

The FLASH IO layer will only pass requests for operations on a single block.

Chapter 63. The legacy Version 1 eCos FLASH API

The library has a number of limitations:

1. Only one family of FLASH device may be supported at once.

2. Multiple devices of one family are supported, but they must be contiguous in memory.

3. The library is not thread or interrupt safe under some conditions.

4. The library currently does not use the eCos naming convention for its functions. This may change in the future but backward compatibility is likely to be kept.

There are two APIs described here. The first is the application API which programs should use. The second API is that between the FLASH io library and the device drivers.

FLASH user API

All of the functions described below are declared in the header file `<cyg/io/flash.h>` which all users of the FLASH library should include.

Initializing the FLASH library

The FLASH library needs to be initialized before other FLASH operations can be performed. This only needs to be done once. The following function will only do the initialization once so it's safe to call multiple times:

```
externC int flash_init( _printf *pf );
typedef int _printf(const char *fmt, …);
```

The parameter *`pf`* is a pointer to a function which is to be used for diagnostic output. Typically the function `diag_printf()` will be passed. Normally this function is not used by the higher layer of the library unless `CYGSEM_IO_FLASH_CHATTER` is enabled. Passing a *`NULL`* is not recommended, even when CYGSEM_IO_FLASH_CHATTER is disabled. The lower layers of the library may unconditionally call this function, especially when errors occur, probably resulting in a more serious error/crash!.

Retrieving information about the FLASH

The following four functions return information about the FLASH.

```
externC int flash_get_block_info(int *block_size, int *blocks);
externC int flash_get_limits(void *target, void **start, void **end);
externC int flash_verify_addr(void *target);
externC bool flash_code_overlaps(void *start, void *end);
```

The function `flash_get_block_info()` returns the size and number of blocks. When the device has a mixture of block sizes, the size of the "normal" block will be returned. Please read the source code to determine exactly what this means. `flash_get_limits()` returns the lower and upper memory address the FLASH occupies (NOTE: For the upper memory address this is the last valid FLASH location, and not the first memory address after the FLASH). The *`target`* parameter is currently unused. `flash_verify_addr()` tests if the target addresses is within the flash, returning `FLASH_ERR_OK` if so. Lastly, `flash_code_overlaps()` checks if the executing code is resident in the section of flash indicated by *`start`* and *`end`*. If this function returns true, erase and program operations within this range are very likely to cause the target to crash and burn horribly. Note the FLASH library does allow you to shoot yourself in the foot in this way.

Reading from FLASH

There are two methods for reading from FLASH. The first is to use the following function.

```
externC int flash_read(void *flash_base, void *ram_base, int len, void **err_address);
```

flash_base is where in the flash to read from. *ram_base* indicates where the data read from flash should be placed into RAM. *len* is the number of bytes to be read from the FLASH and *err_address* is used to return the location in FLASH that any error occurred while reading.

The second method is to simply `memcpy()` directly from the FLASH. This is not recommended since some types of device cannot be read in this way, eg NAND FLASH. Using the FLASH library function to read the FLASH will always work so making it easy to port code from one FLASH device to another.

Erasing areas of FLASH

Blocks of FLASH can be erased using the following function:

```
externC int flash_erase(void *flash_base, int len, void **err_address);
```

flash_base is where in the flash to erase from. *len* is the minimum number of bytes to erase in the FLASH and *err_address* is used to return the location in FLASH that any error occurred while erasing. It should be noted that FLASH devices are block oriented when erasing. It is not possible to erase a few bytes within a block, the whole block will be erased. *flash_base* may be anywhere within the first block to be erased and *flash_base+len* may be anywhere in the last block to be erased.

Programming the FLASH

Programming of the flash is achieved using the following function.

```
externC int flash_program(void *flash_base, void *ram_base, int len, void **err_address);
```

flash_base is where in the flash to program from. *ram_base* indicates where the data to be programmed into FLASH should be read from in RAM. *len* is the number of bytes to be program into the FLASH and *err_address* is used to return the location in FLASH that any error occurred while programming.

Locking and unlocking blocks

Some flash devices have the ability to lock and unlock blocks. A locked block cannot be erased or programmed without it first being unlocked. For devices which support this feature and when `CYGHWR_IO_FLASH_BLOCK_LOCKING` is enabled then the following two functions are available:

```
externC int flash_lock(void *flash_base, int len, void **err_address);
externC int flash_unlock(void *flash_base, int len, void **err_address);
```

Return values and errors

All the functions above, except `flash_code_overlaps()` return one of the following return values.

```
FLASH_ERR_OK              No error - operation complete
FLASH_ERR_INVALID         Invalid FLASH address
FLASH_ERR_ERASE           Error trying to erase
FLASH_ERR_LOCK            Error trying to lock/unlock
FLASH_ERR_PROGRAM         Error trying to program
FLASH_ERR_PROTOCOL        Generic error
FLASH_ERR_PROTECT         Device/region is write-protected
FLASH_ERR_NOT_INIT        FLASH info not yet initialized
FLASH_ERR_HWR             Hardware (configuration?) problem
```

```
FLASH_ERR_ERASE_SUSPEND   Device is in erase suspend mode
FLASH_ERR_PROGRAM_SUSPEND Device is in program suspend mode
FLASH_ERR_DRV_VERIFY      Driver failed to verify data
FLASH_ERR_DRV_TIMEOUT     Driver timed out waiting for device
FLASH_ERR_DRV_WRONG_PART  Driver does not support device
FLASH_ERR_LOW_VOLTAGE     Not enough juice to complete job
```

To turn an error code into a human readable string the following function can be used:

```
externC char *flash_errmsg(int err);
```

Notes on using the FLASH library

The FLASH library evolved from the needs and environment of RedBoot rather than being a general purpose eCos component. This history explains some of the problems with the library.

The library is not thread safe. Multiple simultaneous calls to its library functions will likely fail and may cause a crash. It is the callers responsibility to use the necessary mutex's if needed.

FLASH device API

This section describes the API between the FLASH IO library the FLASH device drivers.

The flash_info structure

The *flash_info*structure is used by both the FLASH IO library and the device driver.

```
struct flash_info {
  int   block_size;   // Assuming fixed size "blocks"
  int   blocks;       // Number of blocks
  int   buffer_size;  // Size of write buffer (only defined for some devices)
  unsigned long block_mask;
  void *start, *end;  // Address range
  int   init;         // FLASH API initialised
  _printf *pf;        // printf like function for diagnostics
};
```

block_mask is used internally in the FLASH IO library. It contains a mask which can be used to turn an arbitrary address in flash to the base address of the block which contains the address.

There exists one global instance of this structure with the name *flash_info*. All calls into the device driver makes use of this global structure to maintain state.

Initializing the device driver

The FLASH IO library will call the following function to initialize the device driver:

```
externC int  flash_hwr_init(void);
```

The device driver should probe the hardware to see if the FLASH devices exist. If it does it should fill in *start, end, blocks and block_size.* If the FLASH contains a write buffer the size of this should be placed in *buffer_size*. On successful probing the function should return `FLASH_ERR_OK`. When things go wrong it can be assumed that *pf* points to a printf like function for outputting error messages.

Querying the FLASH

FLASH devices can be queried to return there manufacture ID, size etc. This function allows this information to be returned.

```
int flash_query(unsigned char *data);
```

The caller must know the size of data to be returned and provide an appropriately sized buffer pointed to be parameter `data`. This function is generally used by `flash_hwr_init()`.

Erasing a block of FLASH

So that the FLASH IO layer can erase a block of FLASH the following function should be provided.

```
int flash_erase_block(volatile flash_t *block, unsigned int block_size);
```

Programming a region of FLASH

The following function must be provided so that data can be written into the FLASH.

```
int flash_program_buf(volatile flash_t *addr, flash_t *data, int len,
unsigned long block_mask, int buffer_size);
```

The device will only be asked to program data in one block of the flash. The FLASH IO layer will break longer user requests into a smaller writes.

Reading a region from FLASH

Some FLASH devices are not memory mapped so it is not possible to read there contents directly. The following function read a region of FLASH.

```
int flash_read_buf(volatile flash_t* addr, flash_t* data, int len);
```

As with writing to the flash, the FLASH IO layer will break longer user requests for data into a number of reads which are at maximum one block in size.

A device which cannot be read directy should set `CYGSEM_IO_FLASH_READ_INDIRECT` so that the IO layer makes use of the `flash_read_buf()`function.

Locking and unlocking FLASH blocks

Some flash devices allow blocks to be locked so that they cannot be written to. The device driver should provide the following functions to manipulate these locks.

```
int flash_lock_block(volatile flash_t *block);
int flash_unlock_block(volatile flash_t *block, int block_size, int blocks);
```

These functions are only used if `CYGHWR_IO_FLASH_BLOCK_LOCKING`

Mapping FLASH error codes to FLASH IO error codes

The functions `flash_erase_block(), flash_program_buf(), flash_read_buf(), flash_lock_block() and flash_unlock_block()` return an error code which is specific to the flash device. To map this into a FLASH IO error code, the driver should provide the following function:

```
int flash_hwr_map_error(int err);
```

Determining if code is in FLASH

Although a general function, the device driver is expected to provide the implementation of the function `flash_code_overlaps()`.

Implementation Notes

The FLASH IO layer will manipulate the caches as required. The device drivers do not need to enable/disable caches when performing operations of the FLASH.

Device drivers should keep all chatter to a minimum when `CYGSEM_IO_FLASH_CHATTER` is not defined. All output should use the print function in the *`pf`* in *`flash_info`* and not `diag_printf()`

Device driver functions which manipulate the state of the flash so that it cannot be read from for program execute need to ensure there code is placed into RAM. The linker will do this if the appropriate attribute is added to the function. e.g:

```
int flash_program_buf(volatile flash_t *addr, flash_t *data, int len,
                      unsigned long block_mask, int buffer_size)
__attribute__ ((section (".2ram.flash_program_buf")));
```

Chapter 64. FLASH I/O devices

It can be useful to be able to access FLASH devices using the generic I/O infrastructure found in `CYGPKG_IO`, and the generic FLASH layer provides an optional ability to do so. This allows the use of functions like `cyg_io_lookup()`, `cyg_io_read()`, `cyg_io_write()` etc.

Additionally it means that, courtesy of the “devfs” pseudo-filesystem in the file I/O layer (`CYGPKG_IO_FILEIO`), functions like `open()`, `read()`, `write()` etc. can even be used directly on the FLASH devices.

Overview and CDL Configuration

This package implements support for FLASH as an I/O device by exporting it as if it is a block device. To enable this support, the CDL option titled “Provide /dev block devices”, also known as `CYGPKG_IO_FLASH_BLOCK_DEVICE`, must be enabled. (There is also a legacy format alternative which is now deprecated).

There are two methods of addressing FLASH as a block device:

1. Using the FLASH Information System (FIS) - this is a method of defining and naming FLASH partitions, usually in RedBoot. This option is only valid if RedBoot is resident and was used to boot the application. To reference FLASH partitions in this way, you would use a device name of the form `/dev/flash/fis/`*`partition-name`* , for example `/dev/flash/fis/jffs2` to reference a FIS partition named JFFS2.

   The CDL option `CYGFUN_IO_FLASH_BLOCK_FROM_FIS` must be enabled for this support.

2. Referencing by device number, offset and length - this method extracts addressing information from the name itself. The form of the device would be `/dev/flash/`*`device-number`*`/`*`offset`*`[,`*`length`* `]`

   `device-number` This is a fixed number allocated to identify each FLASH region in the system. The first region is numbered 0, the second 1, and so on. If you have only one FLASH device, it will be numbered 0.

   `offset` This is the index into the FLASH region in bytes to use. It may be specified as decimal, or if prefixed with `0x`, then hexadecimal.

   `length` This field is optional and defaults to the remainder of the FLASH region. Again it may be specified in decimal or hexadecimal.

   Some examples:

   /dev/flash/0/0 This defines a block device that uses the entirety of FLASH region 0.

   /dev/flash/1/0x20000,65536 This defines a block device which points inside FLASH region 1, starting at offset 0x20000 (128Kb) and extending for 64Kb.

   /dev/flash/0/65536 This defines a block device which points inside FLASH region 0, starting at offset 64Kb and continuing up to the end of the device.

   Obviously great care is required when constructing the device names as using the wrong specification may subsequently overwrite important areas of FLASH, such as RedBoot. Using the alternative via FIS names is preferable as these are less error-prone to configure, and also allows for the FLASH region to be relocated without requiring program recompilation.

Using FLASH I/O devices

The FLASH I/O block devices can be accessed, read and written using the standard interface supplied by the generic I/O (CYGPKG_IO) package. These include the functions: `cyg_io_lookup()` to access the device and get a handle, `cyg_io_read()` and `cyg_io_write()` for sequential read and write operations, `cyg_io_bread()` and `cyg_io_bwrite()` for random access read and write operations, and `cyg_io_get_config()` and `cyg_io_setconfig()` for run-time configuration inspection and control.

However there are two aspects that differ from some other I/O devices accessed this way:

1. The first is that the lookup operation uses up resources which must be subsequently freed when the last user of the I/O handle is finished. The number of FLASH I/O devices that may be simultaneously opened is configured with the CYGNUM_IO_FLASH_BLOCK_DEVICES CDL option. After the last user is finished, the device may be closed using `cyg_io_setconfig()` with the CYG_IO_SET_CONFIG_CLOSE key. Reference counting to ensure that it is only the last user that causes a close, is left to higher layers.

2. The second is that write operations assume that the flash is already erased. Attempting to write to Flash that has already been written to may result in errors. Instead FLASH must be erased before it may be written.

FLASH block devices can also be read and written using the standard POSIX primitives, `open()`, `close()`, `read()`, `write()`, `lseek()`, and so on if the POSIX file I/O package (CYGPKG_FILEIO) is included in the configuration. As with the eCos generic I/O interface you must call `close()` to ensure resources are freed when the device is no longer used.

Other configuration keys are provided to perform FLASH erase operations, and to retrieve device sizes, and FLASH block sizes at a particular address. These operations are accessed with `cyg_io_get_config()` (or if using the POSIX file I/O API, `cyg_fs_getinfo()`) with the following keys:

CYG_IO_GET_CONFIG_FLASH_ERASE

This erases a region of FLASH. `cyg_io_get_config()` must be passed a structure defined as per the following, which is also supplied in `<cyg/io/flash.h>`:

```
typedef struct {
  CYG_ADDRESS offset;
  size_t len;
  int flasherr;
  cyg_flashaddr_t err_address;
} cyg_io_flash_getconfig_erase_t;
```

In this structure, *`offset`* specifies the offset within the block device to erase, *`len`* specifies the amount to address, *`flasherr`* is set on return to specify an error with the FLASH erase operation itself, and *`err_address`* is used if there was an error to specify at which address the error happened.

CYG_IO_GET_CONFIG_FLASH_LOCK

This protects a region of FLASH using the locking facilities available on the card, if provided by the underlying driver. `cyg_io_get_config()` must be passed a structure defined as per the following:

```
typedef struct {
  CYG_ADDRESS offset;
  size_t len;
  int flasherr;
  cyg_flashaddr_t err_address;
} cyg_io_flash_getconfig_lock_t;
```

In this structure, *`offset`* specifies the offset within the block device to lock, *`len`* specifies the amount to address, *`flasherr`* is set on return to specify an error with the FLASH lock operation itself, and *`err_address`* is used if there was an error to specify at which address the error happened. If locking support is not available -EINVAL will be returned from `cyg_io_get_config()`.

CYG_IO_GET_CONFIG_FLASH_UNLOCK

This disables protection for a region of FLASH using the unlocking facilities available on the card, if provided by the underlying driver. `cyg_io_get_config()` must be passed a structure defined as per the following:

```
typedef struct {
  CYG_ADDRESS offset;
  size_t len;
  int flasherr;
  cyg_flashaddr_t err_address;
} cyg_io_flash_getconfig_unlock_t;
```

In this structure, *offset* specifies the offset within the block device to unlock, *len* specifies the amount to address, *flasherr* is set on return to specify an error with the FLASH unlock operation itself, and *err_address* is used if there was an error to specify at which address the error happened. If unlocking support is not available -EINVAL will be returned from `cyg_io_get_config()`.

CYG_IO_GET_CONFIG_FLASH_DEVSIZE

This returns the size of the FLASH block device. The `cyg_io_get_config()` function must be passed a structure defined as per the following, which is also supplied in `<cyg/io/flash.h>`:

```
typedef struct {
  size_t dev_size;
} cyg_io_flash_getconfig_devsize_t;
```

In this structure, *dev_size* is used to return the size of the FLASH device.

CYG_IO_GET_CONFIG_FLASH_DEVADDR

This returns the address in the virtual memory map that the generic flash layer has been informed that this FLASH device is mapped to. Note that some flash devices such as dataflash are not truly memory mapped, and so this function only returns useful information when used with a true memory mapped FLASH device. The `cyg_io_get_config()` function must be passed a structure defined as per the following, which is also supplied in `<cyg/io/flash.h>`:

```
typedef struct {
  cyg_flashaddr_t dev_addr;
} cyg_io_flash_getconfig_devaddr_t;
```

In this structure, *dev_addr* is used to return the address corresponding to the base of the FLASH device in the virtual memory map.

CYG_IO_GET_CONFIG_FLASH_BLOCKSIZE

This returns the size of a FLASH block at a supplied offset in the FLASH block device. The `cyg_io_get_config()` function must be passed a structure defined as per the following, which is also supplied in `<cyg/io/flash.h>`:

```
typedef struct {
  CYG_ADDRESS offset;
  size_t block_size;
} cyg_io_flash_getconfig_blocksize_t;
```

In this structure, *offset* specifies the address within the block device of which the FLASH block size is required - a single FLASH device may contain blocks of differing sizes. The *block_size* field is used to return the block size at the specified offset.

Chapter 65. Common SPI Flash Memory Device Driver

Name

eCos Common Support for SPI Flash Memory Devices — Overview

Description

The CYGPKG_DEVS_FLASH_SPI_COMMON package provides an abstraction layer between the standard eCos I/O Flash API package (CYGPKG_IO_FLASH) and hardware specific *x*SPI controller drivers. This allows for serial memory device support to be shared across architectures and platforms, avoiding the need for the H/W specific device drivers to duplicate manufacturer or device specific information in each H/W *x*SPI driver implementation.

Note

Many eCos targets will still use the older driver model where the architecture specific device driver will implement direct support for a specific subset of SPI memory devices. Only newer ports, and some ports that have been explicitly updated, will reference this common approach. The goal is to bring as much support as is relevant for SPI memory devices into this single package, to aid maintenance and porting, with a simpler H/W device driver implementation for the platform specific component.

This common package presents as a Flash V2 device driver to the Flash I/O layer.

The package allows for JEDEC Serial Flash Discoverable Parameters (SFDP) device supplied parameter tables to be used to configure the required device access. The package currently supports JESD216D.01 and earlier devices. It will work with devices that implement newer versions of the standard, but will be limited to the backwards compatible features .

Caution

At the time of writing not all of the SFDP table declared configurations have been tested.

The following table is not an exhaustive list of tested platforms/devices, but an example set:

Platform	Device	*x*SPI	Notes
mimxrt1050_evk	IS25WP064AJBLE	Quad	64-Mbit
samv71_xult	S25FL116K	Quad	16-Mbit
stm32h735_disco	MX25LM51245GXDI00	Octal	512-Mbit
-	W25Q32JV	Quad	32-Mbit
-	W25Q512JV-DTR	Quad	512-Mbit

Configuration Options

The common SPI memory driver package will be loaded automatically when configuring eCos for a target with suitable hardware. However the driver will be inactive unless the generic flash package CYGPKG_IO_FLASH is loaded. It may be necessary to add the generic CYGPKG_IO_FLASH package to the configuration explicitly before the driver functionality becomes available. There should never be any requirement to load or unload the CYGPKG_DEVS_FLASH_SPI_COMMON driver package.

The flash driver provides a small number of configuration options which application developers may use to control features provided by the package.

CYGFUN_DEVS_FLASH_SPI_COMMON_MEMMAPPED

> If this option is enabled then the flash device is configured for memory mapped mode **when** the underlying H/W driver and platform HAL support such use.

Memory mapped access allows the CPU to directly read data or execute code from the flash area. The default is for the feature to be enabled, which is desired for most configurations. However, in some situations, indirect (e.g. DMA) access may be preferred for performance reasons, in which case this feature can be disabled.

When the option is enabled some further configuration options are presented:

`CYGIMP_DEVS_FLASH_SPI_COMMON_MEMMAPPED_XIPISR`

This option should be enabled if ISRs or DSRs are to execute from the memory mapped xSPI space.

Note

This will adversely affect the interrupt latency of the system, since certain xSPI operations will need to disable interrupts when switching out of memory mapped mode (e.g. erasing). So this feature should only be enabled if actually required.

`CYGIMP_DEVS_FLASH_SPI_COMMON_MEMMAPPED_DRIVER`

If the eCos application providing the xSPI flash driver is executing from the flash device (using memory mapped mode) then some critical functionality **must** execute from a different memory space (e.g. SRAM).

`CYGFUN_DEVS_FLASH_SPI_COMMON_SOFTRESET`

This option controls whether support for device soft reset is enabled. The developer is not normally required to modify this option

Fixed settings

If the target system needs to support devices without SFDP tables, or where the tables provide inconsistent or incomplete information, then a hook mechanism is provided based on the standard `RDID` command (`0x9F`). The `flash_csm_fixedset.h` provides the `CYG_CSM_FIXEDSET(localname, mask, id, init_function)` macro to allow an instantation of a `cyg_csm_family_t` structure to be added to the table scanned by this common flash driver.

This provides a mechanism for partially or completely updating the internal context used to describe a device to the common flash code and the underlying H/W driver layer.

Currently SFDP fix-up support is provided for the Winbond `W25Q512JV` parts when the `CYGINT_DEVS_FLASH_SPI_COMMON_HARDWIRED_W25Q512` interface is implemented. Normally the required `implements` is performed by the target platform CDL as required, and should not need to be managed by application developers.

Name

Common SPI Memory Device Hardware Driver — Interface to a hardware device driver

Description

Note

Application developers should not normally need to concern themselves with the internal API between this common layer and the H/W specific device drivers. The following information is primarily for H/W device driver developers.

In most cases the platform (PLF) declares the individual flash driver instances. The top-level descriptor as used with the flash API (`CYGPKG_IO_FLASH`) should reference the flash API functions provided by this package (`cyg_devs_flash_common_funs`) as well as provide a per-instance `cyg_flash_csm_context_t` structure initialised with a reference to the instance-specific hardware driver descriptor in the `p_hwdriver` field.

The driver instance specific `cyg_spi_common_hwdriver_t` descriptor is used to describe the hardware driver specific features to this common layer.

```
Flash API                      Common                                   H/W Driver
(struct cyg_flash_dev).priv -> (cyg_flash_csm_context_t).p_hwdriver -> (cyg_spi_common_hwdriver_t)
```

All architecture/platform/HAL eCos *x*SPI device drivers using the `CYGPKG_DEVS_FLASH_SPI_COMMON` package must implement a standard interface defined by the header `<cyg/io/flash_csm_dev.h>`. The interface descriptor structure includes a private pointer for the H/W driver context, a “features” set and a set of function pointers for various operations: initialization, memory operation, memory-mapped access and general configuration.

```
struct cyg_spi_common_hwdriver {
    // H/W driver private (opaque) context:
    const void *p_io; // H/W driver specific I/O information

    // H/W driver feature set descriptor:
    const cyg_flash_csm_features_t * const p_features;

    // Common H/W driver API
    cyg_spi_common_hwdriver_init *init; // initialisation function
    cyg_spi_common_hwdriver_op *op; // single command operation function
    cyg_spi_common_hwdriver_mm_start *mm_start; // memory-mapped start/enable
    cyg_spi_common_hwdriver_mm_stop *mm_stop; // memory-mapped stop/disable
    cyg_spi_common_hwdriver_config *config; // get/set config+control
};
```

Hardware Driver Features

The `p_features` structure provides fixed information used to describe to this common layer the features and settings of the H/W driver instance:

```
typedef struct cyg_flash_csm_features {
    cyg_uint32 avail; // bitmask of H/W driver available features
    cyg_uint32 mmaddr; // if MM capable, base address for MM region
    // Since early JESD216 standards do not provide a mechanism for the device
    // to report its maximum frequency we allow the platform/variant HAL to be
    // configured with maximum rates.
    cyg_uint32 max_sdr; // if non-zero platform/variant HAL provided maximum SDR baudrate
    cyg_uint32 max_ddr; // if non-zero platform/variant HAL provided maximum DDR baudrate
    cyg_uint32 nmodes; // number of modes present in modes vector
    const cyg_uint32 * const p_modes; // pointer to vector of FLASH_CSM_OP_MODE_MASK
                                      // covered bitmasks for available modes
} cyg_flash_csm_features_t;
```

The `p_features` structure allows the H/W driver to report the SPI modes capable by the device driver. This can, for example, be used in conjunction with information gathered from the device using SFDP to select the common subset of supported access methods: e.g. Quad (QSPI) vs Octal (OSPI).

The current set of **avail**able feature flags indicating H/W driver support is:

Flag	Description
`FLASH_CSM_FEATURE_ADDR3`	3-byte addressing supported
`FLASH_CSM_FEATURE_ADDR4`	4-byte addressing supported
`FLASH_CSM_FEATURE_ADDR5`	5-byte addressing supported
`FLASH_CSM_FEATURE_MODEBITS`	Driver supports writing mode bits (sometimes referred to as OPT or Alternate) bits
`FLASH_CSM_FEATURE_CMD8`	8-bit commands supported
`FLASH_CSM_FEATURE_CMD16`	16-bit commands supported
`FLASH_CSM_FEATURE_MM`	Memory mapped access supported
`FLASH_CSM_FEATURE_MM_XIP`	eXecute-In-Place supported
`FLASH_CSM_FEATURE_MM_SM`	Driver can memory-map serial-memory as well as data-memory
`FLASH_CSM_FEATURE_MM_SM_RA`	Random Access supported for memory mapped serial-memory
`FLASH_CSM_FEATURE_CR`	Continuous Read supported
`FLASH_CSM_FEATURE_DS`	Data Strobe signalling available

The `p_modes` pointer references the `nmodes` deep vector of access modes supported, encoded using the same OP bitmask encoding as used for the individual memory operations. For example an Octal (OSPI) capable driver might define:

```
// List of possible modes for this driver:
static const cyg_uint32 cyg_hwdriver_modes[] = {
    // 8-line Octal (OSPI)
    FLASH_CSM_OP_MODE_1S1S8S, //  0
    FLASH_CSM_OP_MODE_1S8S8S, //  1
    FLASH_CSM_OP_MODE_8S8S8S, //  2
    FLASH_CSM_OP_MODE_8D8D8D, //  3
    // 4-line QSPI
    FLASH_CSM_OP_MODE_1S1S4S, //  4
    FLASH_CSM_OP_MODE_1S4S4S, //  5
    FLASH_CSM_OP_MODE_4S4S4S, //  6
    FLASH_CSM_OP_MODE_4S4D4D, //  7
    // 2-line
    FLASH_CSM_OP_MODE_1S1S2S, //  8
    FLASH_CSM_OP_MODE_1S2S2S, //  9
    FLASH_CSM_OP_MODE_2S2S2S, // 10
    // 1-line
    FLASH_CSM_OP_MODE_1S1S1S, // 11
};
```

Referencing the vector in its feature descriptor:

```
static const cyg_flash_csm_features_t hwdriver1_features = {
    ..elided..
    .nmodes = NUMOF_(cyg_hwdriver_modes),
    .p_modes = &cyg_hwdriver_modes[0]
};
```

Hardware Driver-Specific Structure

The `p_io` pointer allows the H/W device driver to hold per-instance private data as needed for the operation of the driver.

Normally the driver context would be split into read-only, constant, data that could be held in the code with only the truly dynamic context occupying RAM space. See the Hardware Example below for an outline.

Functions

The H/W driver provides its common driver API via the `cyg_spi_common_hwdriver_t` descriptor. For the function pointers the `NULL` value can be used to indicate that the relevant support is not required. Only the `op` function **must** be provided, though it is unlikely that the driver would not require a `init` function to be called at startup.

Initialization

```
typedef int cyg_spi_common_hwdriver_init(const void *p_info, cyg_bool do_reset, cyg_uint32 baudrate);
```

This function allows the H/W driver to complete the run-time initialisation of any dynamic context needed, along with setting up the controller in preperation for the first operation.

This can consist of attaching any ISR/DSR or DMA handlers needed, setting up I/O pin configurations (if the platform/architecture uses pin multiplexing), etc.

The `reset` parameter indicates whether the upper layer requires the hardware to be “reset” back to a known state.

The `baudrate` is the clock frequency that will be used for the initial operations. Normally (for SFDP devices) this will be 50MHz.

The function call should return standard flash API status code. e.g. `CYG_FLASH_ERR_OK` to indicate success.

Memory Operation

```
typedef cyg_bool cyg_spi_common_hwdriver_op(const void *p_info, const cyg_flash_csm_op_t *p_op);
```

This is the core operation of the H/W driver interface. The referenced `cyg_flash_csm_op_t` pointer `p_op` describes the basic operation to be performed on the serial memory device.

The `p_info` pointer is a reference to the H/W driver specific context supplied when declaring the flash descriptor.

The function should return a simple boolean `true` success indication, or `false` if an error occurred.

The `<cyg/io/flash_csm_dev.h>` header defines the referenced `p_op` structure:

```
typedef struct cyg_flash_csm_op {
    cyg_uint32 mode; // Encoded bus information and control
    cyg_uint32 cmdflags; // Instruction CMD and extra control flags
    cyg_uint32 address; // Device relative address
    cyg_uint32 opt; // Upto 32-bits of OPT (mode-bits; alternate) data
    cyg_uint32 timeout; // Millisecond timeout for operation
    cyg_uint32 nbytes; // Non-zero is number of valid bytes from p_buff
    cyg_uint8 *p_buff; // Pointer to data buffer for transfer
} cyg_flash_csm_op_t;
```

The `mode` and `cmdflags` fields define whether the other fields are used/required. For example, a simple device operation to enable the write-latch will not normally require any data to be written (or read) and so the `nbytes` and `p_buff` fields would not be referenced for that operation.

The `<cyg/io/flash_csm_dev.h>` header is the definitive source for the bitmask use for the `mode` and `cmdflags` fields and should be examined by the developer writing a H/W driver. The header contains helper manifests and macros to aid the decoding of the fields.

mode

The `mode` bitmask encodes the operation. It contains some single-bit boolean flags as well as some multi-bit values with specific encodings.

The value `0x00000000` (`CSM_OP_INVALID`) is never a valid descriptor since we should always have at least one of the instruction, address, opt or data phases defined.

An operation compromises one or more phases in the order: Instruction, Address, Mode and Data. The `mode` bitmask encodes which phases are enabled, and hence their associated bitmask flags and values are valid, as well as some general operation control flags.

1. **Instruction phase**

   If an **instruction** phase is required then the `FLASH_CSM_OP_IP` mask will have the value `FLASH_CSM_OP_IP_ACTIVE`, otherwise the flag will have the value `FLASH_CSM_OP_IP_NONE`.

   If `FLASH_CSM_OP_IP_ACTIVE` then the `FLASH_CSM_OP_IW_MASK` bits encode the number of lines to be used for the instruction phase:

Value	Description
`FLASH_CSM_OP_IW_LINE1`	1-line (SPI)
`FLASH_CSM_OP_IW_LINE2`	2-lines (Dual)
`FLASH_CSM_OP_IW_LINE4`	4-lines (Quad)
`FLASH_CSM_OP_IW_LINE8`	8-lines (Octal)

   If `FLASH_CSM_OP_IP_ACTIVE` then the `p_op` field `cmdflags` holds the command instruction.

   The command length is encoded by the `FLASH_CSM_OP_CL` mask. The value should be `FLASH_CSM_OP_CL_8BIT` for 8-bit commands, and `FLASH_CSM_OP_CL_16BIT` for 16-bit commands.

   If `FLASH_CSM_OP_IP_ACTIVE` then the `FLASH_CSM_OP_IP_IR` mask encodes whether the instruction phase is Single-Data-Rate (`FLASH_CSM_OP_IR_SDR`) or Dual-Data-Rate (`FLASH_CSM_OP_IR_DDR`).

2. **Address phase**

   If an **address** phase is required then the `FLASH_CSM_OP_AP` mask will have the value `FLASH_CSM_OP_AP_ACTIVE`, otherwise the flag will have the value `FLASH_CSM_OP_AP_NONE`.

   If `FLASH_CSM_OP_AP_ACTIVE` then the `FLASH_CSM_OP_AB_MASK` bits encode the number of bytes used for an address:

Value	Description
`FLASH_CSM_OP_AB_3BYTE`	3-byte (24-bit) address
`FLASH_CSM_OP_AB_4BYTE`	4-byte (32-bit) address
`FLASH_CSM_OP_AB_5BYTE`	5-byte (40-bit) address (not currently supported)

   If `FLASH_CSM_OP_AP_ACTIVE` then the `FLASH_CSM_OP_AW_MASK` bits encode the number of lines to be used for the address phase:

Value	Description
`FLASH_CSM_OP_AW_LINE1`	1-line (SPI)
`FLASH_CSM_OP_AW_LINE2`	2-lines (Dual)
`FLASH_CSM_OP_AW_LINE4`	4-lines (Quad)
`FLASH_CSM_OP_AW_LINE8`	8-lines (Octal)

   If `FLASH_CSM_OP_AP_ACTIVE` then the `p_op` field `address` should define the **device** relative address for the operation.

If FLASH_CSM_OP_AP_ACTIVE then the FLASH_CSM_OP_AR mask encodes whether the address phase is Single-Data-Rate (FLASH_CSM_OP_AR_SDR) or Dual-Data-Rate (FLASH_CSM_OP_AR_DDR).

3. **Mode phase**

   Different hardware implementations support OPT/Alternate bytes of differing sizes and limitations. The JESD216D.01 standard describes these as “mode bits” and are sent after the address phase.

   If a **mode** phase is required then the FLASH_CSM_OP_MP mask will have the value FLASH_CSM_OP_MP_ACTIVE, otherwise the flag will have the value FLASH_CSM_OP_MP_NONE.

   If FLASH_CSM_OP_MP_ACTIVE then the FLASH_CSM_OP_MB_MASK bits encode the number of **bits** (range 1..32). The mode bits are signalled on the same number of SPI lines as the address phase.

   If FLASH_CSM_OP_MP_ACTIVE then the p_op field opt holds the mode bits value.

   If FLASH_CSM_OP_MP_ACTIVE then the FLASH_CSM_OP_MR mask encodes whether the mode bits phase is Single-Data-Rate (FLASH_CSM_OP_MR_SDR) or Dual-Data-Rate (FLASH_CSM_OP_MR_DDR).

4. **Data phase**

   If an **data** phase is required then the FLASH_CSM_OP_DP mask will have the value FLASH_CSM_OP_DP_ACTIVE, otherwise the flag will have the value FLASH_CSM_OP_DP_NONE.

   If FLASH_CSM_OP_DP_ACTIVE then the FLASH_CSM_OP_DW_MASK bits encode the number of lines to be used for the data phase:

Value	**Description**
FLASH_CSM_OP_DW_LINE1	1-line (SPI)
FLASH_CSM_OP_DW_LINE2	2-lines (Dual)
FLASH_CSM_OP_DW_LINE4	4-lines (Quad)
FLASH_CSM_OP_DW_LINE8	8-lines (Octal)

   If FLASH_CSM_OP_DP_ACTIVE then the p_op field nbytes should define the number of valid memory bytes referenced by the p_buff pointer.

   If FLASH_CSM_OP_DP_ACTIVE then the FLASH_CSM_OP_DR mask encodes whether the address phase is Single-Data-Rate (FLASH_CSM_OP_DR_SDR) or Dual-Data-Rate (FLASH_CSM_OP_DR_DDR).

The mode field also encodes other information that may be required by the H/W driver.

The FLASH_CSM_OP_SD mask has the value FLASH_CSM_OP_SD_DATA when the operation is accessing the data-memory of the flash device, and the value FLASH_CSM_OP_SD_DEVICE if accessing device-internal “memory” (e.g. SFDP tables, unique IDs, etc.).

The FLASH_CSM_OP_TD mask encodes the Transfer Direction, whether the operation is a read (FLASH_CSM_OP_TD_READ) or a write (FLASH_CSM_OP_TD_WRITE).

The FLASH_CSM_OP_DA indicates whether the transfer should be undertaken by the operation call directly (FLASH_CSM_OP_DA_XFER) or should be deferred for subsequent memory-mapped access (FLASH_CSM_OP_DA_DEFER).

When reading the FLASH_CSM_OP_CR mask indicates that the device is configured for Continuous Read. If FLASH_CSM_OP_CR_NONE then continuous read is not configured. If FLASH_CSM_OP_CR_ACTIVE then it indicates that the controller can setup access for continuous read mode.

The FLASH_CSM_OP_DS encodes whether the operation requires the Data Strobe signal (FLASH_CSM_OP_DS_ACTIVE) or the signal is not required (FLASH_CSM_OP_DS_NONE).

cmdflags

When required by the mode bitmask the cmdflags field encodes the command code (8- or 16-bit), the number of Delay Cycles and whether the timeout is valid.

timeout

The timeout value is only valid if the cmdflag flag FLASH_CSM_CMD_TO_VALID is set, otherwise the field is ignored.

The timeout field is a millisecond operation timeout, or one of the special values: CYG_FLASH_CSM_TO_NOWAIT or CYG_FLASH_CSM_TO_INFINITY. The ...NOWAIT value is for an immediate, polled, return without waiting, operation. The ...INFINITY value is for when the operation should block indefinately until completion (success or error indicated).

Memory Mapped

```
typedef cyg_bool cyg_spi_common_hwdriver_mm_start(const void *p_info);
```

```
typedef cyg_bool cyg_spi_common_hwdriver_mm_stop(const void *p_info);
```

The optional mm_start and mm_stop functions are used to notify the H/W driver when memory-mapped state is being changed.

Since most devices cannot continue to provide memory-mapped access whilst being erased or programmed the common driver layer allows the H/W driver to perform any controller operations needed to ensure the hardware is in the correct mode. For example, this may include changing the cached/uncached state for the memory covered by flash device, or require specific controller operations to abort any active memory-mapped pre-fetching that may be occurring.

Configuration

```
typedef cyg_bool cyg_spi_common_hwdriver_config(const void *p_info,
                                                cyg_uint32 key, void *p_buff, cyg_uint32 *p_len);
```

The optional H/W driver supplied config function is used with specific configuration key values to interact with the H/W driver:

CYG_CSM_CFG_SET_BAUDRATE
CYG_CSM_CFG_GET_BAUDRATE

> Used by the common layer to control the clock frequency (normally named SCK) of the H/W driver instance. The max_sdr and max_ddr fields of the H/W driver supplied (cyg_flash_csm_features_t) descriptor allow the H/W driver to limit the upper frequency to that supported by the specific controller, with the common layer device support being used for the actual flash memory device maximum rates possible.
>
> The frequency setting is a simple 32-bit unsigned integer (e.g. cyg_uint32).

CYG_CSM_CFG_SET_MEMTYPE
CYG_CSM_CFG_GET_MEMTYPE

> If required, for OCTOSPI devices, these options provide common layer control of the memory type as used by the H/W driver.
>
> The memory type setting is currently a simple 32-bit unsigned integer (e.g. cyg_uint32):
>
> CYG_CSM_MEMTYPE_DTR_D0D1
>
> > This option indicates Micron style byte-ordering.

CYG_CSM_MEMTYPE_DTR_D1D0

This option indicates Macronix style byte-ordering.

CYG_CSM_MEMTYPE_STANDARD

Indicates normal SPI access.

CYG_CSM_MEMTYPE_UNDEFINED

This value indicates that no specific memory type has been set.

CYG_CSM_CFG_SET_DATASTROBE
CYG_CSM_CFG_GET_DATASTROBE

For configurarions that use a data strobe signal (DQS) these config options provide the mechanism for informing the H/W driver of the device data strobe timing.

The data strobe settings are a simple 32-bit unsigned integer (e.g. cyg_uint32):

CYG_CSM_DATASTROBE_START

Start of first data bit aligned with the first rising edge of DQS.

CYG_CSM_DATASTROBE_MIDDLE

First rising edge of DQS in the middle of the first data bit.

CYG_CSM_DATASTROBE_HALF

First rising edge of DQS is half a clock cycle before the start of the first data bit.

CYG_CSM_DATASTROBE_UNDEFINED

This setting is used to indicate that the data strobe timing is not defined or unknown.

Example

The following section provides an example skeleton of how a H/W driver instance can be declared.

Since device drivers normally have a requirement for some fixed (constant) information describing the hardware configuration as well as possibly some dynamic state to hold run-time information (e.g. ISR or DSR state) the example below shows a simple framework. The example hw_driver_ctx_t structure used for the dynamic context and the hw_driver_io_t structure holding the constant/fixed information are specific to the H/W driver implementation and the underlying H/W controller requirements.

For our example instance in the H/W driver source we can provide a RAM based private context for the dynamic state:

```
static hw_driver_ctx_t hw_dynamic1 = {};
```

This can then be referenced from a constant (normally placed in read-only memory by the linker) structure with the fixed information for the driver along with a pointer to the RAM based dynamic run-time context structure:

```
static const hw_driver_io_t hw_context1 {
    .p_ctx = &hw_driver_dynamic1, // dynamic H/W driver state
    // The fixed information needed by the H/W driver
    .intr_vec = <HAL_INTERRUPT_NUMBER>
    .pin_sclk = <HAL/PLF_SCLK_PIN_DESCRIPTOR>
    ..elided..
};
```

The driver can then provide a per-instance common H/W driver API structure referencing the H/W driver context and the features and functions provided by the driver:

```
const cyg_spi_common_hwdriver_t cyg_dev_flash_csm_example1= {
    .p_io = &hw_context1,
    .p_features = &hw_features,
    .init = hw_init,
    .op = hw_op,
    .mm_start = NULL, // op interface sufficient for this driver
    .mm_stop = NULL, // op interface sufficient for this driver
    .config = hw_config
};
```

With the H/W driver providing the `cyg_spi_common_hwdriver_t` structure the platform specific sources would then reference the H/W driver instance when declaring the flash object in the platform/HAL specific source file:

```
static struct cyg_flash_block_info cyg_flash_common_block_info;

static cyg_flash_csm_context_t cyg_flash_common_ctx = {
    .p_hwdriver = &cyg_dev_flash_csm_example1, // reference H/W instance
};

CYG_FLASH_DRIVER(cyg_common_device,
                 &cyg_devs_flash_common_funs,
                 0,
                 <BASE_ADDR>, // start (normally same as p_features.mmaddr field
                 <BASE_ADDR>, // end (depends on detected device, so filled in at run-time)
                 1, // number of flash block info structures
                 &cyg_flash_common_block_info,
                 &cyg_flash_common_ctx);
```

After successful flash device initialisation the `struct cyg_flash_dev` field `end` will hold the end address for the flash area. The start and end addresses are used by the flash API to select the relevant device descriptor when accessing a flashg area.

When called, the common layer code can use the `p_hwdriver` field to access the specific H/W instance used to access the actual flash device for the area, with the H/W driver subsequently de-referencing its own structures to access the fixed and dynamic portions of its context.

Chapter 66. AMD AM29xxxxx Flash Device Driver

Name

eCos Support for AMD AM29xxxxx Flash Devices and Compatibles — Overview

Description

The CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2 AMD AM29xxxxx V2 flash driver package implements support for the AM29xxxxx family of flash devices and compatibles. Normally the driver is not accessed directly. Instead application code will use the API provided by the generic flash driver package CYGPKG_IO_FLASH, for example by calling functions like cyg_flash_program.

The driver imposes one restriction on application code which developers should be aware of: when programming the flash the destination addresses must be aligned to a bus boundary. For example if the target hardware has a single flash device attached to a 16-bit bus then program operations must involve a multiple of 16-bit values aligned to a 16-bit boundary. Note that it is the bus width that matters, not the device width. If the target hardware has two 16-bit devices attached to a 32-bit bus then program operations must still be aligned to a 32-bit boundary, even though in theory a 16-bit boundary would suffice. In practice this is rarely an issue, and requiring the larger boundary greatly simplifies the code and improves performance.

Note

Many eCos targets with AM29xxxxx or compatible flash devices will still use the older driver package CYGPKG_DEVS_FLASH_AMD_AM29XXXXX. Only newer ports and some older ports that have been converted will use the V2 driver. This documentation only applies to the V2 driver.

Configuration Options

The AM29xxxxx flash driver package will be loaded automatically when configuring eCos for a target with suitable hardware. However the driver will be inactive unless the generic flash package CYGPKG_IO_FLASH is loaded. It may be necessary to add this generic package to the configuration explicitly before the driver functionality becomes available. There should never be any need to load or unload the AM29xxxx driver package.

The driver contains a small number of configuration options which application developers may wish to tweak. CYGNUM_DEVS_FLASH_AMD_AM29XXXXX_V2_PROGRAM_BURST_SIZE controls the program operation. On typical hardware programming the flash requires disabling interrupts and the cache for an extended period of time. Some or all of the flash hardware will be unusable while each word is programmed, and disabling interrupts is the only reliable way of ensuring that no interrupt handler or other thread will try to access the flash in the middle of an operation. This can have a major impact on the real-time responsiveness of the typical applications. To ameliorate this the driver wil perform writes in small bursts, briefly re-enabling the cache and interrupts between each burst. The number of words written per burst is controlled by this configuration operation: reducing the value will improve real-time response but will add overhead, so the actual flash program operation will take longer; conversely more writes per burst will worsen response times but reduce overhead.

Similarly erasing a block of flash safely requires disabling interrupts and the cache. Erasing a block can easily take a second or so, and disabling interrupts for such a long period of time is usually undesirable. Hence the driver can also perform the erase in bursts, using the hardware's suspend and resume capabilities. CYGNUM_DEVS_FLASH_AM29XXXXX_V2_ERASE_BURST_DURATION controls the number of polling loops during which interrupts are disabled. Reducing its value improves responsiveness at the cost of performance, and increasing its value has the opposite effect. Note that too low a value may prevent the erase operation from working at all: the chip will be spending its time suspending and resuming, rather than actually performing the erase. The minimum value will depend on the specific hardware.

There are a number of other options, relating mostly to hardware characteristics. It is very rare that application developers need to change any of these. For example the option CYGNUM_DEVS_FLASH_AMD_AM29XXXXX_V2_ERASE_REGIONS may need a non-default value if the flash devices used on the target have an unusual boot block layout. If so the platform HAL will impose a requires constraint on this option and the configuration system will resolve the constraint. The only time it might be necessary to change the value manually is if the actual board being used is a variant of the one supported by the platform HAL and uses a different flash chip.

Name

Instantiating — including the driver in an eCos target

Synopsis

#include <cyg/io/am29xxxxx_dev.h>

`int` **`cyg_am29xxxxx_read_devid_XX`**`(`*`device`*`);`

Description

The AM29xxxxx family contains some hundreds of different flash devices, all supporting the same basic set of operations but with various common or uncommon extensions. The devices vary in capacity, performance, boot block layout, and width. There are also platform-specific issues such as how many devices are actually present on the board and where they are mapped in the address space. The AM29xxxxx driver package cannot know the details of every chip and every platform. Instead it is the responsibility of another package, usually the platform HAL, to supply the necessary information by instantiating some data structures. Two pieces of information are especially important: the bus configuration and the boot block layout.

Flash devices are typically 8-bits, 16-bits, or 32-bits wide (64-bit devices are not yet in common use). Most 16-bit devices will also support 8-bit accesses, but not all. Similarly 32-bit devices can be accessed 16-bits at a time or 8-bits at a time. A board will have one or more of these devices on the bus. For example there may be a single 16-bit device on a 16-bit bus, or two 16-bit devices on a 32-bit bus. The processor's bus logic determines which combinations are possible, and there will be a trade off between cost and performance: two 16-bit devices in parallel can provide twice the memory bandwidth of a single device. The driver supports the following combinations:

8
: A single 8-bit flash device on an 8-bit bus.

16
: A single 16-bit flash device on a 16-bit bus.

32
: A single 32-bit flash device on an 32-bit bus.

88
: Two parallel 8-bit devices on an 16-bit bus.

8888
: Four parallel 8-bit devices on a 32-bit bus.

1616
: Two parallel 16-bit devices on a 32-bit bus, with one device providing the bottom two bytes of each 32-bit datum and the other device providing the top two bytes.

16as8
: A single 16-bit flash device connected to an 8-bit bus.

32as16 A single 32-bit flash device connected to a 16-bit bus.

These configuration all require slightly different code to manipulate the hardware. The AM29xxxxx driver package provides separate functions for each configuration, for example `cyg_am29xxxxx_erase_16` and `cyg_am29xxxxx_program_1616`.

Caution

At the time of writing not all the configurations have been tested.

The second piece of information is the boot block layout. Flash devices are subdivided into blocks (also known as sectors - both terms are in common use). Some operations such as erase work on a whole block at a time, and for most applications a block is the smallest unit that gets updated. A typical block size is 64K. It is inefficient to use an entire 64K block for small bits of configuration data and similar information, so many flash devices also support a number of smaller boot blocks. A typical 2MB flash device could have a single 16K block, followed by two 8K blocks, then a 32K block, and finally 31 full-size 64K blocks. The boot blocks may appear at the bottom or the top of the device. So-called uniform devices do not have boot blocks, just full-size ones. The driver needs to know the boot block layout. With modern devices it can work this out at run-time, but often it is better to provide the information statically.

Example

In most cases flash support is specific to a platform. Even if two platforms happen to use the same flash device there are likely to be differences such as the location in the address map. Hence there is little possibility of re-using the platform-specific code, and this code should be placed in the platform HAL rather than in a separate package. Typically this involves a separate file and a corresponding compile property in the platform HAL's CDL:

```
cdl_package CYGPKG_HAL_M68K_ALAIA {
    …
    compile -library=libextras.a alaia_flash.c
    …
}
```

The contents of this file will not be accessed directly, only indirectly via the generic flash API, so normally it would be removed by link-time garbage collection. To avoid this the object file has to go into `libextras.a`.

The actual file `alaia_flash.c` will look something like:

```
#include <pkgconf/system.h>
#ifdef CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2

#include <cyg/io/flash.h>
#include <cyg/io/flash_dev.h>
#include <cyg/io/am29xxxxx_dev.h>

static const CYG_FLASH_FUNS(hal_alaia_flash_amd_funs,
    &cyg_am29xxxxx_init_check_devid_16,
    &cyg_flash_devfn_query_nop,
    &cyg_am29xxxxx_erase_16,
    &cyg_am29xxxxx_program_16,
    (int (*)(struct cyg_flash_dev*, const cyg_flashaddr_t, void*, size_t))0,
    &cyg_flash_devfn_lock_nop,
    &cyg_flash_devfn_unlock_nop);

static const cyg_am29xxxxx_dev hal_alaia_flash_priv = {
    .devid      = 0x45,
    .block_info = {
        { 0x00004000, 1 },
        { 0x00002000, 2 },
        { 0x00008000, 1 },
        { 0x00010000, 63 }
    }
};
```

```
CYG_FLASH_DRIVER(hal_alaia_flash,
                 &hal_alaia_flash_amd_funs,
                 0,
                 0xFFC00000,
                 0xFFFFFFFF,
                 4,
                 hal_alaia_flash_priv.block_info,
                 &hal_alaia_flash_priv
);
#endif
```

The bulk of the file is protected by an `#ifdef` for the AM29xxxxx flash driver. That driver will only be active if the generic flash support is enabled. Without that support there will be no way of accessing the device so instantiating the data structures would serve no purpose. The rest of the file is split into three structure definitions. The first supplies the functions which will be used to perform the actual flash accesses, using a macro provided by the generic flash code in `cyg/io/flash_dev.h`. The relevant ones have an `_16` suffix, indicating that on this board there is a single 16-bit flash device on a 16-bit bus. The second provides information specific to AM29xxxxx flash devices. The third provides the cyg_flash_dev structure needed by the generic flash code, which contains pointers to the previous two.

Functions

All eCos flash device drivers must implement a standard interface, defined by the generic flash code `CYGPKG_IO_FLASH`. This interface includes a table of seven function pointers for various operations: initialization, query, erase, program, read, locking and unlocking. The query operation is optional and the generic flash support provides a dummy implementation `cyg_flash_devfn_query_nop`. AM29xxxxx flash devices are always directly accessible so there is no need for a separate read function. The remaining functions are more complicated.

Usually the table can be declared `const`. In a ROM startup application this avoids both ROM and RAM copies of the table, saving a small amount of memory. `const` should not be used if the table may be modified by a platform-specific initialization routine.

Initialization

There is a choice of three main initialization functions. The simplest is `cyg_flash_devfn_init_nop`, which does nothing. It can be used if the cyg_am29xxxxx_dev and cyg_flash_dev structures are fully initialized statically and the flash will just work without special effort. This is useful if it is guaranteed that the board will always be manufactured using the same flash chip, since the nop function involves the smallest code size and run-time overheads.

The next step up is `cyg_am29xxxxx_init_check_devid_XX`, where `XX` will be replaced by the suffix appropriate for the bus configuration. It is still necessary to provide all the device information statically, including the *`devid`* field in the cyg_am29xxxxx_dev structure. This initialization function will attempt to query the flash device and check that the provided device id matches the actual hardware. If there is a mismatch the device will be marked uninitialized and subsequent attempts to manipulate the flash will fail.

If the board may end up being manufactured with any of a number of different flash chips then the driver can perform run-time initialization, using a `cyg_am29xxxxx_init_cfi_XX` function. This queries the flash device as per the Common Flash Memory Interface Specification, supported by all current devices (although not necessarily by older devices). The *`block_info`* field in the cyg_am29xxxxx_dev structure and the *`end`* and *`num_block_infos`* fields in the cyg_flash_dev structure will be filled in. It is still necessary to supply the *`start`* field statically since otherwise the driver will not know how to access the flash device. The main disadvantage of using CFI is that it increases the code size.

Caution

If CFI is used then the cyg_am29xxxxx_dev structure must not be declared `const`. The CFI code will attempt to update the structure and will fail if the structure is held in read-only memory. This would leave the flash driver non-functional.

A final option is to use a platform-specific initialization function. This may be useful if the board may be manufactured with one of a small number of different flash devices and the platform HAL needs to adapt to this. The AM29xxxxx driver provides a utility function to read the device id, `cyg_am29xxxxx_read_devid_XX`:

```
static int
alaia_flash_init(struct cyg_flash_dev* dev)
{
    int devid = cyg_am29xxxxx_read_devid_1616(dev);
    switch(devid) {
        case 0x0042 :
          …
        case 0x0084 :
          …
        default:
          return CYG_FLASH_ERR_DRV_WRONG_PART;
    }
}
```

There are many other possible uses for a platform-specific initialization function. For example initial prototype boards might have only supported 8-bit access to a 16-bit flash device rather than 16-bit access, but this problem was fixed in the next revision. The platform-specific initialization function can figure out which model board it is running on and replace the default `16as8` functions with faster `16` ones.

Erase and Program

The AM29xxxxx driver provides erase and program functions appropriate for the various bus configurations. On most targets these can be used directly. On some targets it may be necessary to do some extra work before and after the erase and program operations. For example if the hardware has an MMU then the part of the address map containing the flash may have been set to read-only, in an attempt to catch spurious memory accesses. Erasing or programming the flash requires write-access, so the MMU settings have to be changed temporarily. As another example some flash device may require a higher voltage to be applied during an erase or program operation. or a higher voltage may be desirable to make the operation proceed faster. A typical platform-specific erase function would look like this:

```
static int
alaia_flash_erase(struct cyg_flash_dev* dev, cyg_flashaddr_t addr)
{
    int result;
    …  // Set up the hardware for an erase
    result = cyg_am29xxxxx_erase_32(dev, addr);
    …  // Revert the hardware change
    return result;
}
```

There are two configurations which affect the erase and program functions, and which a platform HAL may wish to change: `CYGNUM_DEVS_FLASH_AMD_AM29XXXXX_V2_ERASE_TIMEOUT` and `CYGNUM_DEVS_FLASH_AMD_AM29XXXXX_V2_PROGRAM_TIMEOUT`. The erase and program operations both involve polling for completion, and these timeout impose an upper bound on the polling loop. Normally these operations should never take anywhere close to the timeout period, so a timeout indicates a catastrophic failure that should really be handled by a watchdog reset. A reset is particularly appropriate because there will be no clean way of aborting the flash operation. The main reason for the timeouts is to help with debugging when porting to new hardware. If there is a valid reason why a particular platform needs different timeouts then the platform HAL's CDL can require appropriate values for these options.

Locking

There is no single way of implementing the block lock and unlock operations on all AM29xxxxx devices. If these operations are supported at all then usually they involve manipulating the voltages on certain pins. This would not be able to be handled by generic driver code since it requires knowing how these pins can be manipulated via the processor's GPIO lines. Therefore the AM29xxxxx driver does not usually provide lock and unlock functions, and instead the generic dummy functions `cyg_flash_devfn_lock_nop` and `cyg_flash_devfn_unlock_nop` should be used. An exception exists for the

AT49xxxx family of devices which are sufficiently AMD compatible in other respects. Otherwise, if a platform does provide a way of implementing the locking then this can be handled by platform-specific functions.

```
static int
alaia_lock(struct cyg_flash_dev* dev, const cyg_flashaddr_t addr)
{
    …
}

static int
alaia_unlock(struct cyg_flash_dev* dev, const cyg_flashaddr_t addr)
{
    …
}
```

If real locking functions are implemented then the platform HAL's CDL script should implement the CDL interface `CYGHWR_IO_FLASH_BLOCK_LOCKING`. Otherwise the generic flash package may believe that none of the flash drivers in the system provide locking functionality and disable the interface functions.

AT49xxxx locking

As locking is standardised across the AT49xxxx family of AMD AM29xxxxx compatible Flash parts, a method supporting this is included within this driver. `cyg_at49xxxx_softlock_XX` provides a means of locking a Flash sector such that it may be subsequently unlocked. `cyg_at49xxxx_hardlock_XX` locks a sector such that it cannot be unlocked until after reset or a power cycle. `cyg_at49xxxx_unlock_XX` unlocks a sector that has previously been softlocked. At power on or Flash device reset, all sectors default to being softlocked.

Other

The driver provides a set of functions `cyg_am29xxxxx_read_devid_XX`, one per supported bus configuration. These functions take a single argument, a pointer to the cyg_flash_dev structure, and return the chip's device id. For older devices this id is a single byte. For more recent devices the id is a 3-byte value, 0x7E followed by a further two bytes that actually identify the device. `cyg_am29xxxxx_read_devid_XX` is usually called only from inside a platform-specific driver initialization routine, allowing the platform HAL to adapt to the actual device present on the board.

Device-Specific Structure

The cyg_am29xxxxx_dev structure provides information specific to AM29xxxxx flash devices, as opposed to the more generic flash information which goes into the cyg_flash_dev structure. There are only two fields: *`devid`* and *`block_info`*.

`devid` is only needed if the driver's initialization function is set to `cyg_am29xxxxx_init_check_devid_XX`. That function will extract the actual device info from the flash chip and compare it with the *`devid`* field. If there is a mismatch then subsequent operations on the device will fail.

The *`block_info`* field consists of one or more pairs of the block size in bytes and the number of blocks of that size. The order must match the actual hardware device since the flash code will use the table to determine the start and end locations of each block. The table can be initialized in one of three ways:

1. If the driver initialization function is set to `cyg_flash_devfn_init_nop` or `cyg_am29xxxxx_init_check_devid_XX` then the block information should be provided statically. This is appropriate if the board will also be manufactured using the same flash chip.

2. If `cyg_am29xxxxx_init_cfi_XX` is used then this will fill in the block info table. Hence there is no need for static initialization.

3. If a platform-specific initialization function is used then either this should fill in the block info table, or the info should be provided statically.

The size of the *block_info* table is determined by the configuration option CYGNUM_DEVS_FLASH_AMD_AM29XXXXX_V2_ERASE_REGIONS. This has a default value of 4, which should suffice for nearly all AM29xxxxx flash devices. If more entries are needed then the platform HAL's CDL script should require a larger value.

If the cyg_am29xxxxx_dev structure is statically initialized then it can be const. This saves a small amount of memory in ROM startup applications. If the structure is updated at run-time, either by cyg_am29xxxxx_init_cfi_XX or by a platform-specific initialization routine, then it cannot be const.

Flash Structure

Internally the generic flash code works in terms of cyg_flash_dev structures, and the platform HAL should define one of these. The structure should be placed in the cyg_flashdev table. The following fields need to be provided:

funs
: This should point at the table of functions.

start
: The base address of the flash in the address map. On some board the flash may be mapped into memory several times, for example it may appear in both cached and uncached parts of the address space. The *start* field should correspond to the cached address.

end
: The address of the last byte in the flash. It can either be statically initialized, or cyg_am29xxxxx_init_cfi_XX will calculate its value at run-time.

num_block_infos
: This should be the number of entries in the *block_info* table. It can either be statically initialized or it will be filled in by cyg_am29xxxxx_init_cfi_XX.

block_info
: The table with the block information is held in the cyg_am29xxxxx_dev structure, so this field should just point into that structure.

priv
: This field is reserved for use by the device driver. For the AM29xxxxx driver it should point at the appropriate cyg_am29xxxxx_dev structure.

The cyg_flash_dev structure contains a number of other fields which are manipulated only by the generic flash code. Some of these fields will be updated at run-time so the structure cannot be declared const.

Multiple Devices

A board may have several flash devices in parallel, for example two 16-bit devices on a 32-bit bus. It may also have several such banks to increase the total amount of flash. If each device provides 2MB, there could be one bank of 2 parallel flash devices at 0xFF800000 and another bank at 0xFFC00000, giving a total of 8MB. This setup can be described in several ways. One approach is to define two cyg_flash_dev structures. The table of function pointers can usually be shared, as can the cyg_am29xxxxx_dev structure. Another approach is to define a single cyg_flash_dev structure but with a larger *block_info* table, covering the blocks in both banks of devices. The second approach makes more efficient use of memory.

Many variations are possible, for example a small slow flash device may be used for initial bootstrap and holding the configuration data, while there is also a much larger and faster device to hold a file system. Such variations are usually best described by separate cyg_flash_dev structures.

If more than one cyg_flash_dev structure is instantiated then the platform HAL's CDL script should implement the CDL interface CYGHWR_IO_FLASH_DEVICE once for every device past the first. Otherwise the generic code may default to the case of a single flash device and optimize for that.

Platform-Specific Macros

The AM29xxxxx driver source code includes the header files cyg/hal/hal_arch.h and cyg/hal/hal_io.h, and hence indirectly the corresponding platform header files (if defined). Optionally these headers can define macros which are used inside the driver, thus giving the HAL limited control over how the driver works.

Cache Management

By default the AM29xxxxx driver assumes that the flash can be accessed uncached, and it will use the HAL CYGARC_UNCACHED_ADDRESS macro to map the cached address in the *start* field of the cyg_flash_dev structure into an uncached address. If for any reason this HAL macro is inappropriate for the flash then an alternative macro HAL_AM29XXXXX_UNCACHED_ADDRESS can be defined instead. However fixing the CYGARC_UNCACHED_ADDRESS macro is normally the better solution.

If there is no way of bypassing the cache then the platform HAL should implement the CDL interface CYGHWR_DEVS_FLASH_AMD_AM29XXXXX_V2_CACHED_ONLY. The flash driver will now disable and re-enable the cache as required. For example a program operation will involve the following:

```
AM29_INTSCACHE_STATE;
AM29_INTSCACHE_BEGIN();
while ( ! finished ) {
    write a burst of CYGNUM_DEVS_FLASH_AMD_AM29XXXXX_V2_PROGRAM_BURST_SIZE
    AM29_INTSCACHE_SUSPEND();
    AM29_INTSCACHE_RESUME();
}
AM29_INTSCACHE_END();
```

The default implementations of these INTSCACHE macros are as follows: STATE defines any local variables that may be needed, e.g. to save the current interrupt state; BEGIN disables interrupts, synchronizes the data caches, disables it, and invalidates the current contents; SUSPEND re-enables the data cache and then interrupts; RESUME disables interrupts and the data cache; END re-enables the cache and then interrupts. The cache is only disabled when interrupts are disabled, so there is no possibility of an interrupt handler running or a context switch occurring while the cache is disabled, potentially leaving the system running very slowly. The data cache synchronization ensures that there are no dirty cache lines, so when the cache is disabled the low-level flash write code will not see stale data in memory. The invalidate ensures that at the end of the operation higher-level code will not pick up stale cache contents instead of the newly written flash data. The SUSPEND and RESUME macros only re-enable and disable the data cache. An interrupt and possibly a context switch may occur between these macros and use the cache normally. It is assumed that any code which runs at this time will not touch the memory being used by the flash operation, so as far as the low-level program code is concerned it can just continue to use the uncached memory contents as set up by the BEGIN macro. If any code modifies the const data currently being written to a flash block or tries to read the flash block being modified then the system's behaviour is undefined. Theoretically a more robust approach is possible, synchronizing and invalidating the cache again in every RESUME. However these cache operations can be expensive and RESUME may get invoked some thousands of times for every flash block, so this alternative approach would cripple the driver's performance.

Some implementations of the HAL cache macros may not provide the exact semantics required by the flash driver. For example HAL_DCACHE_DISABLE may have an unwanted side effect, or it may do more work than is needed here. The driver will check for alternative macros HAL_AM29XXXXX_INTSCACHE_STATE, HAL_AM29XXXXX_INTSCACHE_BEGIN, HAL_AM29XXXXX_INTSCACHE_SUSPEND, HAL_AM29XXXXX_INTSCACHE_RESUME and HAL_AM29XXXXX_INTSCACHE_END, using these instead of the defaults.

Chapter 67. Atmel AT45xxxxxx DataFlash Device Driver

Name

Overview — eCos Support for Atmel AT45xxxxxx DataFlash Devices and Compatibles

Description

The `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` Atmel AT45xxxxxx V2 flash driver package implements support for the AT45xxxxxx family of flash devices and compatibles. The driver is not normally accessed directly. Instead application code will use the API provided by the generic flash driver package `CYGPKG_IO_FLASH`, for example by calling functions like `cyg_flash_program`.

DataFlash devices are accessed via the SPI bus. Therefore, any platform on which this driver is to be used must also have an SPI driver. The DataFlash driver accesses the driver via the standard SPI API calls defined in the `CYGPKG_IO_SPI` package.

Configuration

The DataFlash flash driver package will be loaded automatically when configuring eCos for a target with suitable hardware. However the driver will be inactive unless the generic flash package `CYGPKG_IO_FLASH` is loaded. It may be necessary to add this generic package to the configuration explicitly before the driver functionality becomes available. There should never be any need to load or unload the DataFlash driver package.

Name

Instantiating — including the driver in an eCos target

Synopsis

#include <cyg/io/dataflash.h>

`CYG_DATAFLASH_FLASH_DRIVER` (*`name`*, *`sdev`*, *`addr`*, *`start`*, *`end`*);

Description

The DataFlash family contains several different flash devices, all supporting the same basic set of operations The devices vary in capacity, performance and sector layout. There are also platform-specific issues such as which SPI bus the device is connected to, and which chip select it uses. The DataFlash driver package cannot know all this information. Instead it is the responsibility of another package, either the platform HAL or a flash configuration package, to instantiate some DataFlash device structures.

The definition of the parameters is split between two data structures. The first is an SPI specific data structure describing the SPI bus, chip select and signalling characteristics for the device. This is usually defined in an SPI specific configuration package or the platform HAL. The reader is referred to the SPI documentation for details of the contents of this structure, but see later for an example.

The second data structure defines the characteristics of the DataFlash device for use by the flash subsystem. For convenience a macro, `CYG_DATAFLASH_FLASH_DRIVER`, has been defined to automate the generation of this structure. This macro takes a number of arguments:

`name`

This provides a name fragment for distinguishing this DataFlash device from any others. It is concatenated with `cyg_dataflash_priv_` to form a static variable name. Any unique string that obeys the rules of C variable names is sufficient.

`sdev`

A pointer to the SPI device object that describes this flash device. If the SPI device has been declared with the name `spi_dataflash_dev0` then this argument should be `(&spi_dataflash_dev0.spi_device)`.

`addr`

SPI DataFlash devices do not have a physical address in the system memory space. However, the flash subsystem expects all flash devices to have an address. This argument gives the DataFlash device a virtual address in the memory space. This should be allocated to a location that contains no other flash devices, and to avoid confusion, no other memory or devices. Subsequently, the DataFlash may be accessed by performing flash system accesses starting at this address.

`start`

This parameter defines the sector at which the flash device mapping starts. The beginning of this sector is mapped to the virtual address given in the `addr` argument. This value will usually be zero, but may be non-zero if there is reserved data at the beginning of the DataFlash.

`end`

This parameter defines the sector at which the flash device mapping ends. The end of this sector defines the maximum extent in the address space that the DataFlash occupies. The exact size of the mapping will depend on the number and sizes of the flash sectors covered. This value will usually be the number of sectors in the device, but may be less if there is reserved data at the end of the DataFlash.

Example

DataFlash support is usually specific to each platform. Even if two platforms happen to use the same flash device there are likely to be differences such as the SPI bus, chip select and location in the address map. Hence there is little possibility of re-using the platform-specific code, and this code is generally placed in the platform HAL or in a separate platform specific package.

The code to declare a DataFlash device might appear as follows:

```
#include <cyg/io/spi.h>
#include <cyg/io/spi_at91.h>
#include <cyg/io/dataflash.h>

__externC cyg_spi_at91_device_t spi_dataflash_dev0;

CYG_DATAFLASH_FLASH_DRIVER( eb55_dataflash,
                            (&spi_dataflash_dev0.spi_device),
                            0x08000000,
                            0,
                            16 );
```

Here, we are defining a dataflash device that is mapped to virtual address 0x08000000. The start and end sectors cover the entire flash device, 17 sectors. In addition to a DataFlash specific structure, this macro also creates a cyg_flash_dev structure which supplies the driver interface to the flash subsystem. The SPI device structure is defined elsewhere, in an SPI specific package, and has the following format:

```
#include <cyg/infra/cyg_type.h>
#include <cyg/io/spi.h>
#include <cyg/io/spi_at91.h>

// AT45DB321B DataFlash
cyg_spi_at91_device_t spi_dataflash_dev0 CYG_SPI_DEVICE_ON_BUS(0) =
{
    .spi_device.spi_bus = &cyg_spi_at91_bus.spi_bus,

    .dev_num     = 0,       // Device number
    .cl_pol      = 1,       // Clock polarity (0 or 1)
    .cl_pha      = 0,       // Clock phase (0 or 1)
    .cl_brate    = 8192000, // Clock baud rate
    .cs_up_udly  = 1,       // Delay in usec between CS up and transfer start
    .cs_dw_udly  = 1,       // Delay in usec between transfer end and CS down
    .tr_bt_udly  = 1        // Delay in usec between two transfers
};
```

The parameters here attach the device to the only SPI bus in the hardware, use chip select 0 to access it, and set the communication parameters for the clock polarity, phase, baud rate and delays.

Device Info

The exact DataFlash device attached to the SPI bus is discovered by the driver by querying it and matching the device ID against an internal table of supported devices. If a particular device is not currently supported, it must be added to the table in `devs_flash_atmel_dataflash.c`. A typical entry in this table appears as follows:

```
{   // AT45DB321B
    device_id:    0x0D,
    page_size:    528,
    page_count:   8192,
    baddr_bits:   10,
    block_size:   8,
    sector_sizes: {  1, 63, 64, 64, 64, 64, 64, 64,
                    64, 64, 64, 64, 64, 64, 64, 64, 64 },
    sector_count: 17
},
```

The fields of this structure are:

`device_id` This defines the device ID returned as part of the status register. This is the field that is matched to select this DataFlash device.

`page_size` This gives the size of pages in this flash device.

`page_size` This gives the total number of pages in this device.

`baddr_bits` This gives the number of bits used in the SPI command address format for specifying a byte address within a page.

`block_size` This gives the number of pages in a block.

`sector_sizes` This is an array giving the size, in blocks, of each sector of the DataFlash.

`sector_count` This gives the number of entries in the *`sector_sizes`* array.

Chapter 68. Freescale MCFxxxx CFM Flash Device Driver

Name

CYGPKG_DEVS_FLASH_M68K_MCFxxxx_CFM — eCos Flash Driver for MCFxxxx CFM On-chip Flash

Description

Some members of the Freescale MCFxxxx family, for example the MCF5213, come with on-chip flash in the form of a ColdFire Flash Module or CFM. This package `CYGPKG_DEVS_FLASH_M68K_MCFxxxx_CFM` provides an eCos flash device driver for CFM hardware. Normally the driver is not accessed directly. Instead application code will use the API provided by the generic flash driver package `CYGPKG_IO_FLASH`, for example by calling functions like `cyg_flash_program`.

Configuration Options

The CFM flash driver package will be loaded automatically when configuring eCos for a target with suitable hardware. However the driver will be inactive unless the generic flash package `CYGPKG_IO_FLASH` is loaded. It may be necesary to add this generic package to the configuration explicitly before the driver functionality becomes available. There should never be any need to load or unload the CFM driver package.

The driver contains a small number of configuration options which application developers may wish to tweak.

Misaligned Writes

The CFM hardware only supports writes of a whole 32-bit integer at a time. For most applications this is not a problem and the driver imposes this restriction on higher-level code, so when calling `cyg_flash_program` the destination address must be on a 32-bit boundary and the length must be a multiple of four bytes. If this restriction is unacceptable then support for misaligned writes of arbitrary lengths can be enabled via configuration option `CYGIMP_DEVS_FLASH_M68K_MCFxxxx_CFM_MISALIGNED_WRITES`. The implementation involves reading in the existing flash contents and or'ing in the new data. The default behaviour is to leave this disabled since most applications do not require the functionality and it just adds to the code size.

Locking

CFM has a somewhat unusual approach to implementing lock and unlock support. The first 1K of on-chip flash is normally reserved for the M68K exception vectors, on the assumption that the processor will or may boot from here. This is immediately followed by a hal_mcfxxxx_cfm_security_settings data structure at offset 0x400. The structure has a 32-bit field *`cfm_prot`* which determines the initial locking status. The whole CFM flash array is split into 32 sectors. Each bit in *`cfm_prot`* determines the initial locked state of all blocks within that sector, with 1 for locked and 0 for unlocked. Locking and unlocking can only affect a whole sector at a time, not individual flash blocks (unless of course the flash is organized such that there exactly 32 flash blocks).

In typical usage the on-chip flash will be used for bootstrap and hence the security settings are part of the boot image. The default security settings are supplied by the processor or platform HAL and will be such that all flash sectors are unlocked. This is the most convenient setting when developing software. However an application can override this and thus lock part or all of the flash.

The driver provides two configuration options related to flash locking. `CYGIMP_DEVS_FLASH_M68K_MCFxxxx_CFM_AUTO_UNLOCK` causes all of flash to be unlocked automatically during driver initialization. This gives simple and deterministic behaviour irrespective of the current contents of the flash security settings structure. However it leaves the flash more vulnerable to accidental corruption by an errant application. `CYGIMP_DEVS_FLASH_M68K_MCFxxxx_CFM_SUPPORT_LOCKING` enables support for fine-grained locking using the generic functions `cyg_flash_lock` and `cyg_flash_unlock`. This provides more protection against errant applications, at the cost of increased application complexity.

RAM Functions and Interrupts

When performing a flash erase or program operation part or all of the flash may become inaccessible. The exact details of this vary between ColdFire processors. Obviously this means that the low-level functions which manipulate the flash cannot reside in the same area of flash as any blocks that may get erased or programmed. Worse, if an interrupt happens during an erase or program operation and the interrupt handler involves code or data in the same area of flash, or may cause a higher priority thread to wake up which accesses that area of flash, then the system is likely to fail. To avoid problems the flash driver takes two precautions by default:

1. The low-level flash functions are located in RAM. If necessary they are copied from ROM from RAM during system initialization.
2. The low-level flash functions disable interrupts around any code which may leave parts of the flash inaccessible.

This combination avoids problems but at the cost of increased RAM usage and often increased interrupt latency. In some circumstances these precautions are unnecessary. For example suppose there is 512K of flash split into two logical blocks of 256K each, such that an erase or program operation affects all of one logical block but not the other. If the application has been arranged such that all code and constant data resides in the bottom 256K and flash operations are only performed on the remaining 256K then there is no need to place the low-level flash functions in RAM. The configuration option `CYGIMP_DEVS_FLASH_M68K_MCFxxxx_CFM_FUNCTIONS_IN_RAM` can then be disabled. In a similar scenario, if the top 256K of flash are only ever accessed via the flash API then there is no need to disable interrupts: the generic flash layer ensures only one thread can perform flash operations on a given device via a mutex. The configuration option `CYGIMP_DEVS_FLASH_M68K_MCFxxxx_CFM_LEAVE_INTERRUPTS_ENABLED` can then be enabled.

Additional Functionality

The driver exports two functions which offer functionality not accessible via the standard flash API:

```
#include <cyg/io/mcfxxxx_cfm_dev.h>

externC void     cyg_mcfxxxx_cfm_unlockall(void);
externC cyg_bool cyg_mcfxxxx_cfm_is_locked(const cyg_flashaddr_t addr);
```

The first can be used to unlock all flash sectors, effectively bypassing any locking set by the hal_mcfxxxx_cfm_security_settings structure. The second can be used to query whether or not the block containing the specified address is currently locked. Both functions should be called only after flash has been initialized.

Instantiating a CFM Flash device

The CFM package only provides the device driver functions needed for manipulating CFM flash. It does not actually create a device instance. The amount of on-chip flash varies between ColdFire processors and the driver package does not maintain any central repository about the characteristics of each processor. Instead it is left to other code, usually the processor HAL, to instantiate the flash device. That makes it possible to add support for new processors simply by adding a new processor HAL, with no need to change the flash driver package.

The CFM package provides a utility macro for instantiating a device. Typical usage would be:

```
#include <cyg/io/mcfxxxx_cfm_dev.h>

CYG_MCFxxxx_CFM_INSTANCE(0x00000000, 0x0003FFFF, 2048);
```

The first two arguments specify the base and end address of the flash in the memory map. In this example there is 256K of flash mapped to location 0. Typically the base address is set via the FLASHBAR system register and the size is of course determined by the specific ColdFire processor being used. The final argument is the size of a flash block, in other words the unit of erase operations. This will have to obtained from the processor documentation.

The `CYG_MCFxxxx_CFM_INSTANCE` macro may instantiate a device with or without software locking support, as determined by the driver configuration option `CYGIMP_DEVS_FLASH_M68K_MCFxxxx_CFM_SUPPORT_LOCKING` .

If for some reason the `CYG_MCFxxxx_CFM_INSTANCE` is inappropriate for a specific processor then the mcfxxxx_cfm_dev.h header file exports all the device driver functions, so code can create a flash device instance explicitly.

Chapter 69. Intel Strata Flash Device Driver

Name

Overview — eCos Support for Intel Strata Flash Devices and Compatibles

Description

The CYGPKG_DEVS_FLASH_STRATA_V2 flash driver package implements support for the Intel Strata family of flash devices and compatibles. The driver is not normally accessed directly. Instead application code will use the API provided by the generic flash driver package CYGPKG_IO_FLASH, for example by calling functions like cyg_flash_program. There are a small number of additional functions specific to Strata devices.

The driver imposes one restriction on application code which developers should be aware of: when programming the flash the destination addresses must be aligned to a bus boundary. For example if the target hardware has a single flash device attached to a 16-bit bus then program operations must involve a multiple of 16-bit values aligned to a 16-bit boundary. Note that it is the bus width that matters, not the device width. If the target hardware has two 16-bit devices attached to a 32-bit bus then program operations must still be aligned to a 32-bit boundary, even though in theory a 16-bit boundary would suffice. In practice this is rarely an issue, and requiring the larger boundary greatly simplifies the code and improves performance.

Note

Many eCos targets with Strata or compatible flash devices will still use the older driver package CYGPKG_DEVS_FLASH_STRATA. Only newer ports and some older ports that have been converted will use the V2 driver. This documentation only applies to the V2 driver.

Configuration Options

The Strata flash driver package will be loaded automatically when configuring eCos for a target with suitable hardware. However the driver will be inactive unless the generic flash package CYGPKG_IO_FLASH is loaded. It may be necessary to add this generic package to the configuration explicitly before the driver functionality becomes available. There should never be any need to load or unload the Strata driver package.

The Strata flash driver package contains a small number of configuration options which application developers may wish to tweak. CYGNUM_DEVS_FLASH_STRATA_V2_PROGRAM_BURST_SIZE controls the program operation. On typical hardware programming the flash requires disabling interrupts and possibly the cache for an extended period of time. If the hardware does not provide any way of bypassing the cache when writing to the flash then the cache must be disabled or the commands written to the flash may get stuck inside the cache instead of going directly to the flash chip. Some or all of the flash hardware will be unusable while each word is programmed, and disabling interrupts is the only reliable way of ensuring that no interrupt handler or other thread will try to access the flash in the middle of an operation. This can have a major impact on the real-time responsiveness of the typical applications. To ameliorate this the driver will perform writes in small bursts, briefly re-enabling the cache and interrupts between each burst. The number of words written per burst is controlled by this configuration operation: reducing the value will improve real-time response but will add overhead, so the actual flash program operation will take longer; conversely more writes per burst will worsen response times but reduce overhead. For flash devices which support buffered writes the driver will always try to use a full buffer so there is no point in reducing the burst size to less than the buffer size, but setting the burst size to a larger value is permitted.

Similarly erasing a block of flash safely requires disabling interrupts and possibly the cache. Erasing a block can easily take a second or so, and disabling interrupts for such a long period of time is usually undesirable. Hence the driver can also perform the erase in bursts, using the hardware's suspend and resume capabilities. CYGNUM_DEVS_FLASH_STRATA_V2_ERASE_BURST_DURATION controls the number of polling loops during which interrupts are disabled. Reducing its value improves responsiveness at the cost of performance, and increasing its value has the opposite effect. Note that too low a value may prevent the erase operation from working at all: the chip will be spending its time suspending and resuming, rather than actually performing the erase. The minimum value will depend on the specific hardware.

There are a number of other options, relating mostly to hardware characteristics. It is very rare that application developers need to change any of these. For example the option CYGNUM_DEVS_FLASH_STRATA_V2_ERASE_REGIONS may need a non-default value if the flash devices used on the target have an unusual boot block layout. If so the platform HAL will impose a requires constraint on this option and the configuration system will resolve the constraint. The only time it might be necessary to change the value manually is if the actual board being used is a variant of the one supported by the platform HAL and uses a different flash chip.

Name

Instantiating — including the driver in an eCos target

Synopsis

#include <cyg/io/strata_dev.h>

```
int cyg_strata_init_nop(device);

int cyg_strata_init_check_devid_XX(device);

int cyg_strata_init_cfi_XX(device);

int cyg_strata_erase_XX(device, addr);

int cyg_strata_program_XX(device, addr, data, len);

int cyg_strata_bufprogram_XX(device, addr, data, len);

int cyg_strata_lock_j3_XX(device, addr);

int cyg_strata_unlock_j3_XX(device, addr);

int cyg_strata_lock_k3_XX(device, addr);

int cyg_strata_unlock_k3_XX(device, addr);
```

Description

The Strata family contains a number of different devices, all supporting the same basic set of operations but with various common or uncommon extensions. The range includes:

28FxxxB3 Boot Block
: These support 8 8K boot blocks as well as the usual 64K blocks. There is no buffered write capability. The only locking mechanism available involves manipulating voltages on certain pins.

28FxxxC3
: These also have boot blocks. There is no buffered write capability. Individual blocks can be locked and unlocked in software.

28FxxxJ3
: These are uniform devices where all blocks are 128K. Buffered writes are supported. Blocks can be locked individually, but the only unlock operation is a global unlock-all.

28FxxxK3
: These are also uniform devices with 128K blocks. Buffered writes are supported. Individual blocks can be locked and unlocked in software.

Each of these comes in a range of sizes and bus widths. There are also platform-specific issues such as how many devices are actually present on the board and where they are mapped in the address space. The Strata driver package cannot know all this information. Instead it is the responsibility of another package, usually the platform HAL, to instantiate some flash device structures. Two pieces of information are especially important: the bus configuration and the boot block layout.

Flash devices are typically 8-bits, 16-bits, or 32-bits wide (64-bit devices are not yet in common use). Most 16-bit devices will also support 8-bit accesses, but not all. Similarly 32-bit devices can be accessed 16-bits at a time or 8-bits at a time. A board will have one or more of these devices on the bus. For example there may be a single 16-bit device on a 16-bit bus, or two 16-bit devices on a 32-bit bus. The processor's bus logic determines which combinations are possible, and usually there will be a trade off between cost and performance. For example two 16-bit devices in parallel can provide twice the memory bandwidth of a single device. The driver supports the following combinations:

8 A single 8-bit flash device on an 8-bit bus.

16 A single 16-bit flash device on a 16-bit bus.

32 A single 32-bit flash device on an 32-bit bus.

88 Two parallel 8-bit devices on an 16-bit bus.

8888 Four parallel 8-bit devices on a 32-bit bus.

1616 Two parallel 16-bit devices on a 32-bit bus, with one device providing the bottom two bytes of each 32-bit datum and the other device providing the upper two bytes.

16as8 A single 16-bit flash device connected to an 8-bit bus.

These configuration all require slightly different code to manipulate the hardware. The Strata driver package provides separate functions for each configuration, for example `cyg_strata_erase_16` and `cyg_strata_program_1616`.

Caution

At the time of writing not all the configurations have been tested.

The second piece of information is the boot block layout. Flash devices are subdivided into blocks (also known as sectors, both terms are in common use). Some operations such as erase work on a whole block at a time, and for most applications a block is the smallest unit that gets updated. A typical block size is 64K. It is inefficient to use an entire 64K block for small bits of configuration data and similar information, so some flash devices also support a number of smaller boot blocks. A typical 2MB flash device could have eight 8K blocks and 31 full-size 64K blocks. The boot blocks may appear at the bottom or the top of the device. So-called uniform devices do not have boot blocks, just full-size ones. The driver needs to know the boot block layout. With modern devices it can work this out at run-time, but often it is better to provide the information statically.

Example

Flash support is usually specific to each platform. Even if two platforms happen to use the same flash device there are likely to be differences such as the location in the address map. Hence there is little possibility of re-using the platform-specific code, and this code is generally placed in the platform HAL rather than in a separate package. Typically this involves a separate file and a corresponding compile property in the platform HAL's CDL:

```
cdl_package CYGPKG_HAL_M68K_KIKOO {
    …
    compile -library=libextras.a kikoo_flash.c
    …
}
```

The contents of this file will not be accessed directly, only indirectly via the generic flash API, so normally it would be removed by link-time garbage collection. To avoid this the object file has to go into `libextras.a`.

The actual file `kikoo_flash.c` will look something like:

```
#include <pkgconf/system.h>
#ifdef CYGPKG_DEVS_FLASH_STRATA_V2

#include <cyg/io/flash.h>
#include <cyg/io/strata_dev.h>

static const CYG_FLASH_FUNS(hal_kikoo_flash_strata_funs,
    &cyg_strata_init_check_devid_16,
    &cyg_flash_devfn_query_nop,
    &cyg_strata_erase_16,
    &cyg_strata_bufprogram_16,
    (int (*)(struct cyg_flash_dev*, const cyg_flashaddr_t, void*, size_t))0,
    &cyg_strata_lock_j3_16,
    &cyg_strata_unlock_j3_16);

static const cyg_strata_dev hal_kikoo_flash_priv = {
    .manufacturer_code = CYG_FLASH_STRATA_MANUFACTURER_INTEL,
    .device_code = 0x0017,
    .bufsize    = 16,
    .block_info = {
        { 0x00020000, 64 } // 64 * 128K blocks
    }
};

CYG_FLASH_DRIVER(hal_kikoo_flash,
                 &hal_kikoo_flash_strata_funs,
                 0,
                 0x60000000,
                 0x601FFFFF,
                 1,
                 hal_kikoo_flash_priv.block_info,
                 &hal_kikoo_flash_priv
);
#endif
```

The bulk of the file is protected by an ifdef for the Strata flash driver. That driver will only be active if the generic flash support is enabled. Without that support there will be no way of accessing the device so there is no point in instantiating the device. The rest of the file is split into three definitions. The first supplies the functions which will be used to perform the actual flash accesses, using a macro provided by the generic flash code in `cyg/io/flash_dev.h`. The relevant ones have an `_16` suffix, indicating that on this board there is a single 16-bit flash device on a 16-bit bus. The second definition provides information specific to Strata flash devices. The third provides the cyg_flash_dev structure needed by the generic flash code, which contains pointers to the previous two.

Functions

All eCos flash device drivers must implement a standard interface, defined by the generic flash code `CYGPKG_IO_FLASH`. This interface includes a table of 7 function pointers for various operations: initialization, query, erase, program, read, locking and unlocking. The query operation is optional and the generic flash support provides a dummy implementation `cyg_flash_devfn_query_nop`. Strata flash devices are always directly accessible so there is no need for a separate read function. The remaining functions are more complicated.

Usually the table can be declared `const`. In a ROM startup application this avoids both ROM and RAM copies of the table, saving a small amount of memory. `const` should not be used if the table may be modified by a platform-specific initialization routine.

Initialization

There is a choice of three main initialization functions. The simplest is `cyg_flash_devfn_init_nop`, which does nothing. It can be used if the cyg_strata_dev and cyg_flash_dev structures are fully initialized statically and the flash will just work without special effort. This is useful if it is guaranteed that the board will always be manufactured using the same flash chip, since the nop function involves the smallest code size and run-time overheads.

The next step up is `cyg_strata_init_check_devid_XX`, where `XX` will be replaced by the suffix appropriate for the bus configuration. It is still necessary to provide all the device information statically, including the *`devid`* field in the cyg_strata_dev structure. However this initialization function will attempt to query the flash device and check that the provided manufacturer and device codes matches the actual hardware. If there is a mismatch the device will be marked uninitialized and subsequent attempts to manipulate the flash will fail.

If the board may end up being manufactured with any of a number of different flash chips then the driver can perform run-time initialization, using a `cyg_strata_init_cfi_XX` function. This queries the flash device as per the Common Flash Memory

Interface Specification, supported by all current devices (although not necessarily by older devices). The *block_info* field in the cyg_strata_dev structure and the *end* and *num_block_infos* fields in the cyg_flash_dev structure will be filled in. It is still necessary to supply the *start* field statically since otherwise the driver will not know how to access the flash device. The main disadvantage of using CFI is that it will increase the code size.

A final option is to use a platform-specific initialization function. This may be useful if the board may be manufactured with one of a small number of different flash devices and the platform HAL needs to adapt to this. The Strata driver provides a utility function to read the device id, `cyg_strata_read_devid_XX`:

```
static int
kikoo_flash_init(struct cyg_flash_dev* dev)
{
    int manufacturer_code, device_code;
    cyg_strata_read_devid_1616(dev, &manufacturer_code, &device_code);
    if (manufacturer_code != CYG_FLASH_STRATA_MANUFACTURER_STMICRO) {
        return CYG_FLASH_ERR_DRV_WRONG_PART;
    }
    switch(device_code) {
        case 0x0042 :
          …
        case 0x0084 :
          …
        default:
          return CYG_FLASH_ERR_DRV_WRONG_PART;
    }
}
```

There are many other possible uses for a platform-specific initialization function. For example initial prototype boards might have only supported 8-bit access to a 16-bit flash device rather than 16-bit access, but this was fixed in the next revision. The platform-specific initialization function could figure out which model board it is running on and replace the default `16as8` functions with `16` ones.

Erase and Program

The Strata driver provides erase and program functions appropriate for the various bus configurations. On most targets these can be used directly. On some targets it may be necessary to do some extra work before and after the erase and program operations. For example if the hardware has an MMU then the part of the address map containing the flash may have been set to read-only, in an attempt to catch spurious memory accesses. Erasing or programming the flash requires write-access, so the MMU settings have to be changed temporarily. For another example some flash device may require a higher voltage to be applied during an erase or program operation. or a higher voltage may be desirable to make the operation proceed faster. A typical platform-specific erase function would look like this:

```
static int
kikoo_flash_erase(struct cyg_flash_dev* dev, cyg_flashaddr_t addr)
{
    int result;
    …  // Set up the hardware for an erase
    result = cyg_strata_erase_32(dev, addr);
    …  // Revert the hardware change
    return result;
}
```

There are two versions of the program function. `cyg_strata_bufprogram_xx` uses the buffered write capability of some strata chips. This allows the flash chip to perform the writes in parallel, thus greatly improving performance. It requires that the *bufsize* field of the cyg_strata_dev structure is set correctly to the number of words in the write buffer. The usual value for this is 16, corresponding to a 32-byte write buffer. The alternative `cyg_strata_program_xx` writes the data one word at a time so is significantly slower. It should be used only with strata chips that do not support buffered writes, for example the b3 and c3 series.

There are two configuration options which affect the erase and program functions, and which a platform HAL may wish to change: `CYGNUM_DEVS_FLASH_STRATA_V2_ERASE_TIMEOUT` and `CYGNUM_DEVS_FLASH_STRATA_V2_PROGRAM_TIME-`

OUT. The erase and program operations both involve polling for completion, and these timeout impose an upper bound on the polling loop. Normally these operations should never take anywhere close to the timeout period, and hence a timeout probably indicates a catastrophic failure that should really be handled by a watchdog reset. A reset is particularly appropriate because there will be no clean way of aborting the flash operation. The main reason for the timeouts is to help with debugging when porting to new hardware. If there is a valid reason why a particular platform needs different timeouts then the platform HAL's CDL can require appropriate values for these options.

Locking

Current Strata devices implement locking in three different ways, requiring different sets of functions:

28FxxxB3 There is no software locking support. The `cyg_flash_devfn_lock_nop` and `cyg_flash_devfn_unlock_nop` functions should be used.

28FxxxC3
28FxxxK3 These support locking and unlocking individual blocks. The `cyg_strata_lock_k3_XX` and `cyg_strata_unlock_k3_XX` functions should be used. All blocks are locked following power-up or reset, so the unlock function must be used before any erase or program operation. Theoretically the lock function is optional and `cyg_flash_devfn_lock_nop` can be used instead, saving a small amount of code space.

28FxxxJ3 Individual blocks can be locked using `cyg_strata_lock_j3_XX`, albeit using a slightly different algorithm from the C3 and K3 series. However the only unlock support is a global unlock of all blocks. Hence the only way to unlock a single block is to check the locked status of every block, unlock them all, and relock the ones that should still be locked. This time-consuming operation is implemented by `cyg_strata_unlock_j3_XX`. Worse, unlocking all blocks can take approximately a second. During this time the flash is unusable so normally interrupts have to be disabled, affecting real-time responsiveness. There is no way of suspending this operation.

Unlike the C3 and K3 chips, on a J3 blocks are not automatically locked following power-up or reset. Hence lock and unlock support is optional, and `cyg_flash_devfn_lock_nop` and `cyg_flash_devfn_unlock_nop` can be used.

If real locking functions are used then the platform HAL's CDL script should implement the CDL interface `CYGHWR_IO_FLASH_BLOCK_LOCKING`. Otherwise the generic flash package may believe that none of the flash drivers in the system provide locking functionality and disable the interface functions.

Device-Specific Structure

The cyg_strata_dev structure provides information specific to Strata flash devices, as opposed to the more generic flash information which goes into the cyg_flash_dev structure. There are only two fields: *`devid`* and *`block_info`*.

`manufacturer_code` and *`device_code`* are needed only if the driver's initialization function is set to `cyg_strata_init_check_devid_XX`. That function will extract the actual device info from the flash chip and compare it with these fields. If there is a mismatch then subsequent operations on the device will fail. Definitions of `CYG_FLASH_STRATA_MANUFACTURER_INTEL` and `CYG_FLASH_STRATA_MANUFACTURER_STMICRO` are provided for convenience.

The *`bufsize`* field is needed only if a buffered program function `cyg_strata_bufprogram_XX` is used. It should give the size of the buffer in words. Typically Strata devices have a 32-byte buffer, so when attached to an 8-bit bus *`bufsize`* should be 32 and when attached to a 16-bit bus it should be 16.

The *`block_info`* field consists of one or more pairs of the block size in bytes and the number of blocks of that size. The order must match the actual hardware device since the flash code will use the table to determine the start and end locations of each block. The table can be initialized in one of three ways:

1. If the driver initialization function is set to `cyg_strata_init_nop` or `cyg_strata_init_check_devid_XX` then the block information should be provided statically. This is appropriate if the board will also be manufactured using the same flash chip.

2. If cyg_strata_init_cfi_XX is used then this will fill in the block info table. Hence there is no need for static initialization.
3. If a platform-specific initialization function is used then either this should fill in the block info table, or the info should be provided statically.

The size of the *block_info* table is determined by the configuration option CYGNUM_DEVS_FLASH_STRATA_V2_ERASE_REGIONS. This has a default value of 2, which should suffice for nearly all Strata flash devices. If more entries are needed then the platform HAL's CDL script should require a larger value.

If the cyg_strata_dev structure is statically initialized then it can be const. This saves a small amount of memory in ROM startup applications. If the structure may be updated at run-time, either by cyg_strata_init_cfi_XX or by a platform-specific initialization routine, then it cannot be const.

Flash Structure

Internally the flash code works in terms of cyg_flash_dev structures, and the platform HAL should define one of these. The structure should be placed in the cyg_flashdev table. The following fields need to be provided:

funs
This should point at the table of functions.

start
The base address of the flash in the address map. On some board the flash may be mapped into memory several times, for example it may appear in both cached and uncached parts of the address space. The *start* field should correspond to the cached address.

end
The address of the last byte in the flash. It can either be statically initialized, or cyg_strata_init_cfi_XX will calculate its value at run-time.

num_block_infos
This should be the number of entries in the *block_info* table. It can either be statically initialized or it will be filled in by cyg_strata_init_cfi_XX.

block_info
The table with the block information is held in the cyg_strata_dev structure, so this field should just point into that structure.

priv
This field is reserved for use by the device driver. For the Strata driver it should point at the appropriate cyg_strata_dev structure.

The cyg_flash_dev structure contains a number of other fields which are manipulated only by the generic flash code. Some of these fields will be updated at run-time so the structure cannot be declared const.

Multiple Devices

A board may have several flash devices in parallel, for example two 16-bit devices on a 32-bit bus. It may also have several such banks to increase the total amount of flash. If each device provides 2MB, there could be one bank of 2 parallel flash devices at 0xFF800000 and another bank at 0xFFC00000, giving a total of 8MB. This setup can be described in several ways. One approach is to define two cyg_flash_dev structures. The table of function pointers can usually be shared, as can the cyg_strata_dev structure. Another approach is to define a single cyg_flash_dev structure but with a larger *block_info* table, covering the blocks in both banks of devices. The second approach makes more efficient use of memory.

Many variations are possible, for example a small slow flash device may be used for initial bootstrap and holding the configuration data, while there is also a much larger and faster device to hold a file system. Such variations are usually best described by separate cyg_flash_dev structures.

If more than one cyg_flash_dev structure is instantiated then the platform HAL's CDL script should implement the CDL interface CYGHWR_IO_FLASH_DEVICE once for every device past the first. Otherwise the generic code may default to the case of a single flash device and optimize for that.

Platform-Specific Macros

The Strata driver source code includes the header files cyg/hal/hal_arch.h and cyg/hal/hal_io.h, and hence indirectly the corresponding platform header files (if defined). Optionally these headers can define macros which are used inside the driver, thus giving the HAL limited control over how the driver works.

Cache Management

By default the strata driver assumes that the flash can be accessed uncached, and it will use the HAL CYGARC_UNCACHED_ADDRESS macro to map the cached address in the *start* field of the cyg_flash_dev structure into an uncached address. If for any reason this HAL macro is inappropriate for the flash then an alternative macro HAL_STRATA_UNCACHED_ADDRESS can be defined instead. However fixing the CYGARC_UNCACHED_ADDRESS macro is normally the better solution.

If there is no way of bypassing the cache then the platform HAL should implement the CDL interface CYGHWR_DEVS_FLASH_STRATA_V2_CACHED_ONLY. The flash driver will now disable and re-enable the cache as required. For example a program operation will involve the following:

```
STRATA_INTSCACHE_STATE;
STRATA_INTSCACHE_BEGIN();
while ( ! finished ) {
    write a burst of CYGNUM_DEVS_FLASH_STRATA_V2_PROGRAM_BURST_SIZE
    STRATA_INTSCACHE_SUSPEND();
    STRATA_INTSCACHE_RESUME();
}
STRATA_INTSCACHE_END();
```

The default implementations of these INTSCACHE macros are as follows: STATE defines any local variables that may be needed, e.g. to save the current interrupt state; BEGIN disables interrupts, synchronizes the data caches, disables it, and invalidates the current contents; SUSPEND re-enables the data cache and then interrupts; RESUME disables interrupts and the data cache; END re-enables the cache and then interrupts. The cache is only disabled when interrupts are disabled, so there is no possibility of an interrupt handler running or a context switch occurring while the cache is disabled, potentially leaving the system running very slowly. The data cache synchronization ensures that there are no dirty cache lines, so when the cache is disabled the low-level flash write code will not see stale data in memory. The invalidate ensures that at the end of the operation higher-level code will not pick up stale cache contents instead of the newly written flash data. The SUSPEND and RESUME macros only re-enable and disable the data cache. An interrupt and possibly a context switch may occur between these macros and use the cache normally. It is assumed that any code which runs at this time will not touch the memory being used by the flash operation, so as far as the low-level program code is concerned it can just continue to use the uncached memory contents as set up by the BEGIN macro. If any code modifies the const data currently being written to a flash block or tries to read the flash block being modified then the system's behaviour is undefined. Theoretically a more robust approach is possible, synchronizing and invalidating the cache again in every RESUME. However these cache operations can be expensive and RESUME may get invoked some thousands of times for every flash block, so this alternative approach would cripple the driver's performance.

Some implementations of the HAL cache macros may not provide the exact semantics required by the flash driver. For example HAL_DCACHE_DISABLE may have an unwanted side effect, or it may do more work than is needed here. The driver will check for alternative macros HAL_STRATA_INTSCACHE_STATE, HAL_STRATA_INTSCACHE_BEGIN, HAL_STRATA_INTSCACHE_SUSPEND, HAL_STRATA_INTSCACHE_RESUME and HAL_STRATA_INTSCACHE_END, using these instead of the defaults.

Polling Support

On some platforms it may be necessary to perform some additional action in the middle of a lengthy erase or program operation. For example, consider a platform with a watchdog device that cannot be disabled: when running in a polled environment such as RedBoot the flash operation run will run to completion, and there will be no opportunity for higher-level code to reset the watchdog; if the flash operation takes long enough the watchdog will trigger. To avoid problems in such scenarios, the platform HAL can define a macro HAL_STRATA_POLL. The macro is optional: if absent then the driver will automatically substitute a no-op.

Name

Strata — driver-specific functions

Synopsis

#include <cyg/io/strata_dev.h>

`void cyg_strata_read_devid_XX(device, manufacturer, device);`

`int cyg_strata_unlock_all_j3_XX(device);`

Description

The driver provides two sets of functions specific to Strata devices and not accessible via the standard eCos flash API. Both may be used safely before the flash subsystem is initialized using `cyg_flash_init`.

`cyg_strata_read_devid_XX` can be used to get the manufacturer and device codes. Typically it is called from a platform-specific driver initialization routine, allowing the platform HAL to adapt to the actual device present on the board. This may be useful if a board may get manufactured with several different and somewhat incompatible chips, although usually `cyg_strata_init_cfi` is the better approach. It may also be used during testing and porting to check that the chip is working correctly.

`cyg_strata_unlock_all_j3_XX` is only useful with 28FxxxJ3 chips and compatibles. These do not allow individual blocks to be unlocked. Hence the standard block unlock functionality is expensive: it requires checking the locked state of every block, unlocking every block, and then relocking all the blocks that should still be blocked. Worse, unlocking every block is a time-consuming operation, taking approximately a second, that needs to run with interrupts disabled. For many applications it is better to just ignore the chip's locking capabilities and run with all blocks permanently unlocked. Invoking `cyg_strata_unlock_all_j3_XX` during manufacture or when the board is commissioned achieves this.

Chapter 70. SST 39VFXXX Flash Device Driver

Name

Overview — eCos Support for SST 39VFXXX Flash Devices and Compatibles

Description

The CYGPKG_DEVS_FLASH_SST_39VFXXX_V2 SST 39VFXXX V2 flash driver package implements support for the 39VFXXX family of flash devices and compatibles. Normally the driver is not accessed directly. Instead application code will use the API provided by the generic flash driver package CYGPKG_IO_FLASH, for example by calling functions like cyg_flash_program.

The driver imposes one restriction on application code which developers should be aware of: when programming the flash the destination addresses must be aligned to a bus boundary. For example if the target hardware has a single flash device attached to a 16-bit bus then program operations must involve a multiple of 16-bit values aligned to a 16-bit boundary. Note that it is the bus width that matters, not the device width. If the target hardware has two 16-bit devices attached to a 32-bit bus then program operations must still be aligned to a 32-bit boundary, even though in theory a 16-bit boundary would suffice. In practice this is rarely an issue, and requiring the larger boundary greatly simplifies the code and improves performance.

Note

Many eCos targets with 39vfxxx or compatible flash devices will still use the older driver package CYGPKG_DEVS_FLASH_SST_39VFXXX. Only newer ports and some older ports that have been converted will use the V2 driver. This documentation only applies to the V2 driver.

Configuration Options

The 39vfxxx flash driver package will be loaded automatically when configuring eCos for a target with suitable hardware. However the driver will be inactive unless the generic flash package CYGPKG_IO_FLASH is loaded. It may be necessary to add this generic package to the configuration explicitly before the driver functionality becomes available. There should never be any need to load or unload the AM29xxxx driver package.

The driver contains a small number of configuration options which application developers may wish to tweak. CYGNUM_DEVS_FLASH_SST_39VFXXX_V2_PROGRAM_BURST_SIZE controls the program operation. On typical hardware programming the flash requires disabling interrupts and the cache for an extended period of time. Some or all of the flash hardware will be unusable while each word is programmed, and disabling interrupts is the only reliable way of ensuring that no interrupt handler or other thread will try to access the flash in the middle of an operation. This can have a major impact on the real-time responsiveness of the typical applications. To ameliorate this the driver wil perform writes in small bursts, briefly re-enabling the cache and interrupts between each burst. The number of words written per burst is controlled by this configuration operation: reducing the value will improve real-time response but will add overhead, so the actual flash program operation will take longer; conversely more writes per burst will worsen response times but reduce overhead.

Similarly erasing a block of flash safely requires disabling interrupts and the cache. Erasing a block can easily take a second or so, and disabling interrupts for such a long period of time is usually undesirable. Hence the driver can also perform the erase in bursts, using the hardware's suspend and resume capabilities. CYGNUM_DEVS_FLASH_STRATA_V2_ERASE_BURST_DURATION controls the number of polling loops during which interrupts are disabled. Reducing its value improves responsiveness at the cost of performance, and increasing its value has the opposite effect. Note that too low a value may prevent the erase operation from working at all: the chip will be spending its time suspending and resuming, rather than actually performing the erase. The minimum value will depend on the specific hardware.

There are a number of other options, relating mostly to hardware characteristics. It is very rare that application developers need to change any of these. For example the option CYGNUM_DEVS_FLASH_SST_39VFXXX_V2_ERASE_REGIONS may need a non-default value if the flash devices used on the target have an unusual boot block layout. If so the platform HAL will impose a requires constraint on this option and the configuration system will resolve the constraint. The only time it might be necessary to change the value manually is if the actual board being used is a variant of the one supported by the platform HAL and uses a different flash chip.

Name

Instantiating — including the driver in an eCos target

Synopsis

#include <cyg/io/39vfxxx_dev.h>

int **cyg_at49xxxx_unlock**(*device*, *addr*);

int **cyg_39vfxxx_read_devid_XX**(*device*);

Description

The 39VFXXX family contains several different flash devices, all supporting the same basic set of operations but with various common or uncommon extensions. The devices vary in capacity, performance, boot block layout, and width. There are also platform-specific issues such as how many devices are actually present on the board and where they are mapped in the address space. The 39vfxxx driver package cannot know the details of every chip and every platform. Instead it is the responsibility of another package, usually the platform HAL, to supply the necessary information by instantiating some data structures. Two pieces of information are especially important: the bus configuration and the boot block layout.

Flash devices are typically 8-bits, 16-bits, or 32-bits wide (64-bit devices are not yet in common use). Most 16-bit devices will also support 8-bit accesses, but not all. Similarly 32-bit devices can be accessed 16-bits at a time or 8-bits at a time. A board will have one or more of these devices on the bus. For example there may be a single 16-bit device on a 16-bit bus, or two 16-bit devices on a 32-bit bus. The processor's bus logic determines which combinations are possible, and there will be a trade off between cost and performance: two 16-bit devices in parallel can provide twice the memory bandwidth of a single device. The driver supports the following combinations:

8 A single 8-bit flash device on an 8-bit bus.

16 A single 16-bit flash device on a 16-bit bus.

32 A single 32-bit flash device on an 32-bit bus.

88 Two parallel 8-bit devices on an 16-bit bus.

8888 Four parallel 8-bit devices on a 32-bit bus.

1616 Two parallel 16-bit devices on a 32-bit bus, with one device providing the bottom two bytes of each 32-bit datum and the other device providing the top two bytes.

16as8 A single 16-bit flash device connected to an 8-bit bus.

These configuration all require slightly different code to manipulate the hardware. The 39vfxxx driver package provides separate functions for each configuration, for example `cyg_39vfxxx_erase_16` and `cyg_39vfxxx_program_1616`.

Caution

At the time of writing not all the configurations have been tested.

The second piece of information is the boot block layout. Flash devices are subdivided into blocks (also known as sectors - both terms are in common use). Some operations such as erase work on a whole block at a time, and for most applications a block is the smallest unit that gets updated. A typical block size is 64K. It is inefficient to use an entire 64K block for small bits of configuration data and similar information, so many flash devices also support a number of smaller boot blocks. A typical 2MB flash device could have a single 16K block, followed by two 8K blocks, then a 32K block, and finally 31 full-size 64K blocks. The boot blocks may appear at the bottom or the top of the device. So-called uniform devices do not have boot blocks, just full-size ones. The driver needs to know the boot block layout. With modern devices it can work this out at run-time, but often it is better to provide the information statically.

Example

In most cases flash support is specific to a platform. Even if two platforms happen to use the same flash device there are likely to be differences such as the location in the address map. Hence there is little possibility of re-using the platform-specific code, and this code should be placed in the platform HAL rather than in a separate package. Typically this involves a separate file and a corresponding compile property in the platform HAL's CDL:

```
cdl_package CYGPKG_HAL_M68K_ALAIA {
    …
    compile -library=libextras.a alaia_flash.c
    …
}
```

The contents of this file will not be accessed directly, only indirectly via the generic flash API, so normally it would be removed by link-time garbage collection. To avoid this the object file has to go into `libextras.a`.

The actual file `alaia_flash.c` will look something like:

```
#include <pkgconf/system.h>
#ifdef CYGPKG_DEVS_FLASH_SST_39VFXXX_V2

#include <cyg/io/flash.h>
#include <cyg/io/flash_dev.h>
#include <cyg/io/39vfxxx_dev.h>

static const CYG_FLASH_FUNS(hal_alaia_flash_amd_funs,
    &cyg_39vfxxx_init_check_devid_16,
    &cyg_flash_devfn_query_nop,
    &cyg_39vfxxx_erase_16,
    &cyg_39vfxxx_program_16,
    (int (*)(struct cyg_flash_dev*, const cyg_flashaddr_t, void*, size_t))0,
    &cyg_flash_devfn_lock_nop,
    &cyg_flash_devfn_unlock_nop);

static const cyg_39vfxxx_dev hal_alaia_flash_priv = {
    .devid      = 0x45,
    .block_info = {
        { 0x00004000, 1 },
        { 0x00002000, 2 },
        { 0x00008000, 1 },
        { 0x00010000, 63 }
    }
};

CYG_FLASH_DRIVER(hal_alaia_flash,
                 &hal_alaia_flash_amd_funs,
                 0,
                 0xFFC00000,
                 0xFFFFFFFF,
                 4,
                 hal_alaia_flash_priv.block_info,
                 &hal_alaia_flash_priv
);
#endif
```

The bulk of the file is protected by an `#ifdef` for the 39vfxxx flash driver. That driver will only be active if the generic flash support is enabled. Without that support there will be no way of accessing the device so instantiating the data structures would serve no purpose. The rest of the file is split into three structure definitions. The first supplies the functions which will be used to perform the actual flash accesses, using a macro provided by the generic flash code in `cyg/io/flash_dev.h`. The relevant ones have an `_16` suffix, indicating that on this board there is a single 16-bit flash device on a 16-bit bus. The second provides information specific to 39vfxxx flash devices. The third provides the cyg_flash_dev structure needed by the generic flash code, which contains pointers to the previous two.

Functions

All eCos flash device drivers must implement a standard interface, defined by the generic flash code `CYGPKG_IO_FLASH`. This interface includes a table of seven function pointers for various operations: initialization, query, erase, program, read, locking and unlocking. The query operation is optional and the generic flash support provides a dummy implementation `cyg_flash_devfn_query_nop`. 39vfxxx flash devices are always directly accessible so there is no need for a separate read function. The remaining functions are more complicated.

Usually the table can be declared `const`. In a ROM startup application this avoids both ROM and RAM copies of the table, saving a small amount of memory. `const` should not be used if the table may be modified by a platform-specific initialization routine.

Initialization

There is a choice of three main initialization functions. The simplest is `cyg_flash_devfn_init_nop`, which does nothing. It can be used if the cyg_39vfxxx_dev and cyg_flash_dev structures are fully initialized statically and the flash will just work without special effort. This is useful if it is guaranteed that the board will always be manufactured using the same flash chip, since the nop function involves the smallest code size and run-time overheads.

The next step up is `cyg_39vfxxx_init_check_devid_XX`, where `XX` will be replaced by the suffix appropriate for the bus configuration. It is still necessary to provide all the device information statically, including the *`devid`* field in the cyg_39vfxxx_dev structure. This initialization function will attempt to query the flash device and check that the provided device id matches the actual hardware. If there is a mismatch the device will be marked uninitialized and subsequent attempts to manipulate the flash will fail.

If the board may end up being manufactured with any of a number of different flash chips then the driver can perform run-time initialization, using a `cyg_39vfxxx_init_cfi_XX` function. This queries the flash device as per the Common Flash Memory Interface Specification, supported by all current devices (although not necessarily by older devices). The *`block_info`* field in the cyg_39vfxxx_dev structure and the *`end`* and *`num_block_infos`* fields in the cyg_flash_dev structure will be filled in. It is still necessary to supply the *`start`* field statically since otherwise the driver will not know how to access the flash device. The main disadvantage of using CFI is that it increases the code size.

Caution

If CFI is used then the cyg_39vfxxx_dev structure must not be declared `const`. The CFI code will attempt to update the structure and will fail if the structure is held in read-only memory. This would leave the flash driver non-functional.

A final option is to use a platform-specific initialization function. This may be useful if the board may be manufactured with one of a small number of different flash devices and the platform HAL needs to adapt to this. The 39vfxxx driver provides a utility function to read the device id, `cyg_39vfxxx_read_devid_XX`:

```
static int
alaia_flash_init(struct cyg_flash_dev* dev)
{
    int devid = cyg_39vfxxx_read_devid_1616(dev);
    switch(devid) {
        case 0x0042 :
          …
        case 0x0084 :
          …
        default:
          return CYG_FLASH_ERR_DRV_WRONG_PART;
    }
}
```

There are many other possible uses for a platform-specific initialization function. For example initial prototype boards might have only supported 8-bit access to a 16-bit flash device rather than 16-bit access, but this problem was fixed in the next revision. The platform-specific initialization function can figure out which model board it is running on and replace the default `16as8` functions with faster `16` ones.

Erase and Program

The 39vfxxx driver provides erase and program functions appropriate for the various bus configurations. On most targets these can be used directly. On some targets it may be necessary to do some extra work before and after the erase and program operations. For example if the hardware has an MMU then the part of the address map containing the flash may have been set to read-only, in an attempt to catch spurious memory accesses. Erasing or programming the flash requires write-access, so the MMU settings have to be changed temporarily. As another example some flash device may require a higher voltage to be applied during an erase or program operation. or a higher voltage may be desirable to make the operation proceed faster. A typical platform-specific erase function would look like this:

```
static int
alaia_flash_erase(struct cyg_flash_dev* dev, cyg_flashaddr_t addr)
{
    int result;
    …  // Set up the hardware for an erase
    result = cyg_39vfxxx_erase_32(dev, addr);
    …  // Revert the hardware change
    return result;
}
```

There are two configurations which affect the erase and program functions, and which a platform HAL may wish to change: `CYGNUM_DEVS_FLASH_SST_39VFXXX_V2_ERASE_TIMEOUT` and `CYGNUM_DEVS_FLASH_SST_39VFXXX_V2_PROGRAM_TIMEOUT`. The erase and program operations both involve polling for completion, and these timeout impose an upper bound on the polling loop. Normally these operations should never take anywhere close to the timeout period, so a timeout indicates a catastrophic failure that should really be handled by a watchdog reset. A reset is particularly appropriate because there will be no clean way of aborting the flash operation. The main reason for the timeouts is to help with debugging when porting to new hardware. If there is a valid reason why a particular platform needs different timeouts then the platform HAL's CDL can require appropriate values for these options.

Locking

There is no single way of implementing the block lock and unlock operations on all 39vfxxx devices. If these operations are supported at all then usually they involve manipulating the voltages on certain pins. This would not be able to be handled by generic driver code since it requires knowing how these pins can be manipulated via the processor's GPIO lines. Therefore the 39vfxxx driver does not usually provide lock and unlock functions, and instead the generic dummy functions `cyg_flash_devfn_lock_nop` and `cyg_flash_devfn_unlock_nop` should be used. An exception exists for the AT49xxxx family of devices which are sufficiently SST compatible in other respects. Otherwise, if a platform does provide a way of implementing the locking then this can be handled by platform-specific functions.

```
static int
alaia_lock(struct cyg_flash_dev* dev, const cyg_flashaddr_t addr)
{
    …
}
```

```
static int
alaia_unlock(struct cyg_flash_dev* dev, const cyg_flashaddr_t addr)
{
    …
}
```

If real locking functions are implemented then the platform HAL's CDL script should implement the CDL interface CYGHWR_IO_FLASH_BLOCK_LOCKING. Otherwise the generic flash package may believe that none of the flash drivers in the system provide locking functionality and disable the interface functions.

AT49xxxx locking

As locking is standardised on across the AT49xxxx family of SST 39vfxxx compatible Flash parts, a method is supporting this is included within this driver. cyg_at49xxxx_softlock_XX provides a means of locking a Flash sector such that it may be subsequently unlocked. cyg_at49xxxx_hardlock_XX locks a sector such that it cannot be unlocked until after reset or a power cycle. cyg_at49xxxx_unlock_XX unlocks a sector that has previously been softlocked. At power on or Flash device reset, all sectors default to being softlocked.

Other

The driver provides a set of functions cyg_39vfxxx_read_devid_XX, one per supported bus configuration. These functions take a single argument, a pointer to the cyg_flash_dev structure, and return the chip's device id. For older devices this id is a single byte. For more recent devices the id is a 3-byte value, 0x7E followed by a further two bytes that actually identify the device. cyg_39vfxxx_read_devid_XX is usually called only from inside a platform-specific driver initialization routine, allowing the platform HAL to adapt to the actual device present on the board.

Device-Specific Structure

The cyg_39vfxxx_dev structure provides information specific to 39vfxxx flash devices, as opposed to the more generic flash information which goes into the cyg_flash_dev structure. There are only two fields: *devid* and *block_info*.

devid is only needed if the driver's initialization function is set to cyg_39vfxxx_init_check_devid_XX. That function will extract the actual device info from the flash chip and compare it with the *devid* field. If there is a mismatch then subsequent operations on the device will fail.

The *block_info* field consists of one or more pairs of the block size in bytes and the number of blocks of that size. The order must match the actual hardware device since the flash code will use the table to determine the start and end locations of each block. The table can be initialized in one of three ways:

1. If the driver initialization function is set to cyg_flash_devfn_init_nop or cyg_39vfxxx_init_check_devid_XX then the block information should be provided statically. This is appropriate if the board will also be manufactured using the same flash chip.

2. If cyg_39vfxxx_init_cfi_XX is used then this will fill in the block info table. Hence there is no need for static initialization.

3. If a platform-specific initialization function is used then either this should fill in the block info table, or the info should be provided statically.

The size of the *block_info* table is determined by the configuration option CYGNUM_DEVS_FLASH_SST_39VFXXX_V2_ERASE_REGIONS. This has a default value of 4, which should suffice for nearly all 39vfxxx flash devices. If more entries are needed then the platform HAL's CDL script should require a larger value.

If the cyg_39vfxxx_dev structure is statically initialized then it can be const. This saves a small amount of memory in ROM startup applications. If the structure is updated at run-time, either by cyg_39vfxxx_init_cfi_XX or by a platform-specific initialization routine, then it cannot be const.

Flash Structure

Internally the generic flash code works in terms of cyg_flash_dev structures, and the platform HAL should define one of these. The structure should be placed in the `cyg_flashdev` table. The following fields need to be provided:

funs
: This should point at the table of functions.

start
: The base address of the flash in the address map. On some board the flash may be mapped into memory several times, for example it may appear in both cached and uncached parts of the address space. The *start* field should correspond to the cached address.

end
: The address of the last byte in the flash. It can either be statically initialized, or `cyg_39vfxxx_init_cfi_XX` will calculate its value at run-time.

num_block_infos
: This should be the number of entries in the *block_info* table. It can either be statically initialized or it will be filled in by `cyg_39vfxxx_init_cfi_XX`.

block_info
: The table with the block information is held in the cyg_39vfxxx_dev structure, so this field should just point into that structure.

priv
: This field is reserved for use by the device driver. For the 39vfxxx driver it should point at the appropriate cyg_39vfxxx_dev structure.

The cyg_flash_dev structure contains a number of other fields which are manipulated only by the generic flash code. Some of these fields will be updated at run-time so the structure cannot be declared `const`.

Multiple Devices

A board may have several flash devices in parallel, for example two 16-bit devices on a 32-bit bus. It may also have several such banks to increase the total amount of flash. If each device provides 2MB, there could be one bank of 2 parallel flash devices at 0xFF800000 and another bank at 0xFFC00000, giving a total of 8MB. This setup can be described in several ways. One approach is to define two cyg_flash_dev structures. The table of function pointers can usually be shared, as can the cyg_39vfxxx_dev structure. Another approach is to define a single cyg_flash_dev structure but with a larger *block_info* table, covering the blocks in both banks of devices. The second approach makes more efficient use of memory.

Many variations are possible, for example a small slow flash device may be used for initial bootstrap and holding the configuration data, while there is also a much larger and faster device to hold a file system. Such variations are usually best described by separate cyg_flash_dev structures.

If more than one cyg_flash_dev structure is instantiated then the platform HAL's CDL script should implement the CDL interface `CYGHWR_IO_FLASH_DEVICE` once for every device past the first. Otherwise the generic code may default to the case of a single flash device and optimize for that.

Platform-Specific Macros

The 39vfxxx driver source code includes the header files `cyg/hal/hal_arch.h` and `cyg/hal/hal_io.h`, and hence indirectly the corresponding platform header files (if defined). Optionally these headers can define macros which are used inside the driver, thus giving the HAL limited control over how the driver works.

Cache Management

By default the 39vfxxx driver assumes that the flash can be accessed uncached, and it will use the HAL `CYGARC_UNCACHED_ADDRESS` macro to map the cached address in the *start* field of the cyg_flash_dev structure into an uncached address. If for any reason this HAL macro is inappropriate for the flash then an alternative macro HAL_39VFXXX_UNCACHED_ADDRESS can be defined instead. However fixing the CYGARC_UNCACHED_ADDRESS macro is normally the better solution.

If there is no way of bypassing the cache then the platform HAL should implement the CDL interface CYGHWR_DEVS_FLASH_SST_39VFXXX_V2_CACHED_ONLY. The flash driver will now disable and re-enable the cache as required. For example a program operation will involve the following:

```
AM29_INTSCACHE_STATE;
AM29_INTSCACHE_BEGIN();
while ( ! finished ) {
    write a burst of CYGNUM_DEVS_FLASH_SST_39VFXXX_V2_PROGRAM_BURST_SIZE
    AM29_INTSCACHE_SUSPEND();
    AM29_INTSCACHE_RESUME();
}
AM29_INTSCACHE_END();
```

The default implementations of these INTSCACHE macros are as follows: STATE defines any local variables that may be needed, e.g. to save the current interrupt state; BEGIN disables interrupts, synchronizes the data caches, disables it, and invalidates the current contents; SUSPEND re-enables the data cache and then interrupts; RESUME disables interrupts and the data cache; END re-enables the cache and then interrupts. The cache is only disabled when interrupts are disabled, so there is no possibility of an interrupt handler running or a context switch occurring while the cache is disabled, potentially leaving the system running very slowly. The data cache synchronization ensures that there are no dirty cache lines, so when the cache is disabled the low-level flash write code will not see stale data in memory. The invalidate ensures that at the end of the operation higher-level code will not pick up stale cache contents instead of the newly written flash data. The SUSPEND and RESUME macros only re-enable and disable the data cache. An interrupt and possibly a context switch may occur between these macros and use the cache normally. It is assumed that any code which runs at this time will not touch the memory being used by the flash operation, so as far as the low-level program code is concerned it can just continue to use the uncached memory contents as set up by the BEGIN macro. If any code modifies the const data currently being written to a flash block or tries to read the flash block being modified then the system's behaviour is undefined. Theoretically a more robust approach is possible, synchronizing and invalidating the cache again in every RESUME. However these cache operations can be expensive and RESUME may get invoked some thousands of times for every flash block, so this alternative approach would cripple the driver's performance.

Some implementations of the HAL cache macros may not provide the exact semantics required by the flash driver. For example HAL_DCACHE_DISABLE may have an unwanted side effect, or it may do more work than is needed here. The driver will check for alternative macros HAL_39VFXXX_INTSCACHE_STATE, HAL_39VFXXX_INTSCACHE_BEGIN, HAL_39VFXXX_INTSCACHE_SUSPEND, HAL_39VFXXX_INTSCACHE_RESUME and HAL_39VFXXX_INTSCACHE_END, using these instead of the defaults.

Part XIX. ecoflash Flash Programming Utility

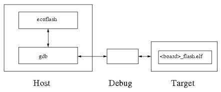
Description

ecoflash is a utility for programming on-board flash via BDM, jtag, or similar hardware debug technology. There is nothing particularly original about this. Most manufacturers will provide similar utilities, and in fact those are likely to offer better performance because they operate at a lower level. The main advantages of ecoflash are: it provides a common user experience across a range of hardware; it is designed to work within a typical eCos development environment; and it has some built-in knowledge of how eCos systems work.

ecoflash works by running a suitable version of **gdb** on the host machine and running gdb commands. That version of gdb must either be able to drive the hardware debug technology directly, or more commonly it will in turn interact with some stub or daemon that knows how to drive the debug hardware. The target is initialized and a small target-side executable, for example `m5213evb_flash.elf`, is then loaded on to the target. The target-side executable is a simple eCos application that is linked with the eCos flash driver support, so it can be readily ported to any target for which a suitable flash driver is available. Manipulating the flash involves setting target-side variables used gdb commands, letting the target-side executable run until a breakpoint is hit, and then examining more target-side variables to determine the status.



The basic syntax is: ecoflash [standard options] subcommand [options] args [optional args]. The standard options provide information such as the target board, and most of these can be specified instead using environment variables. The subcommands specify the exact operation to be performed, for example to program an executable at the default location within the flash. Some subcommands take additional options, for example to suppress automatic erasure of flash blocks. These are followed by required arguments such as the executable filename, and possibly optional arguments. **ecoflash -h** with no additional argument provides help information for the utility as a whole. Additional information for a specific subcommand can be obtained using e.g. **ecoflash -h program**.

Standard Options

ecoflash accepts a number of standard options, for example the target board can be specified using `-b board`. These options will be used by several but not all of the subcommands.

-h
--help

Obtain help information about ecoflash or one of its subcommands.

--version

Display the ecoflash version string.

--dry-run

This suppresses the low-level block erase and write operations so the flash state does not actually change, but otherwise ecoflash operates normally including initializing the board, downloading the target-side executable, and having the latter initialize the eCos flash driver. It can be used to verify that the hardware is operating correctly.

-q
--quiet
-v
--verbose

These can be used to reduce or increase the amount of feedback generated by ecoflash. `-v` can be specified several times for increased verbosity.

-b <board>
--board=<board>

ecoflash needs to know which target board it should access, so that it can perform appropriate initialization and download the right target-side executable. **ecoflash boards** can be used to get a list of supported boards. It is possible to set an environment variable `ECOFLASH_BOARD` as an alternative to specifying this option on the command line every time:

```
$ export ECOFLASH_BOARD=m5213evb
```

The board name has two effects. It causes ecoflash to load a configuration file `<board>.ecf` with hardware-specific information, for example how to initialize the board using gdb commands. It also determines the target-side executable `<board>_flash.elf`. For both files ecoflash will first look in the current directory. If an `ECOFLASH_DIR` environment variable is defined then it will look in that directory. Finally it will look in the directory `../share/ecos/ecoflash` relative to the ecoflash executable.

-g <gdb executable>
--gdb=<gdb executable>

All subcommands except **boards** involve starting a gdb session on the host and downloading a target-side executable. Usually the gdb executable, for example **m68k-elf-gdb**, is specified in the board `.ecf` configuration file and found in the current `PATH`, so there is no need to use this option. However an alternative gdb can be specified if desired, for example when building and debugging an experimental version of gdb. The environment variable `ECOFLASH_GDB` can also be used instead of the command line option.

-o <objcopy executable>
--objcopy=<objcopy executable>

The **program** subcommand can take an eCos executable in ELF format and automatically convert it to raw binary to program into flash. This involves running the appropriate host-side objcopy utility, for example **m68k-elf-objcopy**. By default ecoflash will munge the gdb file name to generate the objcopy name and will look for it on the `PATH`, so there is no need to use this option. An alternative objcopy can be specified on the command line or via the `ECOFLASH_OBJCOPY` environment variable.

-t <target command>
--target=<target command

ecoflash needs to know how to get gdb to interact with the debug hardware. The exact details of this depend not just on the hardware but also on the developer's setup, so cannot be provided by the board `.ecf` configuration file. Instead it must be provided by the user, in the form of a gdb target command. For example, if the debug hardware is accessed via a daemon on the local machine and that daemon listens on TCP/IP port 9000 for gdb remote protocol traffic then the gdb command to connect to the target hardware would be: `target remote localhost:9000`. The ecoflash `-t` option should consist of everything after `target`, for example:

```
$ ecoflash -b alaia -t 'remote localhost:9000' info
```

Note the use of quote marks to make the shell treat it as a single argument, even though it contains spaces, and to prevent any processing of special characters like $ and |. The `ECOFLASH_TARGET` environment variable can be set instead:

```
$ export ECOFLASH_TARGET='remote localhost:9000'
```

Supported Boards

ecoflash boards can be used to get the names of the boards supported in the current installation, in other words what `-b` options are valid. A board is considered supported if ecoflash can find a `<board>.ecf` configuration file and a target-side executable `<board>_flash.elf`. It will search in the current directory, in the directory specified by the `ECOFLASH_DIR` environment variable if that is defined, and in a directory relative to the ecoflash executable. For example if ecoflash is installed in `/usr/local/ecos/bin` then it will search in `/usr/local/ecos/share/ecos/ecoflash`.

Note that **ecoflash boards** only examines the file system and does not attempt to start gdb or interact in any way with target hardware.

Board Information

ecoflash info can be used to get information about a particular board, and also to verify that everything is working correctly.

```
% ecoflash -b m5213evb -t 'remote localhost:9000' info
Target board is m5213evb.
  gdb is "m68k-elf-gdb", gdb target is "remote localhost:9000"
  Target-side executable is version 1.
  Detected 1 bank of flash.
    Start 0x00000000, end 0x0003ffff -> 256K.
      128 blocks of 2K.
  Flash block locking is not supported.
  Default program location for executables is 0x00000000.
  Target-side buffer for read and write operation is 16K.
```

This shows the gdb command and the target string, which can be useful if that information comes from environment variables rather than the command line. ecoflash will run gdb and download the target-side executable, which reports itself as version 1. The target-side executable initializes the eCos flash driver and has detected the amount of flash reported and that lock and unlock operations are not supported. By default executables will be programmed at location 0x0, and transfers between host and target use a 16k buffer (the M5213EVB only has a small amount of RAM, usually a larger buffer will be used).

Programming an Executable

ecoflash program can be used to install an eCos executable at the boot location within the flash. The executable should be linked against an eCos configuration with a suitable startup type, usually ROM or ROMRAM although this may vary between platforms. In its simplest form the subcommand just takes a single argument, a filename for the executable:

```
$ ecoflash program redboot.elf
Erasing 0x00000000 - 0x0000be57
Writing 0x00000000 - 0x00003fff (16384 bytes) from file "/tmp/redboot.1495", offset 0
Writing 0x00004000 - 0x00007fff (16384 bytes) from file "/tmp/redboot.1495", offset 16384
Writing 0x00008000 - 0x0000be57 (15960 bytes) from file "/tmp/redboot.1495", offset 32768
```

This assumes the `ECOFLASH_BOARD` and `ECOFLASH_TARGET` environment variables are set. ecoflash will examine the specified file. ELF executables will be automatically converted to a temporary raw binary file before being programmed into flash, using the objcopy utility. The default address within the flash is supplied by the target-side executable. Usually this will be the processor's boot location but the exact boot mechanism varies widely between processors and platforms.

ecoflash program takes two options. `-r` or `--raw` can be used to suppress the detection of ELF format files. Instead the file will be treated as a raw binary and no conversion is performed. This may be useful if the board has its own primary bootloader which expects to find an ELF executable at a particular address within the flash. `-n` or `--no-erase` can be used to suppress the automatic erase of the flash blocks prior to programming the flash. This may be useful on hardware where flash erase is optional, or if ecoflash is used in a batch environment where a previous step will have already erased the required amount of flash.

ecoflash program takes an optional additional argument, an alternative address within the flash. This may be useful if for example the board can boot from one of two locations depending on the state of a jumper.

Dumping Flash Contents

ecoflash dump can be used to read part or all of the flash and dump the data to a file on the host. This can be particularly useful when saving a known working image prior to replacing it with an experimental version. The default behaviour is to dump the entire flash contents:

```
$ ecoflash dump /tmp/working.bin
Dumping 0x00000000 - 0x00003fff (16384 bytes) to file "/tmp/working.bin"
Dumping 0x00004000 - 0x00007fff (16384 bytes) to file "/tmp/working.bin"
…
```

Optionally the starting address and the length can be specified:

```
$ ecoflash dump /tmp/working.bin 0xFFF00000 128K
```

Lengths can be specified in bytes, kilobytes using a K suffix, megabytes using an M suffix, or flash blocks using a B suffix. Note that some flash devices have boot blocks of varying sizes so specifying a size in terms of blocks can be confusing.

ecoflash dump takes a single option, `-a` or `--append`. This causes ecoflash to append to the specified file instead of overwriting it.

Erasing Flash Blocks

ecoflash erase can be used to erase one or more flash blocks. This command is rarely needed since both the program and write subcommands will erase the required number of flash blocks by default, but may prove useful if the flash contains data other than an eCos executable and that data should be reset to uninitialized. In its simplest form the erase subcommand just takes an address:

```
$ ecoflash erase 0x40000
```

This causes ecoflash to erase the single flash block containing the specified address. Optionally a length can be specified, for example to erase 8 flash blocks:

```
$ ecoflash erase 0x40000 8B
```

The length can be specified in bytes, in kilobytes using a K suffix, in megabytes using an M suffix, or in flash blocks using a B suffix. Care must be taken if the specified address is not at the start of a flash block. For example if the address is 0x48000, the length is 128K, and flash blocks are 64K, then this is treated as a request to erase flash from 0x48000 to 0x67FFF. Since erase operations always involve whole flash blocks the actual erase affects all memory from 0x40000 to 0x6FFFF, so a total of 192K gets erased.

The erase subcommand does not have any options of its own, just the standard ones for all subcommands.

Writing Raw Data

ecoflash write can be used to write a raw data file to an arbitrary location within the flash. It is intended for installing additional data rather than the main executable, since the **program** subcommand is more appropriate for the latter. At least a filename and an address within the flash should be specified:

```
$ ecoflash write data.bin 0x00040000
Erasing 0x00040000 - 0x0004297c
Writing 0x00040000 - 0x0004297c (10621 bytes) from file "data.bin", offset 0
```

Optionally a length can be specified, for example:

```
$ ecoflash write data.bin 0x00040000 64K
```

This will write only the first 64K of data.bin rather than the whole file. The length can be specified in bytes, in kilobytes using a K suffix, in megabytes using an M suffix, or in flash blocks using a B suffix.

ecoflash write takes two options. `-n` or `--no-erase` can be used to suppress the automatic erase before the data is written to flash. This can be useful if a single flash block should contain data from more than one file: **ecoflash erase** would be used to erase the whole flash black, then two **ecoflash write -n** commands would program the two files at the appropriate locations; alternatively the erase step can be skipped in subsumed by the first write, with only the second write using a `-n` option.

`-o <offset>` or `-offset=<offset>` can be used to skip part of a file. For example the following writes 12K of a file starting at a 4K offset:

```
$ ecoflash write --offset=4096 data.bin 12K
```

The offset can be specified in bytes, kilobytes using a K suffix, or megabytes using an M suffix.

Locking and Unlocking

On targets where the hardware and the flash driver support locking, the **lock** and **unlock** subcommands can be used to manipulate the locked status of one or more flash blocks. Both subcommands take an address and an optional length:

```
$ ecoflash lock 0x40000
…
$ ecoflash unlock 0x50000 256K
```

If no length is specified then just a single flash block is affected, unless the hardware implements locking at a coarser grain than individual flash blocks. The length can be specified in bytes, in kilobytes using a K suffix, in megabytes using an M suffix, or in flash blocks using a B suffix.

With some flash hardware locking is not persistent. Instead the locks are set to a default state when the flash chips are powered up or reset, usually locked. On such hardware the ecoflash lock and unlock subcommands are of little use since the locks would revert to their default state when ecoflash exits. Instead the target-side executable will either unlock all flash blocks during initialization or take whatever action is needed at run-time to handle erase and write operations.

Installation

Depending on your eCos distribution ecoflash may already be installed on your system. If not, installation is straightforward. The host-side consists of a single executable `ecoflash` in the package's `host` subdirectory. This is actually a platform-independent script written in the expect scripting language. It needs to be installed in a suitable location on the user's search `PATH`. The file can just be copied manually, or alternatively the `host` subdirectory contains a suitable configure script and support files:

```
$ <package path>/host/configure --prefix=/usr/local
$ make
$ make install
```

This will install ecoflash in the directory `/usr/local/bin`. Note that eCos also has a top-level `configure` script which will find subsidiary `configure` scripts inside the individual packages. A top-level configure/make/make install sequence will automatically install ecoflash as well as host-side support from other packages.

The ecoflash package contains only the generic support. It should be complemented by a `.ecf` configuration file and a `_flash.elf` target-side executable for every supported platform. The platform HAL's `misc` subdirectory usually holds a suitable `.ecf` file. The target-side executable will need to be rebuilt:

```
$ ecosconfig new <target> minimal
$ ecosconfig import <path>/ecoflash.ecm
$ ecosconfig tree
$ make
```

For an existing port there should be an `ecoflash.ecm` file in the platform HAL's misc subdirectory. Importing this will add the ecoflash package and any necessary support packages, set any platform-specific configuration options, and resolve any conflicts. After the make there should be a file `install/bin/flash.elf`, the target-side executable, and this should get renamed to `<board>_flash.elf` and installed in a location where ecoflash will find it.

Porting

Typically the only hard part of porting ecoflash to a new platform is to get gdb to interact with the jtag or BDM hardware and initialize the board. The porting process involves three steps: adding appropriate definitions to the platform HAL; building the target-side executable `<board>_flash.elf`; and writing the platform configuration file `<board>.ecf`.

The platform HAL must supply a single #define'd symbol corresponding to the default base address for **ecoflash program** operations. Usually this symbol gets defined in `cyg/hal/plf_io.h`, but the details may vary between architectures.

```
#define HAL_ECOFLASH_PROGRAM_BASE        0x00000000
```

Optionally the platform HAL can define a buffer size using `HAL_ECOFLASH_BUFLEN`, an additional header file to include using `HAL_ECOFLASH_HEADER`, and an initialization macro `HAL_ECOFLASH_EXTRA_INIT()`. The latter may perform operations such as unlocking all flash blocks on hardware where locks are transient.

The target-side executable is a very simple eCos application that uses the generic flash driver support to interact with the the hardware. Hence it assumes that a suitable flash driver is already available. Code and data sizes are both of the order of 4K, although obviously that will depend on the processor architecture. Usually the code will be RAM-resident and linked with a JTAG or RAM startup configuration. In addition a buffer is needed for transferring data between host and target. By default that buffer is 64K, corresponding to typical flash block sizes, but can be smaller if there is not enough RAM for a buffer that size. Building the target-side executable is straightforward:

```
$ ecosconfig new <target> minimal
$ ecosconfig add CYGPKG_IO_FLASH CYGPKG_LIBC_STRING CYGPKG_ECOFLASH
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

It may be necessary to tweak the configuration data before generating the build tree, for example to change the startup type to JTAG or RAM. Adding the ecoflash package will result in one conflict related to the global compiler flags: by default ecoflash is built with no eCos debugging information, except for the ecoflash application itself. The target-side executable may get checked into the source code control system as a binary, so avoiding debug information helps to keep the size down. Stripping out all debug information after the build is not possible because it would interfere with some of the gdb commands that ecoflash uses to interact with the target.

The result of the make is an executable `flash.elf` in the `install/bin` subdirectory. This should get renamed to `<target>_flash.elf` and installed to a directory where ecoflash will find it. Optionally an `ecoflash.ecm` file containing the configuration settings can be exported to facilitate future rebuilding.

Next it is necessary to write the configuration file `<target>.ecf`. This is a straightforward expect script that gets included by the main ecoflash executable. It should set variables `::gdb_executable` and `::command_prefix`. Optionally it may also define procedures `target_init0`, `target_init1`, and `target_kill`. `target_init0` is invoked after gdb has been started but before the gdb target command has been issued. `target_init1` is invoked after the gdb target command has been issued, and typically takes care of initializing the board via a sequence of gdb commands. To facilitate this the main ecoflash script provides procedures gdb_run_command and gdb_run_quiet_command which will do the hard work. `target_kill` is invoked just before shutting down the gdb session. The `<target>.ecf` file is typically placed in the platform HAL's `misc` subdirectory.

Part XX. Flash Safe

Name

CYGPKG_FLASHSAFE — provide safe storage for data in flash memory

Description

The Flash Safe package provides a robust and simple mechanism for storing data in flash memory. It is intended for relatively small quantities of data such as configuration and customization data. For larger amounts of data, the JFFS2 flash filesystem is available.

The Flash Safe operates by dividing a region of the flash into a number of equal sized blocks. Each block is given a sequence number and is checksummed. A header containing these is stored at the start and end of each block. At startup the Flash Safe searches the available blocks for one with the latest sequence number and a valid checksum. The application can now retrieve data stored in the Flash Safe against a numeric key.

To store new data, the application opens a block, which will cause the block with the oldest sequence number to be erased and prepared for writing. Data can now be written to the block with a numeric key identifying each write. When all the data has been written, the block is committed, which will cause the headers to be written with valid checksums. This block now becomes the source of all subsequent data retrieval, freeing the original valid block for reuse.

This approach provides a simple transactional mechanism for storing data across power failures and crashes. At any time at least one committed block is valid and is released only after a new valid block has been committed to replace it. Any interruption during the creation of a new block will leave it invalid and data retrieval will fall back to the last committed block. The use of keys to identify data makes retrieval independent of the order in which the items are stored, of any change in size of the data and of any alignment requirements of the underlying flash device and driver.

The Flash Safe needs a minimum of two blocks to be defined, which must each be a multiple of the block size of the underlying flash device. A single Flash Safe block per flash device block would be the normal approach. More Flash Safe blocks may be used to implement a crude wear levelling mechanism, since under normal circumstances the Flash Safe will use the blocks in a round-robin manner.

Configuration

The flashsafe is mostly configured at runtime. The following CDL configuration options are present:

CYGNUM_FLASHSAFE_BUFFER_SIZE

> This option defines the size of the buffer that the flashsafe uses to store data prior to writing it to disk. Different flash devices have different alignment and minimum sizes for writes to the flash. This buffer collects data items into segments that can be written in single operations.
>
> A flashsafe block can be viewed as an array of segments of `CYGNUM_FLASHSAFE_BUFFER_SIZE` bytes each. The first and last segments are reserved for the flashsafe system's use, and the rest are available for data storage. So the buffer size may be at most one third the size of the block. The buffer size should also be chosen to be an integer fraction of the block size. It is not possible to change the buffer size once a flashsafe has been initialized, since it plays a part in defining the format of the stored data.

CYGPKG_FLASHSAFE_TESTS

> This lists the set of test programs. At present there is only one test, which runs on the synthetic target.

Interaction with RedBoot

The Flash Safe is mainly targetted at small systems where a FIS directory or JFFS2 would not be appropriate. Consequently it does not try to look up a named entry in the FIS or work via the flash IO device. Instead it uses raw flash block addresses. The flashsafe parameters can be set up at runtime by the application querying the RedBoot FIS interface, and the flash subsystem. The following code extract demonstrates how this might be done.

```
cyg_flashsafe flashsafe;
cyg_flash_info_t flashinfo;
cyg_uint32 size;
int err;

// Initialize flash system
err = cyg_flash_init(diag_printf);
if( err != CYG_FLASH_ERR_OK ) …

// Fetch flashsafe region base and size from FIS directory.
err = CYGACC_CALL_IF_FLASH_FIS_OP(CYGNUM_CALL_IF_FLASH_FIS_GET_FLASH_BASE,
                                  "flashsafe",
                                  &flashsafe.base);
if( err == 0 ) …

err = CYGACC_CALL_IF_FLASH_FIS_OP(CYGNUM_CALL_IF_FLASH_FIS_GET_SIZE,
                                  "flashsafe",
                                  &size);
if( err == 0 ) …

// Fetch flash device info from flash system
err = cyg_flash_get_info_addr( flashsafe.base, &flashinfo );
if( err != CYG_FLASH_ERR_OK ) …

// Calculate block number and size.
flashsafe.block_size = flashinfo.block_info[0].block_size;
flashsafe.block_count = size/flashsafe.block_size;

err = cyg_flashsafe_init( &flashsafe );
if(err != CYG_FLASHSAFE_ERR_OK) …
```

Name

Flash Safe — API Details

Synopsis

#include <cyg/flashsafe/flashsafe.h>

```
int cyg_flashsafe_init(*flashsafe);

int cyg_flashsafe_data(*flashsafe, key, **data);

int cyg_flashsafe_read(*flashsafe, key, *data, *len);

int cyg_flashsafe_open(*flashsafe);

int cyg_flashsafe_write(*flashsafe, key, *data, len);

int cyg_flashsafe_commit(*flashsafe);

const char *cyg_flashsafe_errmsg(err);
```

Description

The flash safe is accessed through this API. The flashsafe is initialized by calling `cyg_flashsafe_init()` passing it a pointer to a cyg_flashsafe structure. Within this structure the *`base`*, *`block_count`* and *`block_size`* fields must have been initialized to describe the area of flash to be managed. Typically, the structure would be defined statically as follows:

```
cyg_flashsafe flashsafe =
{
    .base               = 0x40000000,
    .block_count        = 3,
    .block_size         = 0x2000
};
```

If the flashsafe already contains data, then items may be retrieved using `cyg_flashsafe_data()`. The *`key`* argument identifies the data item to be retrieved. The *`data`* argument is a pointer to a location where a pointer to the data will be stored. Typically the pointer returned will refer directly to the flash device, and will thus be read-only. No size is returned, the application should either know what size the data is (e.g a structure or fixed sized array), or arrange for the data to be self-sized (e.g. a zero terminated string or contains a size field).

The function `cyg_flashsafe_read()` performs a similar job to `cyg_flashsafe_data()` except that the data is copied out of the flash memory. The *`data`* argument points to a buffer into which the data will be copied, and the *`len`* points to a location where the size of the buffer is stored when the call is made, and will contain the size of data copied in on return. This function is useful where it is intended to update the data read from the flashsafe, possibly to write it back to flashsafe. `cyg_flashsafe_data()` is useful where the data only needs to be read, and saves valuable RAM space.

To open a flashsafe block for update the function `cyg_flashsafe_open()` should be called. This will select the oldest block in the safe, erase it and prepare it for writing.

The function `cyg_flashsafe_write()` is used to write new data to the current open block. The *`key`* argument should be an application selected 16 bit value that is used to identify this data item. This value should be unique for each item, otherwise the behaviour is undefined. The *`data`* and *`len`* arguments describe a buffer containing the data to be written. The size of the data written must be less than or equal to the value of `CYGNUM_FLASHSAFE_BUFFER_SIZE`.

The function `cyg_flashsafe_commit()` causes the current open block to be committed to the flash. This involves calculating the checksum and writing the header and trailer with the current sequence number.

Each of these functions may return one of a number of error codes. These may include the following:

CYG_FLASHSAFE_ERR_OK

This is returned when the operation succeeded.

CYG_FLASHSAFE_ERR_FLASH

This is returned when the flash device failed to initialize.

CYG_FLASHSAFE_ERR_MISMATCH

This is returned when there is a mismatch between the size any layout of the flashsafe described in the initialized cyg_flashsafe structure and the flashsafe found in flash.

CYG_FLASHSAFE_ERR_FLASH_PROG

This is returned when the flash driver reports a programming error.

CYG_FLASHSAFE_ERR_FLASH_ERASE

This is returned when the flash driver reports a block erase error.

CYG_FLASHSAFE_ERR_NO_DATA

This is returned when there is no current valid block in the flashsafe. This will usually only happen when the flashsafe is new.

CYG_FLASHSAFE_ERR_BAD_KEY

This is returned when a given key cannot be found in the flashsafe.

CYG_FLASHSAFE_ERR_NOT_OPEN

This is returned when a `cyg_flashsafe_write()` or `cyg_flashsafe_commit()` are called before making a call to `cyg_flashsafe_open()`.

CYG_FLASHSAFE_ERR_NO_SPACE

This is returned when the size of data is too large for either the buffer or the flashsafe block as a whole.

The function `cyg_flashsafe_errmsg()`, if given one of these error codes, will return a string describing the error.

Part XXI. PCI Library

Table of Contents

Chapter 71. The eCos PCI Library

The PCI library is an optional part of eCos, and is only applicable to some platforms.

PCI Library

The eCos PCI library provides the following functionality:

1. Scan the PCI bus for specific devices or devices of a certain class.
2. Read and change generic PCI information.
3. Read and change device-specific PCI information.
4. Allocate PCI memory and IO space to devices.
5. Translate a device's PCI interrupts to equivalent HAL vectors.

Example code fragments are from the pci1 test (see `io/pci/<release>/tests/pci1.c`).

All of the functions described below are declared in the header file `<cyg/io/pci.h>` which all clients of the PCI library should include.

PCI Overview

The PCI bus supports several address spaces: memory, IO, and configuration. All PCI devices must support mandatory configuration space registers. Some devices may also present IO mapped and/or memory mapped resources. Before devices on the bus can be used, they must be configured. Basically, configuration will assign PCI IO and/or memory address ranges to each device and then enable that device. All PCI devices have a unique address in configuration space. This address is comprised of a bus number, a device number, and a function number. Special devices called bridges are used to connect two PCI busses together. The PCI standard supports up to 255 busses with each bus having up to 32 devices and each device having up to 8 functions.

The environment in which a platform operates will dictate if and how eCos should configure devices on the PCI bus. If the platform acts as a host on a single PCI bus, then devices may be configured individually from the relevant device driver. If the platform is not the primary host, such as a PCI card plugged into a PC, configuration of PCI devices may be left to the PC BIOS. If PCI-PCI bridges are involved, configuration of all devices is best done all at once early in the boot process. This is because all devices on the secondary side of a bridge must be evaluated for their IO and memory space requirements before the bridge can be configured.

Initializing the bus

The PCI bus needs to be initialized before it can be used. This only needs to be done once - some HALs may do it as part of the platform initialization procedure, other HALs may leave it to the application or device drivers to do it. The following function will do the initialization only once, so it's safe to call from multiple drivers:

```
void cyg_pci_init( void );
```

Scanning for devices

After the bus has been initialized, it is possible to scan it for devices. This is done using the function:

```
cyg_bool cyg_pci_find_next(  cyg_pci_device_id cur_devid,
                             cyg_pci_device_id *next_devid );
```

It will scan the bus for devices starting at *`cur_devid`*. If a device is found, its devid is stored in *`next_devid`* and the function returns `true`.

The pci1 test's outer loop looks like:

```
cyg_pci_init();
if (cyg_pci_find_next(CYG_PCI_NULL_DEVID, &devid)) {
    do {
         <use devid>
    } while (cyg_pci_find_next(devid, &devid));
}
```

What happens is that the bus gets initialized and a scan is started. CYG_PCI_NULL_DEVID causes cyg_pci_find_next() to restart its scan. If the bus does not contain any devices, the first call to cyg_pci_find_next() will return false.

If the call returns true, a loop is entered where the found devid is used. After devid processing has completed, the next device on the bus is searched for; cyg_pci_find_next() continues its scan from the current devid. The loop terminates when no more devices are found on the bus.

This is the generic way of scanning the bus, enumerating all the devices on the bus. But if the application is looking for a device of a given device class (e.g., a SCSI controller), or a specific vendor device, these functions simplify the task a bit:

```
cyg_bool cyg_pci_find_class(  cyg_uint32 dev_class,
                              cyg_pci_device_id *devid );

cyg_bool cyg_pci_find_device( cyg_uint16 vendor, cyg_uint16 device,
                              cyg_pci_device_id *devid );
```

They work just like cyg_pci_find_next(), but only return true when the dev_class or vendor/device qualifiers match those of a device on the bus. The devid serves as both an input and an output operand: the scan starts at the given device, and if a device is found devid is updated with the value for the found device.

The <cyg/io/pci_cfg.h> header file (included by pci.h) contains definitions for PCI class, vendor and device codes which can be used as arguments to the find functions. The list of vendor and device codes is not complete: add new codes as necessary. If possible also register the codes at the PCI Database (http://www.pcidatabase.com) which is where the eCos definitions are generated from.

Generic config information

When a valid device ID (devid) is found using one of the above functions, the associated device can be queried and controlled using the functions:

```
void cyg_pci_get_device_info (  cyg_pci_device_id devid,
                                cyg_pci_device *dev_info );

void cyg_pci_set_device_info (  cyg_pci_device_id devid,
                                cyg_pci_device *dev_info );
```

The cyg_pci_device structure (defined in pci.h) primarily holds information as described by the PCI specification [1]. The pci1 test prints out some of this information:

```
// Get device info
cyg_pci_get_device_info(devid, &dev_info);
diag_printf("\n Command   0x%04x, Status 0x%04x\n",
            dev_info.command, dev_info.status);
```

The command register can also be written to, controlling (among other things) whether the device responds to IO and memory access from the bus.

Specific config information

The above functions only allow access to generic PCI config registers. A device can have extra config registers not specified by the PCI specification. These can be accessed with these functions:

```
void cyg_pci_read_config_uint8(   cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint8 *val);

void cyg_pci_read_config_uint16(  cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint16 *val);

void cyg_pci_read_config_uint32(  cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint32 *val);

void cyg_pci_write_config_uint8(  cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint8 val);

void cyg_pci_write_config_uint16( cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint16 val);

void cyg_pci_write_config_uint32( cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint32 val);
```

The write functions should only be used for device-specific config registers since using them on generic registers may invalidate the contents of a previously fetched cyg_pci_device structure.

Allocating memory

A PCI device ignores all IO and memory access from the PCI bus until it has been activated. Activation cannot happen until after device configuration. Configuration means telling the device where it should map its IO and memory resources. This is done with one of the following functions::

```
cyg_bool cyg_pci_configure_device( cyg_pci_device *dev_info );

cyg_bool cyg_pci_configure_bus( cyg_uint8 bus, cyg_uint8 *next_bus );
```

The `cyg_pci_configure_device` handles all IO and memory regions that need configuration on non-bridge devices. On platforms with multiple busses connected by bridges, the `cyg_pci_configure_bus` function should be used. It will recursively configure all devices on the given *`bus`* and all subordinate busses. `cyg_pci_configure_bus` will use `cyg_pci_configure_device` to configure individual non-bridge devices.

Each region is represented in the PCI device's config space by BARs (Base Address Registers) and is handled individually according to type using these functions:

```
cyg_bool cyg_pci_allocate_memory( cyg_pci_device *dev_info,
                                  cyg_uint32 bar,
                                  CYG_PCI_ADDRESS64 *base );

cyg_bool cyg_pci_allocate_io(     cyg_pci_device *dev_info,
                                  cyg_uint32 bar,
                                  CYG_PCI_ADDRESS32 *base );
```

The memory bases (in two distinct address spaces) are increased as memory regions are allocated to devices. Allocation will fail (the function returns false) if the base exceeds the limits of the address space (IO is 1MB, memory is 2^32 or 2^64 bytes).

These functions can also be called directly by the application/driver if necessary, but this should not be necessary.

The bases are initialized with default values provided by the HAL. It is possible for an application to override these using the following functions:

```
void cyg_pci_set_memory_base(  CYG_PCI_ADDRESS64 base );

void cyg_pci_set_io_base( CYG_PCI_ADDRESS32 base );
```

When a device has been configured, the cyg_pci_device structure will contain the physical address in the CPU's address space where the device's memory regions can be accessed.

This information is provided in `base_map[]` - there is a 32 bit word for each of the device's BARs. For 32 bit PCI memory regions, each 32 bit word will be an actual pointer that can be used immediately by the driver: the memory space will normally be linearly addressable by the CPU.

However, for 64 bit PCI memory regions, some (or all) of the region may be outside of the CPUs address space. In this case the driver will need to know how to access the region in segments. This functionality may be adopted by the eCos HAL if deemed useful in the future. The 2GB available on many systems should suffice though.

Interrupts

A device may generate interrupts. The HAL vector associated with a given device on the bus is platform specific. This function allows a driver to find the actual interrupt vector for a given device:

```
cyg_bool cyg_pci_translate_interrupt(  cyg_pci_device *dev_info,
                                       CYG_ADDRWORD *vec );
```

If the function returns false, no interrupts will be generated by the device. If it returns true, the CYG_ADDRWORD pointed to by vec is updated with the HAL interrupt vector the device will be using. This is how the function is used in the `pci1` test:

```
if (cyg_pci_translate_interrupt(&dev_info, &irq))
    diag_printf(" Wired to HAL vector %d\n", irq);
else
    diag_printf(" Does not generate interrupts.\n");
```

The application/drive should attach an interrupt handler to a device's interrupt before activating the device.

Activating a device

When the device has been allocated memory space it can be activated. This is not done by the library since a driver may have to initialize more state on the device before it can be safely activated.

Activating the device is done by enabling flags in its command word. As an example, see the `pci1` test which can be configured to enable the devices it finds. This allows these to be accessed from GDB (if a breakpoint is set on `cyg_test_exit`):

```
#ifdef ENABLE_PCI_DEVICES
    {
        cyg_uint16 cmd;

        // Don't use cyg_pci_set_device_info since it clears
        // some of the fields we want to print out below.
        cyg_pci_read_config_uint16(dev_info.devid,
                                   CYG_PCI_CFG_COMMAND, &cmd);
        cmd |= CYG_PCI_CFG_COMMAND_IO|CYG_PCI_CFG_COMMAND_MEMORY;
        cyg_pci_write_config_uint16(dev_info.devid,
                                    CYG_PCI_CFG_COMMAND, cmd);
    }
    diag_printf(" **** Device IO and MEM access enabled\n");
#endif
```

Note

The best way to activate a device is actually through `cyg_pci_set_device_info()`, but in this particular case the cyg_pci_device structure contents from before the activation is required for printout further down in the code.

PCI Library reference

This document defines the PCI Support Library for eCos.

The PCI support library provides a set of routines for accessing the PCI bus configuration space in a portable manner. This is provided by two APIs. The high level API is used by device drivers, or other code, to access the PCI configuration space portably. The low level API is used by the PCI library itself to access the hardware in a platform-specific manner, and may also be used by device drivers to access the PCI configuration space directly.

Underlying the low-level API is HAL support for the basic configuration space operations. These should not generally be used by any code other than the PCI library, and are present in the HAL to allow low level initialization of the PCI bus and devices to take place if necessary.

PCI Library API

The PCI library provides the following routines and types for accessing the PCI configuration space.

The API for the PCI library is found in the header file `<cyg/io/pci.h>`.

Definitions

The header file contains definitions for the common configuration structure offsets and specimen values for device, vendor and class code.

Types and data structures

The following types are defined:

```
typedef CYG_WORD32 cyg_pci_device_id;
```

This is comprised of the bus number, device number and functional unit numbers packed into a single word. The macro `CYG_PCI_DEV_MAKE_ID()`, in conjunction with the `CYG_PCI_DEV_MAKE_DEVFN()` macro, may be used to construct a device id from the bus, device and functional unit numbers. Similarly the macros `CYG_PCI_DEV_GET_BUS()`, `CYG_PCI_DEV_GET_DEVFN()`, `CYG_PCI_DEV_GET_DEV()`, and `CYG_PCI_DEV_GET_FN()` may be used to extract the constituent parts of a device id. It should not be necessary to use these macros under normal circumstances. The following code fragment demonstrates how these macros may be used:

```
// Create a packed representation of device 1, function 0
cyg_uint8 devfn = CYG_PCI_DEV_MAKE_DEVFN(1,0);

// Create a packed devid for that device on bus 2
cyg_pci_device_id devid = CYG_PCI_DEV_MAKE_ID(2, devfn);

diag_printf("bus %d, dev %d, func %d\n",
            CYG_PCI_DEV_GET_BUS(devid),
            CYG_PCI_DEV_GET_DEV(CYG_PCI_DEV_GET_DEVFN(devid)),
            CYG_PCI_DEV_GET_FN(CYG_PCI_DEV_GET_DEVFN(devid));
```

```
typedef struct cyg_pci_device;
```

This structure is used to contain data read from a PCI device's configuration header by `cyg_pci_get_device_info()`. It is also used to record the resource allocations made to the device.

```
typedef CYG_WORD64 CYG_PCI_ADDRESS64;
typedef CYG_WORD32 CYG_PCI_ADDRESS32;
```

Pointers in the PCI address space are 32 bit (IO space) or 32/64 bit (memory space). In most platform and device configurations all of PCI memory will be linearly addressable using only 32 bit pointers as read from `base_map[]`.

The 64 bit type is used to allow handling 64 bit devices in the future, should it be necessary, without changing the library's API.

Functions

```
void cyg_pci_init(void);
```

Initialize the PCI library and establish contact with the hardware. This function is idempotent and can be called either by all drivers in the system, or just from an application initialization function.

```
cyg_bool cyg_pci_find_device( cyg_uint16        vendor,
                              cyg_uint16        device,
                              cyg_pci_device_id *devid );
```

Searches the PCI bus configuration space for a device with the given *`vendor`* and *`device`* ids. The search starts at the device pointed to by *`devid`*, or at the first slot if it contains `CYG_PCI_NULL_DEVID`. *`*devid`* will be updated with the ID of the next device found. Returns `true` if one is found and `false` if not.

```
cyg_bool cyg_pci_find_class(  cyg_uint32        dev_class,
                              cyg_pci_device_id *devid );
```

Searches the PCI bus configuration space for a device with the given *`dev_class`* class code. The search starts at the device pointed to by *`devid`*, or at the first slot if it contains `CYG_PCI_NULL_DEVID`.

`*devid` will be updated with the ID of the next device found. Returns `true` if one is found and `false` if not.

```
cyg_bool cyg_pci_find_next(  cyg_pci_device_id cur_devid,
                             cyg_pci_device_id *next_devid );
```

Searches the PCI configuration space for the next valid device after *`cur_devid`*. If *`cur_devid`* is given the value `CYG_PCI_NULL_DEVID`, then the search starts at the first slot. It is permitted for *`next_devid`* to point to *`cur_devid`*. Returns `true` if another device is found and `false` if not.

```
cyg_bool cyg_pci_find_matching( cyg_pci_match_func  *matchp,
                                void                *match_callback_data,
                                cyg_pci_device_id   *devid );
```

Searches the PCI bus configuration space for a device whose properties match those required by the caller supplied *`cyg_pci_match_func`*. The search starts at the device pointed to by *`devid`*, or at the first slot if it contains `CYG_PCI_NULL_DEVID`. The *`devid`* will be updated with the ID of the next device found. This function returns `true` if a matching device is found and `false` if not.

The match_func has a type declared as:

```
typedef cyg_bool (cyg_pci_match_func)( cyg_uint16 vendor,
                   cyg_uint16 device,
                   cyg_uint32 class,
                   void *     user_data);
```

The *`vendor`*, *`device`*, and *`class`* are from the device configuration space. The *`user_data`* is the callback data passed to `cyg_pci_find_matching`.

```
void cyg_pci_get_device_info ( cyg_pci_device_id devid,
                               cyg_pci_device *dev_info );
```

This function gets the PCI configuration information for the device indicated in *`devid`*. The common fields of the cyg_pci_device structure, and the appropriate fields of the relevant header union member are filled in from the device's configuration space. If the device has not been enabled, then this function will also fetch the size and type information from the base address registers and place it in the `base_size[]` array.

```
void cyg_pci_set_device_info ( cyg_pci_device_id  devid,
                               cyg_pci_device     *dev_info );
```

This function sets the PCI configuration information for the device indicated in *devid*. Only the configuration space registers that are writable are actually written. Once all the fields have been written, the device info will be read back into **dev_info*, so that it reflects the true state of the hardware.

```
void cyg_pci_read_config_uint8(  cyg_pci_device_id  devid,
                                 cyg_uint8          offset,
                                 cyg_uint8          *val );

void cyg_pci_read_config_uint16( cyg_pci_device_id  devid,
                                 cyg_uint8          offset,
                                 cyg_uint16         *val );

void cyg_pci_read_config_uint32( cyg_pci_device_id  devid,
                                 cyg_uint8 offset,  cyg_uint32 *val );
```

These functions read registers of the appropriate size from the configuration space of the given device. They should mainly be used to access registers that are device specific. General PCI registers are best accessed through `cyg_pci_get_device_info()`.

```
void cyg_pci_write_config_uint8(  cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint8 val );

void cyg_pci_write_config_uint16( cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint16 val );

void cyg_pci_write_config_uint32( cyg_pci_device_id devid,
                                  cyg_uint8 offset, cyg_uint32 val );
```

These functions write registers of the appropriate size to the configuration space of the given device. They should mainly be used to access registers that are device specific. General PCI registers are best accessed through `cyg_pci_get_device_info()`. Writing the general registers this way may render the contents of a cyg_pci_device structure invalid.

Resource allocation

These routines allocate memory and I/O space to PCI devices.

```
cyg_bool cyg_pci_configure_device( cyg_pci_device *dev_info )
```

Allocate memory and IO space to all base address registers using the current memory and IO base addresses in the library. The allocated base addresses, translated into directly usable values, will be put into the matching `base_map[]` entries in **dev_info*. If **dev_info* does not contain valid `base_size[]` entries, then the result is `false`. This function will also call `cyg_pci_translate_interrupt()` to put the interrupt vector into the HAL vector entry.

```
cyg_bool cyg_pci_configure_bus( cyg_uint8 bus, cyg_uint8 *next_bus )
```

Allocate memory and IO space to all base address registers on all devices on the given bus and all subordinate busses. If a PCI-PCI bridge is found on *bus*, this function will call itself recursively in order to configure the bus on the other side of the bridge. Because of the nature of bridge devices, all devices on the secondary side of a bridge must be allocated memory and IO space before the memory and IO windows on the bridge device can be properly configured. The *next_bus* argument points to the bus number to assign to the next subordinate bus found. The number will be incremented as new busses are discovered. If successful, `true` is returned. Otherwise, `false` is returned.

```
cyg_bool cyg_pci_translate_interrupt( cyg_pci_device  *dev_info,
                                      CYG_ADDRWORD    *vec );
```

Translate the device's PCI interrupt (INTA#-INTD#) to the associated HAL vector. This may also depend on which slot the device occupies. If the device may generate interrupts, the translated vector number will be stored in *vec* and the result is `true`. Otherwise the result is `false`.

```
cyg_bool cyg_pci_allocate_memory( cyg_pci_device    *dev_info,
                                  cyg_uint32        bar,
                                  CYG_PCI_ADDRESS64 *base );

cyg_bool cyg_pci_allocate_io( cyg_pci_device    *dev_info,
                              cyg_uint32        bar,
                              CYG_PCI_ADDRESS32 *base );
```

These routines allocate memory or I/O space to the base address register indicated by *`bar`*. The base address in *`*base`* will be correctly aligned and the address of the next free location will be written back into it if the allocation succeeds. If the base address register is of the wrong type for this allocation, or *`dev_info`* does not contain valid `base_size[]` entries, the result is `false`. These functions allow a device driver to set up its own mappings if it wants. Most devices should probably use `cyg_pci_configure_device()`.

```
void cyg_pci_set_memory_base( CYG_PCI_ADDRESS64 base );

void cyg_pci_set_io_base( CYG_PCI_ADDRESS32 base );
```

These routines set the base addresses for memory and I/O mappings to be used by the memory allocation routines. Normally these base addresses will be set to default values based on the platform. These routines allow these to be changed by application code if necessary.

PCI Library Hardware API

This API is used by the PCI library to access the PCI bus configuration space. Although it should not normally be necessary, this API may also be used by device driver or application code to perform PCI bus operations not supported by the PCI library.

```
void cyg_pcihw_init(void);
```

Initialize the PCI hardware so that the configuration space may be accessed.

```
void cyg_pcihw_read_config_uint8(  cyg_uint8 bus,
                                   cyg_uint8 devfn,
                                   cyg_uint8 offset,
                                   cyg_uint8 *val);

void cyg_pcihw_read_config_uint16( cyg_uint8 bus,
                                   cyg_uint8 devfn,
                                   cyg_uint8 offset,
                                   cyg_uint16 *val);

void cyg_pcihw_read_config_uint32( cyg_uint8 bus,
                                   cyg_uint8 devfn,
                                   cyg_uint8 offset,
                                   cyg_uint32 *val);
```

These functions read a register of the appropriate size from the PCI configuration space at an address composed from the *`bus`*, *`devfn`* and *`offset`* arguments.

```
void cyg_pcihw_write_config_uint8(  cyg_uint8 bus,
                                    cyg_uint8 devfn,
                                    cyg_uint8 offset,
                                    cyg_uint8 val);

void cyg_pcihw_write_config_uint16( cyg_uint8 bus,
                                    cyg_uint8 devfn,
                                    cyg_uint8 offset,
                                    cyg_uint16 val);

void cyg_pcihw_write_config_uint32( cyg_uint8 bus,
                                    cyg_uint8 devfn,
                                    cyg_uint8 offset,
                                    cyg_uint32 val);
```

These functions write a register of the appropriate size to the PCI configuration space at an address composed from the *bus*, *devfn* and *offset* arguments.

```
cyg_bool cyg_pcihw_translate_interrupt( cyg_uint8     bus,
                                        cyg_uint8     devfn,
                                        CYG_ADDRWORD  *vec);
```

This function interrogates the device and determines which HAL interrupt vector it is connected to.

HAL PCI support

HAL support consists of a set of C macros that provide the implementation of the low level PCI API.

```
HAL_PCI_INIT()
```

Initialize the PCI bus.

```
HAL_PCI_READ_UINT8( bus, devfn, offset, val )
HAL_PCI_READ_UINT16( bus, devfn, offset, val )
HAL_PCI_READ_UINT32( bus, devfn, offset, val )
```

Read a value from the PCI configuration space of the appropriate size at an address composed from the *bus*, *devfn* and *offset*.

```
HAL_PCI_WRITE_UINT8( bus, devfn, offset, val )
HAL_PCI_WRITE_UINT16( bus, devfn, offset, val )
HAL_PCI_WRITE_UINT32( bus, devfn, offset, val )
```

Write a value to the PCI configuration space of the appropriate size at an address composed from the *bus*, *devfn* and *offset*.

```
HAL_PCI_TRANSLATE_INTERRUPT( bus, devfn, *vec, valid )
```

Translate the device's interrupt line into a HAL interrupt vector.

```
HAL_PCI_ALLOC_BASE_MEMORY
HAL_PCI_ALLOC_BASE_IO
```

These macros define the default base addresses used to initialize the memory and I/O allocation pointers.

```
HAL_PCI_PHYSICAL_MEMORY_BASE
HAL_PCI_PHYSICAL_IO_BASE
```

PCI memory and IO range do not always correspond directly to physical memory or IO addresses. Frequently the PCI address spaces are windowed into the processor's address range at some offset. These macros define offsets to be added to the PCI base addresses to translate PCI bus addresses into physical memory addresses that can be used to access the allocated memory or IO space.

Note

The chunk of PCI memory space directly addressable though the window by the CPU may be smaller than the amount of PCI memory actually provided. In that case drivers will have to access PCI memory space in segments. Doing this will be platform specific and is currently beyond the scope of the HAL.

```
HAL_PCI_IGNORE_DEVICE( bus, dev, fn )
```

This macro, if defined, may be used to limit the devices which are found by the bus scanning functions. This is sometimes necessary for devices which need special handling. If this macro evaluates to `true`, the given device will not be found by `cyg_pci_find_next` or other bus scanning functions.

```
HAL_PCI_IGNORE_BAR( dev_info, bar_num )
```

This macro, if defined, may be used to limit which BARs are discovered and configured. This is sometimes necessary for platforms with limited PCI windows. If this macro evaluates to `true`, the given BAR will not be discovered by `cyg_pci_get_device_info` and therefore not configured by `cyg_pci_configure_device`.

Part XXII. SPI Support

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 72. SPI Support

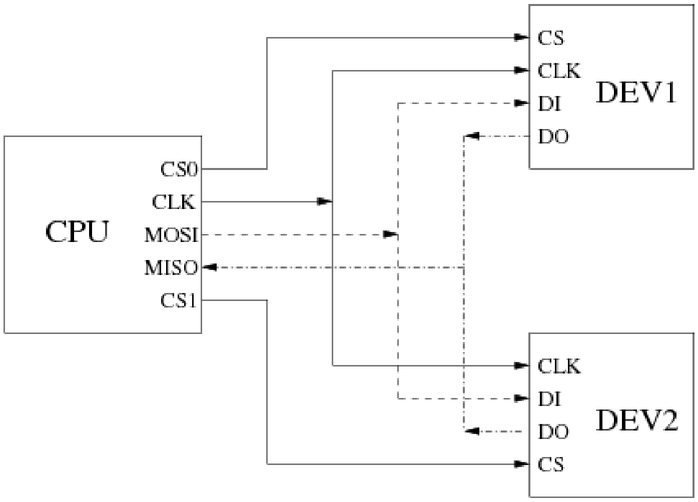
Name

Overview — eCos Support for SPI, the Serial Peripheral Interface

Description

The Serial Peripheral Interface (SPI) is one of a number of serial bus technologies. It can be used to connect a processor to one or more peripheral chips, for example analog-to-digital convertors or real time clocks, using only a small number of pins and PCB tracks. The technology was originally developed by Motorola but is now also supported by other vendors.

A typical SPI system might look like this:



At the start of a data transfer the master cpu asserts one of the chip select signals and then generates a clock signal. During each clock tick the cpu will output one bit on its master-out-slave-in line and read one bit on the master-in-slave-out line. Each device is connected to the clock line, the two data lines, and has its own chip select. If a device's chip select is not asserted then it will ignore any incoming data and will tristate its output. If a device's chip select is asserted then during each clock tick it will read one bit of data on its input pin and output one bit on its output pin.

The net effect is that the cpu can write an arbitrary amount of data to one of the attached devices at a time, and simultaneously read the same amount of data. Some devices are inherently uni-directional. For example an LED unit would only accept data from the cpu: it will not send anything meaningful back; the cpu will still sample its input every clock tick, but this should be discarded.

A useful feature of SPI is that there is no flow control from the device back to the cpu. If the cpu tries to communicate with a device that is not currently present, for example an MMC socket which does not contain a card, then the I/O will still proceed. However the cpu will read random data. Typically software-level CRC checksums or similar techniques will be used to allow the cpu to detect this.

SPI communication is not fully standardized. Variations between devices include the following:

1. Many devices involve byte transfers, where the unit of data is 8 bits. Others use larger units, up to 16 bits.
2. Chip selects may be active-high or active-low. If the attached devices use a mixture of polarities then this can complicate things.
3. Clock rates can vary from 128KHz to 20MHz or greater. With some devices it is necessary to interrogate the device using a slow clock, then use the obtained information to select a faster clock for subsequent transfers.
4. The clock is inactive between data transfers. When inactive the clock's polarity can be high or low.
5. Devices depend on the phase of the clock. Data may be sampled on either the rising edge or the falling edge of the clock.

6. A device may need additional delays, for example between asserting the chip select and the first clock tick.

7. Some devices involve complicated transactions: perhaps a command from cpu to device; then an initial status response from the device; a data transfer; and a final status response. From the cpu's perspective these are separate stages and it may be necessary to abort the operation after the initial status response. However the device may require that the chip select remain asserted for the whole transaction. A side effect of this is that it is not possible to do a quick transfer with another device in the middle of the transaction.

8. Certain devices, for example MMC cards, depend on a clock signal after a transfer has completed and the chip select has dropped. This clock is used to finish some processing within the device.

Inside the cpu the clock and data signals are usually managed by dedicated hardware. Alternatively SPI can be implemented using bit-banging, but that approach is normally used for other serial bus technologies such as I²C. The chip selects may also be implemented by the dedicated SPI hardware, but often GPIO pins are used instead.

eCos Support for SPI

The eCos SPI support for any given platform is spread over a number of different packages:

- This package, `CYGPKG_IO_SPI`, exports an API for accessing devices attached to an SPI bus. This API handles issues such as locking between threads. The package does not contain any hardware-specific code, instead it will call into an SPI bus driver package.

  In future this package may be extended with a bit-banging implementation of an SPI bus driver. This would depend on lower-level code for manipulating the GPIO pins used for the clock, data and chip select signals, but timing and framing could be handled by generic code.

- There will be a bus driver package for the specific SPI hardware on the target hardware, for example `CYGPKG_DEVS_SPI_MCFxxxx_QSPI`. This is responsible for the actual I/O. A bus driver may be used on many different boards, all with the same SPI bus but with different devices attached to that bus. Details of the actual devices should be supplied by other code.

- The generic API depends on cyg_spi_device data structures. These contain the information needed by a bus driver, for example the appropriate clock rate and the chip select to use. Usually the data structures are provided by the platform HAL since it is that package which knows about all the devices on the board.

  On some development boards the SPI pins are brought out to expansion connectors, allowing end users to add extra devices. In such cases the platform HAL may not know about all the devices on the board. Data structures for the additional devices can instead be supplied by application code.

- Some types of SPI devices may have their own driver package. For example the `CYGPKG_DEVS_FLASH_SPI_COMMON` package provides an abstraction layer to the standard eCos I/O Flash API package (`CYGPKG_IO_FLASH`) for SFDP compliant flash devices. Another common use for SPI buses is to provide MultiMediaCard (MMC/SD) support. The `CYGPKG_DEVS_DISK_MMC` package provides a block device interface for higher-level code such as file systems. Other SPI devices such as analog-to-digital converters are much simpler and come in many varieties. There are no dedicated packages to support each such device: the chances are low that another board would use the exact same device, so there are no opportunities for code reuse. Instead the devices may be accessed directly by application code or by extra functions in the platform HAL.

Typically all appropriate packages will be loaded automatically when you configure eCos for a given target. If the application does not use any of the SPI I/O facilities, directly or indirectly, then linker garbage collection should eliminate all unnecessary code and data. All necessary initialization should happen automatically. However the exact details may depend on the target, so the platform HAL documentation should be checked for further details.

There is one important exception to this: if the SPI devices are attached to an expansion connector then the platform HAL will not know about these devices. Instead more work will have to be done by application code.

Name

SPI Functions — allow applications and other packages to access SPI devices

Synopsis

#include <cyg/io/spi.h>

CYG_SPI_OP_RETURN_TYPE **cyg_spi_transfer**(*device*, *polled*, *count*, *tx_data*, *rx_data*);

CYG_SPI_OP_RETURN_TYPE **cyg_spi_transaction_tick**(*device*, *polled*, *count*);

CYG_SPI_OP_RETURN_TYPE **cyg_spi_transaction_end**(*device*);

Description

All SPI functions take a pointer to a cyg_spi_device structure as their first argument. This is an opaque data structure, usually provided by the platform HAL. It contains the information needed by the SPI bus driver to interact with the device, for example the required clock rate and polarity.

An SPI transfer involves the following stages:

1. Perform thread-level locking on the bus. Only one thread at a time is allowed to access an SPI bus. This eliminates the need to worry about locking at the bus driver level. If a platform involves multiple SPI buses then each one will have its own lock. Prepare the bus for transfers to the specified device, for example by making sure it will tick at the right clock rate.
2. Assert the chip select on the specified device, then transfer data to and from the device. There may be a single data transfer or a sequence. It may or may not be necessary to keep the chip select asserted throughout a sequence.
3. Optionally generate some number of clock ticks without asserting a chip select, for those devices which need this to complete an operation.
4. Return the bus to a quiescent state. Then unlock the bus, allowing other threads to perform SPI operations on devices attached to this bus.

The simple functions `cyg_spi_transfer` and `cyg_spi_tick` perform all these steps in a single call. These are suitable for simple I/O operations. The alternative transaction-oriented functions each perform just one of these steps. This makes it possible to perform multiple transfers while only locking and unlocking the bus once, as required for more complicated devices.

With the exception of `cyg_spi_transaction_begin_nb` all the functions will block until completion. The type of the return values depends on whether the underlying hardware driver can return error conditions or not. If it can, this will be indicated with the C preprocessor define `CYGINT_IO_SPI_DRV_REPORTS_ERRORS`, and the return type `CYG_SPI_OP_RETURN_TYPE` will be a standard error code as defined in the C/POSIX header `<errno.h>`. Alternatively for drivers which do not return errors, the return value's type will be `void`, or in other words, no return value. If there are any errors, they would be generated by an SPI bus peripheral, and not by the attached SPI device. The SPI bus does not receive any feedback from a device about possible errors, instead those have to be handled by software at a higher level.

If a driver is capable of indicating errors, and an error value is returned, this may imply the SPI operation requested may not have started, may not have completed, or may only have partially completed. The exact interpretation will depend on both hardware properties and low-level driver implementation. SPI API users are free to ignore all return values, in which case the usage of the SPI API will be identical, irrespective of the setting of `CYGINT_IO_SPI_DRV_REPORTS_ERRORS`.

An SPI transfer will always take a predictable amount of time, depending on the transfer size and the clock rate. If a thread cannot afford the time it will take to perform a complete large transfer then a number of smaller transfers can be used instead.

SPI operations should always be performed at thread-level or during system initialization, and not inside an ISR or DSR. This greatly simplifies locking. Also a typical ISR or DSR should not perform a blocking operation such as an SPI transfer.

SPI transfers can happen in either polled or interrupt-driven mode. Typically polled mode should be used during system initialization, before the scheduler has been started and interrupts have been enabled. Polled mode should also be used in single-threaded applications such as RedBoot. A typical multi-threaded application should normally use interrupt-driven mode because this allows for more efficient use of cpu cycles. Polled mode may be used in a multi-threaded application but this is generally undesirable: the cpu will spin while waiting for a transfer to complete, wasting cycles; also the current thread may get preempted or timesliced, making the timing of an SPI transfer much less predictable. On some hardware interrupt-driven mode is impossible or would be very inefficient. In such cases the bus drivers will only support polled mode and will ignore the `polled` argument.

Simple Transfers

`cyg_spi_transfer` can be used for SPI operations to simple devices. It takes the following arguments:

cyg_spi_device* `device`
: This identifies the SPI device that should be used.

cyg_bool `polled`
: Polled mode should be used during system initialization and in a single-threaded application. Interrupt-driven mode should normally be used in a multi-threaded application.

cyg_uint32 `count`
: This identifies the number of data items to be transferred. Usually each data item is a single byte, but some devices use a larger size up to 16 bits.

const cyg_uint8* `tx_data`
: The data to be transferred to the device. If the device will only output data and ignore its input then a null pointer can be used. Otherwise the array should contain `count` data items, usually bytes. For devices where each data item is larger than one byte the argument will be interpreted as an array of shorts instead, and should be aligned to a 2-byte boundary. The bottom n bits of each short will be sent to the device. The buffer need not be aligned to a cache-line boundary, even for SPI devices which use DMA transfers, but some bus drivers may provide better performance if the buffer is suitably aligned. The buffer will not be modified by the transfer.

cyg_uint8* `rx_data`
: A buffer for the data to be received from the device. If the device does not generate any output then a null pointer can be used. The same size and alignment rules apply as for `tx_data`.

`cyg_spi_transfer` performs all the stages of an SPI transfer: locking the bus; setting it up correctly for the specified device; asserting the chip select and transferring the data; dropping the chip select at the end of the transfer; returning the bus to a quiescent state; and unlocking the bus.

Additional Clock Ticks

Some devices require a number of clock ticks on the SPI bus between transfers so that they can complete some internal processing. These ticks must happen at the appropriate clock rate but no chip select should be asserted and no data transfer will happen.

cyg_spi_tick provides this functionality. The device argument identifies the SPI bus, the required clock rate and the size of each data item. The polled argument has the usual meaning. The count argument specifies the number of data items that would be transferred, which in conjunction with the size of each data item determines the number of clock ticks.

Transactions

A transaction-oriented API is available for interacting with more complicated devices. This provides separate functions for each of the steps in an SPI transfer.

cyg_spi_transaction_begin must be used at the start of a transaction. This performs thread-level locking on the bus, blocking if it is currently in use by another thread. Then it prepares the bus for transfers to the specified device, for example by making sure it will tick at the right clock rate.

cyg_spi_transaction_begin_nb is a non-blocking variant, useful for threads which cannot afford to block for an indefinite period. If the bus is currently locked the function returns false immediately. If the bus is not locked then it acts as cyg_spi_transaction_begin and returns true.

Once the bus has been locked it is possible to perform one or more data transfers by calling cyg_spi_transaction_transfer. This takes the same arguments as cyg_spi_transfer, plus an additional one drop_cs. A non-zero value specifies that the device's chip select should be dropped at the end of the transfer, otherwise the chip select remains asserted. It is essential that the chip select be dropped in the final transfer of a transaction. If the protocol makes this difficult then cyg_spi_transaction_tick can be used to generate dummy ticks with all chip selects dropped.

If the device requires additional clock ticks in the middle of a transaction without being selected, cyg_spi_transaction_tick can be used. This will drop the device's chip select if necessary, then generate the appropriate number of ticks. The arguments are the same as for cyg_spi_tick.

cyg_spi_transaction_end should be called at the end of a transaction. It returns the SPI bus to a quiescent state, then unlocks it so that other threads can perform I/O.

A typical transaction might involve the following. First a command should be sent to the device, consisting of four bytes. The device will then respond with a single status byte, zero for failure, non-zero for success. If successful then the device can accept another n bytes of data, and will generate a 2-byte response including a checksum. The device's chip select should remain asserted throughout. The code for this would look something like:

```
#include <cyg/io/spi.h>
#include <cyg/hal/hal_io.h>    // Defines the SPI devices
…
    cyg_spi_transaction_begin(&hal_spi_eprom);
    // Interrupt-driven transfer, four bytes of command
    cyg_spi_transaction_transfer(&hal_spi_eprom, 0, 4, command, NULL, 0);
    // Read back the status
    cyg_spi_transaction_transfer(&hal_spi_eprom, 0, 1, NULL, status, 0);
    if (!status[0]) {
        // Command failed, generate some extra ticks to drop the chip select
        cyg_spi_transaction_tick(&hal_spi_eprom, 0, 1);
    } else {
        // Transfer the data, then read back the final status. The
        // chip select should be dropped at the end of this.
        cyg_spi_transaction_transfer(&hal_spi_eprom, 0, n, data, NULL, 0);
        cyg_spi_transaction_transfer(&hal_spi_eprom, 0, 2, NULL, status, 1);
        // Code for checking the final status should go here
    }
    // Transaction complete so clean up
    cyg_spi_transaction_end(&hal_spi_eprom);
```

A number of variations are possible. For example the command and status could be packed into the beginning and end of two 5-byte arrays, allowing a single transfer.

Device Configuration

The functions `cyg_spi_get_config` and `cyg_spi_set_config` can be used to examine and change parameters associated with SPI transfers. The only keys that are defined for all devices are `CYG_IO_GET_CONFIG_SPI_CLOCKRATE` and `CYG_IO_SET_CONFIG_SPI_CLOCKRATE`. Some types of device, for example MMC cards, support a range of clock rates. The cyg_spi_device structure will be initialized with a low clock rate. During system initialization the device will be queried for the optimal clock rate, and the cyg_spi_device should then be updated. The argument should be a clock rate in Hertz. For example the following code switches communication to 1Mbit/s:

```
cyg_uint32    new_clock_rate = 1000000;
cyg_uint32    len            = sizeof(cyg_uint32);
if (cyg_spi_set_config(&hal_mmc_device,
                       CYG_IO_SET_CONFIG_SPI_CLOCKRATE,
                       (const void *)&new_clock_rate, &len)) {
    // Error recovery code
}
```

If an SPI bus driver does not support the exact clock rate specified it will normally use the nearest valid one. SPI bus drivers may define additional keys appropriate for specific hardware. This means that the valid keys are not known by the generic code, and theoretically it is possible to use a key that is not valid for the SPI bus to which the device is attached. It is also possible that the argument used with one of these keys is invalid. Hence both `cyg_spi_get_config` and `cyg_spi_set_config` can return error codes. The return value will be 0 for success, non-zero for failure. The SPI bus driver's documentation should be consulted for further details.

Both configuration functions will lock the bus, in the same way as `cyg_spi_transfer`. Changing the clock rate in the middle of a transfer or manipulating other parameters would have unexpected consequences.

Name

Porting — Adding SPI support to new hardware

Description

Adding SPI support to an eCos port can take two forms. If there is already an SPI bus driver for the target hardware then both that driver and this generic SPI package `CYGPKG_IO_SPI` should be included in the ecos.db target entry. Typically the platform HAL will need to supply some platform-specific information needed by the bus driver. In addition the platform HAL should provide cyg_spi_device structures for every device attached to the bus. The exact details of this depend on the bus driver so its documentation should be consulted for further details. If there is no suitable SPI bus driver yet then a new driver package will have to be written.

Adding a Device

The generic SPI package `CYGPKG_IO_SPI` defines a data structure cyg_spi_device. This contains the information needed by the generic package, but not the additional information needed by a bus driver to interact with the device. Each bus driver will define a larger data structure, for example cyg_mcf52xx_qspi_device, which contains a cyg_spi_device as its first field. This is analogous to C++ base and derived classes, but without any use of virtual functions. The bus driver package should be consulted for the details.

During initialization an SPI bus driver may need to know about all the devices attached to that bus. For example it may need to know which cpu pins should be configured as chip selects rather than GPIO pins. To achieve this all device definitions should specify the particular bus to which they are attached, for example:

```
struct cyg_mcf52xx_qspi_device hal_spi_atod CYG_SPI_DEVICE_ON_BUS(0) =
{
    .spi_common.spi_bus = &cyg_mcf52xx_qspi_bus,
    …
};
```

The `CYG_SPI_DEVICE_ON_BUS` macro adds information to the structure which causes the linker to group all such structures in a single table. The bus driver's initialization code can then iterate over this table.

Adding Bus Support

An SPI bus driver usually involves a new hardware package. This needs to perform the following:

1. Define a device structure which contains a cyg_spi_device as its first element. This should contain all the information needed by the bus driver to interact with a device on that bus.

2. Provide functions for the following operations:

   ```
   spi_transaction_begin
   spi_transaction_transfer
   spi_transaction_tick
   spi_transaction_end
   spi_get_config
   spi_set_config
   ```

   These correspond to the main API functions, but can assume that the bus is already locked so no other thread will be manipulating the bus or any of the attached devices. Some of these operations may be no-ops.

3. Define a bus structure which contains a cyg_spi_bus as its first element. This should contain any additional information needed by the bus driver.

4. Optionally, instantiate the bus structure. The instance should have a well-known name since it needs to be referenced by the device structure initializers. For some drivers it may be best to create the bus inside the driver package. For other drivers it

may be better to leave this to the platform HAL or the application. It depends on how much platform-specific knowledge is needed to fill in the bus structure.

5. Create a HAL table for the devices attached to this bus.

6. Arrange for the bus to be initialized early on during system initialization. Typically this will happen via a prioritized static constructor with priority `CYG_INIT_BUS_SPI`. As part of this initialization the bus driver should invoke the `CYG_SPI_BUS_COMMON_INIT` macro on its cyg_spi_bus field.

7. Provide the appropriate documentation, including details of how the SPI device structures should be initialized.

There are no standard SPI testcases. It is not possible to write SPI code without knowing about the devices attached to the bus, and those are inherently hardware-specific.

Chapter 73. Freescale MCFxxxx ColdFire QSPI Bus Driver

Name

CYGPKG_DEVS_SPI_MCFxxxx_QSPI — eCos Support for the Freescale Coldfire QSPI Bus

Description

Several processors in the Freescale ColdFire family come with an on-chip SPI device, also known as QSPI. This package provides an eCos bus driver for that device. It implements the functionality defined by the generic SPI package CYGPKG_IO_SPI. The driver supports both polled and interrupt-driven transfers. Typical supported transfer rates range from 128KHz to 33MHz, although the exact details depend on the specific ColdFire processor being used and on the processor's clock speed. The hardware does not support DMA so large transfers at high transfer rates will consume much of the available cpu time.

This bus driver package does not instantiate any cyg_spi_bus structures. It is possible for a processor to have more than one SPI bus, so it is better to leave it to the processor HAL to define the bus or buses. Instead the bus driver package just provides functions and utility macros for use by the processor HAL. Similarly the bus driver package does not provide any cyg_spi_device structures. Exactly which devices are attached to the SPI bus is a characteristic of the platform so usually it is the platform HAL which provides the device instances.

Configuration Options

This SPI bus driver package should be loaded automatically when selecting a target containing a ColdFire processor with QSPI hardware, and it should never be necessary to load the package explicitly. If the application does not use any of the SPI functionality then all the SPI support code should be removed at link-time and the application does not suffer any overheads.

The package contains a single configuration option CYGHWR_DEVS_SPI_MCFxxxx_QSPI_MULTIPLE_BUSES. Usually this option should not be manipulated by application developers, instead it is set by the processor HAL. When the option is disabled the driver will optimize for the common case of a single bus.

The only other configuration options provided by this package relate to compiler flags.

Defining Buses

The header file cyg/io/mcfxxxx_qspi.h provides a utility macro CYG_MCFxxxx_QSPI_BUS to allow processor HALs to instantiate a bus. Existing HALs such as the MCF521x's will show how to use this macro.

Defining Devices

For most boards the platform HAL will create cyg_spi_device instances for all attached SPI devices, and will initialize the system so that the SPI-related processor pins are connected appropriately. Some development boards may not have any SPI devices but instead export the relevant signals to expansion connectors. In those cases it will be the responsibility of application code to create the device instances and manipulate the GPIO pins appropriately.

Device instances should take the form of a cyg_mcfxxxx_qspi_device structure, which contains a cyg_spi_device as its first field.

```
#include <cyg/io/mcfxxxx_qspi.h>
…
cyg_mcfxxxx_qspi_device hal_spi_atod CYG_SPI_DEVICE_ON_BUS(mcfxxxx_qspi) = {
    .qspi_common.spi_bus    = &cyg_mcfxxxx_qspi_bus,
    …
};
```

This defines a variable hal_spi_atod which can be used by other packages or by application code as an argument to the I/O functions provided by the generic SPI package CYGPKG_IO_SPI. A gcc extension, designated initializers, is used to fill in the *qspi_common.spi_bus* structure field. The structure contains a further seven fields which define exactly how to interact with the SPI device. Most of these fields are simply hardware register values, and the appropriate ColdFire User Manual should be consulted for full details of these registers. The header file `cyg/hal/hal_io.h` will provide #define's for the various bits, for example `HAL_MCFxxxx_QSPIx_QMR_MSTR` for the master mode bit of the QMR register.

qspi_qmr

When performing a transfer to this SPI device the bus driver will use the *qspi_qmr* field for the QSPI hardware's QMR register. The main fields in this register are:

MSTR This bit specifies that the QSPI hardware should operate in master mode. It must always be set.

BITS The data items transferred can range from 8 to 16 bits. For example, to specify 12-bit data items the *qspi_qmr* field should include `HAL_MCFxxxx_QSPIx_QMR_BITS_12`.

CPOL Clock polarity. The default is inactive-low, active-high. If the device requires the opposite polarity then `HAL_MCFxxxx_QSPIx_QMR_CPOL` should be specified.

CPHA Clock phase. The default is to capture data on the leading clock edge. If the device captures data on the trailing edge instead then `HAL_MCFxxxx_QSPIx_QMR_CPHA` should be specified.

BAUD Baud rate divider. This should be a small number, usually between 1 and 255, which controls the clock rate. The value to be used depends on the device's maximum clock rate, the specific processor used, and the processor's clock speed.

qspi_qdlyr

This field is used to set the QSPI delay register QDLYR when performing transfers to this device. It contains two delay fields, QCD and DTL, which can be used in conjunction with *qspi_qcr* for fine control over bus timing. Most devices do not have any special requirements here so a value of 0 can be used. The register also contains an SPE bit to start a transfer, but that bit is used by the bus driver and should not be set in the device structure.

qspi_qwr

This field is used to set the QWR register. Only one bit, CSIV, in this register may be defined. The other fields in the register are manipulated by the bus driver. Usually if the device has an active-low chip select then the CSIV bit should be set, otherwise the structure field should be 0. If a custom chip select control function is used then that may require different CSIV behaviour.

qspi_qcr

This is used to fill in the command RAM registers during a data transfer. It contains five fields. The CONT bit is not normally required but can provide additional control over the chip select. Note that some versions of the various ColdFire User Manuals give an incomplete description of this bit and the errata sheets should be consulted as well. The BITSE bit should be set if transfers involve data items which are not 8 bits. The DT and DSCK bits can be used to enable one or both delays in the QDLYR register. The QSPI_CS field consists of four bits for the four QSPI chip select pins. If all the devices connected to the SPI bus are active-high and each is connected directly to a chip select, then only of these bits should be set. If all the devices are active-low then only one of the bits should be clear.

With some hardware the QSPI_CS bits can be more complicated. For example consider an SPI bus with an active-high device attached to QSPI chip selects 0 and 1, and active-low devices attached to the other two chip selects. The device definition for the CS0 device should have the QWR CSIV bit clear. The QCR QSPI_CS bits should have bits 0, 2 and 3 set. Between transfers all chip select pins will be low. This will activate the devices on CS2 and CS3, but since there is no clock signal this is harmless. When a transfer happens CS0, CS2 and CS3 will all be high, and CS1 will remain low. This will activate the device on CS0, but leave the other three devices inactive. Hence only the specified device is active during a transfer.

If the hardware requires further control over the chip selects then the device definition can include a custom *qspi_cs_control* function.

There is no support for using different QCR values for different parts of a transfer, for example the first data item versus the rest of the transfer. Such functionality is rarely useful and would require extra complexity in the bus driver, including performance-critical parts.

qspi_qcr_tick

This is used to fill in the command RAM registers during a tick operation, when none of the devices should be active. Some devices need to see a certain number of clock signals even when their chip select is not active, or they will not operate correctly. The hardware fields are the same as for *qspi_qcr*. Usually the QSPI_CS bits will be all 0 or all 1, but some hardware may require a more complicated value.

qspi_tick_data

When performing a tick operation this field will be used as the data to be transferred. Usually the value will not matter because, by the definition of an SPI tick, none of the SPI devices will be selected.

qspi_cs_control

Some hardware may have chip select requirements which cannot be satisfied simply by setting the QWR CSIV and the QCR QSPI_CS bits. For example if there are more than four SPI devices then the surplus may have their chip selects connected to GPIO pins. Also some devices may require that the chip select remain asserted for the duration of a multi-transfer transaction, and that is not supported directly by the QSPI hardware. To cope with such cases it is possible to define a custom chip select control function.

Consider a simple SPI device on a board with a 64MHz MCF5282 processor. The device uses 8-bit data, default clock polarity and phase, can be driven at up to 10 MHz, does not require any special delays, has an active-high chip select, and is connected to the processor's QSPI CS0 pin. There are no other devices on the bus.

```
#include <cyg/io/mcfxxxx_qspi.h>
…
cyg_mcfxxxx_qspi_device hal_spi_dev0 CYG_SPI_DEVICE_ON_BUS(mcfxxxx_qspi) = {
    .qspi_common.spi_bus    = &cyg_mcfxxxx_qspi_bus,
    .qspi_qmr               = HAL_MCFxxxx_QSPIx_QMR_MSTR |
                              HAL_MCFxxxx_QSPIx_QMR_BITS_8 |
                              0x04,
    .qspi_qdlyr             = 0,
    .qspi_qwr               = 0,
    .qspi_qcr               = HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS0,
    .qspi_qcr_tick          = 0,
    .qspi_tick_data         = 0xFF,
    .qspi_cs_control        = (void (*)(cyg_mcfxxxx_qspi_device*, int)) 0
};
```

For a more complicated example, consider a board with an MCF5272 processor and an SPI device that involves 12-bit data items, uses inverted clock polarity and phase, can only be driven at the slowest clock rate, does not require any special delays or chip select logic, has an active-low chip select, and is connected to the processor's QSPI CS2 pin:

```
#include <cyg/io/mcfxxxx_qspi.h>
…
cyg_mcfxxxx_qspi_device hal_spi_dev2 CYG_SPI_DEVICE_ON_BUS(mcfxxxx_qspi) = {
    .qspi_common.spi_bus    = &cyg_mcfxxxx_qspi_bus,
    .qspi_qmr               = HAL_MCFxxxx_QSPIx_QMR_MSTR |
                              HAL_MCFxxxx_QSPIx_QMR_BITS_12 |
                              HAL_MCFxxxx_QSPIx_QMR_CPOL |
                              HAL_MCFxxxx_QSPIx_QMR_CPHA |
                              0xFF,
    .qspi_qdlyr             = 0,
    .qspi_qwr               = HAL_MCFxxxx_QSPIx_QWR_CSIV,
    .qspi_qcr               = HAL_MCFxxxx_QSPIx_QCRn_BITSE |
                              HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS0 |
                              HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS1 |
                              HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS3,
    .qspi_qcr_tick          = HAL_MCFxxxx_QSPIx_QCRn_BITSE |
                              HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS0 |
                              HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS1 |
                              HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS2 |
                              HAL_MCFxxxx_QSPIx_QCRn_QSPI_CS_CS3,
    .qspi_tick_data         = 0xFF,
    .qspi_cs_control        = (void (*)(cyg_mcfxxxx_qspi_device*, int)) 0
};
```

This definition assumes that there are no attached SPI devices with an active-high chip select. If there are such devices then the *qspi_qcr* and *qspi_qcr_tick* fields should be modified so that these devices are not activated at the wrong time.

The header file cyg/io/mcfxxxx_qspi.h provides a utility macro CYG_MCFxxxx_QSPI_DEVICE which can be used to instantiate a device. Essentially the macro just expands to a structure definition as above.

Advanced Chip Select Control

The ColdFire QSPI hardware provides support for controlling the chip select signals of up to four SPI devices. In many situations this support is adequate, but there are exceptions:

1. The QSPI chip select outputs may share processor pins with other on-chip ColdFire devices. For example on the mcf5272 the QSPI CS2 signal uses the same pin as the uart1 CTS signal, so if the application needs uart1 and hardware flow-control then that QSPI CS2 pin is no longer available.
2. If the hardware has more than four SPI devices then additional chip selects are needed.
3. With most SPI devices the chip select signal only needs to be asserted while I/O is taking place, but there are exceptions. For example interactions with an MMC card involve a sequence of transfers, and the chip select must remain asserted in between these transfers. Depending on thread priorities and other factors there may be a considerable delay between these transfers and the QSPI hardware does not provide any way of keeping a chip select asserted indefinitely.

The issue of insufficient chip selects can usually be handled by adding extra hardware, for example an external decoder chip possibly complemented by inverters if there is a mixture of active-high and active-low devices. This approach can be supported simply by programming the right values for *qspi_qcr* and *qspi_qcr_tick*, but the cost of the extra hardware may be unacceptable. An alternative approach is to use one or more of the processor's GPIO pins to control the extra devices.

The issue of persistent chip selects can be handled in one of two main ways. A GPIO pin can be used to control the chip select, bypassing the QSPI support. Alternatively the QWR CSIV bit can be used in an inverted sense, to activate an SPI device rather than to define the inactive state.

To support these variations an arbitrary chip select control function can be specified for a device. Such a function takes two arguments. The first is a pointer to the SPI device, possibly allowing the function to be shared between multiple devices. The second is one of the following:

CYG_MCFxxxx_QSPI_CS_INIT

> During system initialization the QSPI bus driver will iterate over all the attached SPI devices. If a device has a *qspi_cs_control* function then this will be invoked. A typical action would be to configure a GPIO pin. Note that these calls happen quite early during system initialization so other subsystems like standard I/O may not be set up yet.

CYG_MCFxxxx_QSPI_CS_ASSERT

> This is used to assert the chip select, in other words to set the chip select to low for an active-low device or high for an active-high device. It will be called at the start of any transfer, unless the previous transfer has left the chip select asserted.

CYG_MCFxxxx_QSPI_CS_DROP

> This is used to deassert the chip select. It will be called at the end of any transfer that specifies drop_cs. It will also be called at the start of a tick operation.

To support persistent chip selects via the CSIV signal the bus driver package provides two chip control functions cyg_mcfxxxx_qspi_csiv_cs_control_active_high and cyg_mcfxxxx_qspi_csiv_cs_control_active_low. To use these with say an active-low device:

1. The *qspi_qwr* field should be set to `HAL_MCFxxxx_QSPIx_QWR_CSIV`, so the chip select is high when there is no I/O taking place.

2. The *qspi_cs_control* field should be set to `&cyg_mcfxxxx_qspi_csiv_cs_control_active_low`. This function will be invoked by the bus driver to assert or drop the signal (initialization is a no-op).

3. The QSPI_CS bits in the *qspi_qcr* field still have the usual meaning.

4. At the start of a transfer `cyg_mcfxxxx_qspi_csiv_cs_control_active_low` will clear the QWR CSIV bit. There is no I/O taking place yet so all chip select outputs will switch to low, activating all active-low devices. This is generally harmless since there is no clock signal.

5. When the I/O actually starts the *qspi_qcr* field will be used, deactivating all devices except the current one.

6. At the end of each individual transfer the chip selects will revert to their inactive state, which because of the CSIV setting means low. Again this will activate all active-low devices, but there is no clock signal so no I/O takes place.

7. For the last transfer of a transaction or for a tick operation `cyg_mcfxxxx_qspi_cs_control_active_low` will be invoked again with a DROP argument. It will reset the QWR CSIV bit to 1, deactivating all devices.

The overall effect is a persistent chip select with the desired polarity, using just the QSPI hardware facilities rather than a GPIO pin.

Chapter 74. Microchip (Atmel) USART-as-SPI Bus Driver

Name

CYGPKG_DEVS_SPI_ATMEL_USPI — eCos Support for the Microchip (Atmel) USART-as-SPI Bus

Description

The Microchip (previously Atmel) SAM E70, S70, V70 and V71 processors do come with on-chip SPI controllers, but also with the ability to configure the on-chip USART controllers as SPI masters. This package provides an eCos bus driver for those USART-as-SPI interfaces. The CYGPKG_DEVS_SPI_ARM_AT91 package provides the bus driver support for the standard SPI controllers.

This package implements the functionality defined by the generic SPI package CYGPKG_IO_SPI. The driver supports both polled and DMA-driven transfers. Typical supported transfer rates range from 3KHz to 25MHz, although the exact details depend on the specific processor configuration.

This bus driver package does not instantiate any cyg_spi_device structures. Exactly which devices are attached to the SPI bus is a characteristic of the platform so usually it is the platform HAL which provides the device instances.

Configuration Options

This SPI bus driver package should be loaded automatically when selecting a target containing a suitable SAM processor with USART-as-SPI hardware, and it should never be necessary to load the package explicitly. If the application does not use any of the SPI functionality then all the SPI support code will be removed at link-time and the application does not suffer any overheads.

The package contains a single configuration option CYGNUM_DEVS_SPI_ATMEL_USPI_BAUD_RATE_MAX. Usually this option will not need to be manipulated by application developers, since it purely sets an upper bound on the acceptable device baudrate that will be accepted, though may not be achievable depending on the CPU configuration.

The only other configuration options provided by this package relate to compiler flags.

Instantiating Buses

In the platform CDL, when this CYGPKG_DEVS_SPI_ATMEL_USPI is configured, an implements entry should be provided for the USART-as-SPI bus to instantiate.

Note

Currently the CYGPKG_HAL_CORTEXM_SAM HAL allows for the dedicated SPI buses numbered 0 and 1, and the USART-as-SPI buses numbered 2..4.

For example, the samx70_ek platform CDL provides for SPI bus#2 by declaring:

```
implements CYGINT_HAL_CORTEXM_SAM_SPI2
```

When a bus is implemented the Chip-Select GPIOs associated with the bus (at **least** one) should be provided by the platform CDL defining a corresponding CYGHWR_HAL_CORTEXM_SAM_SPI*x*_CS_GPIOS definition for the bus in question.

For the SPI bus#2 example above the platform CDL would also define CYGHWR_HAL_CORTEXM_SAM_SPI2_CS_GPIOS option and provide the list of chip-select pins, e.g.:

```
default_value { "SPI_CS(B,3)" }
```

Defining Devices

For most boards the platform HAL will create cyg_spi_device instances for all attached SPI devices, and will initialize the system so that the SPI-related processor pins are connected appropriately.

Device instances should take the form of a cyg_spi_atmel_device_t structure, which contains a cyg_spi_device as its first field. For example, for a device on bus#2:

```
#include <cyg/io/spi_atmel_uspi.h>
…
cyg_spi_atmel_device_t hal_spi_example CYG_SPI_DEVICE_ON_BUS(2) = {
    .spi_device.spi_bus = &cyg_spi_atmel_uspi_bus2,
    …
};
```

This defines a variable `hal_spi_example` which can be used by other packages or by application code as an argument to the I/O functions provided by the generic SPI package `CYGPKG_IO_SPI`. A gcc extension, designated initializers, is used to fill in the *`spi_device.spi_bus`* structure field. The structure contains a further **seven** fields which define exactly how to interact with the specific SPI device.

`dev_num`

This is the index into the `CYGHWR_HAL_CORTEXM_SAM_SPIx_CS_GPIOS` list of GPIOs for the specific Chip-Select GPIO used to select access to the device on the relevant SPI bus.

`cl_pol`

The clock polarity (0 or 1).

`cl_pha`

The clock phase (0 or 1).

`cl_brate`

The `SCK` baudrate used when communicating with the device.

`cs_up_udly`

Required microsecond delay between CS active and the transfer starting.

`cs_dw_udly`

Required microsecond delay between transfer ending and CS going inactive.

`tr_bt_udly`

Minimum microsecond delay between two transfers (between CS inactive to active again).

For example, the following instantaties a AT25080 serial EEPROM memory device on SPI bus#2:

```
#include <cyg/io/spi_atmel_uspi.h>
…
cyg_spi_atmel_device_t cyg_aardvark_at25080 CYG_SPI_DEVICE_ON_BUS(2) = {
    .spi_device.spi_bus = &cyg_spi_atmel_uspi_bus2,
    .dev_num     = 0,       // CS#0
    .cl_pol      = 0,       // Clock polarity
    .cl_pha      = 1,       // Clock phase
    .cl_brate    = 2000000, // Clock baud rate 2MHz. At 3.3v 2.1MHz is allowed for this part.
    .cs_up_udly  = 1,       // Tcss (CS setup time) for this part at 3.3V is 250ns.
    .cs_dw_udly  = 1,       // Tcsh (CS hold time) for this part at 3.3V is 250ns.
    .tr_bt_udly  = 1        // Tcs (CS high time) for this part at 3.3V is 250ns.
};
```

Part XXIII. I^{2}C Support

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 75. I²C Support

Name

Overview — eCos Support for I²C, the Inter IC Bus

Description

The Inter IC Bus (I²C) is one of a number of serial bus technologies. It can be used to connect a processor to one or more peripheral chips, for example analog-to-digital convertors or real time clocks, using only a small number of pins and PCB tracks. The technology was originally developed by Philips Semiconductors but is supported by many other vendors. The bus specification is freely available.

In a typical I²C system the processor acts as the I²C bus master. The peripheral chips act as slaves. The bus consists of just two wires: SCL carries a clock signal generated by the master, and SDA is a bi-directional data line. The normal clock frequency is 100KHz. Each slave has a 7-bit address. With some chips the address is hard-wired, and it is impossible to have two of these chips on the same bus. With other chips it is possible to choose between one of a small number of addresses by connecting spare pins to either VDD or GND.

An I²C data transfer involves a number of stages:

1. The bus master generates a start condition, a high-to-low transition on the SDA line while SCL is kept high. This signalling cannot occur during data transfer.

2. The bus master clocks the 7-bit slave address onto the SDA line, followed by a direction bit to distinguish between reads and writes.

3. The addressed device acknowledges. If the master does not see an acknowledgement then this suggests it is using the wrong address for the slave device.

4. If the master is transmitting data to the slave then it will send this data one byte at a time. The slave acknowledges each byte. If the slave is unable to accept more data, for example because it has run out of buffer space, then it will generate a nack and the master should stop sending.

5. If the master is receiving data from the slave then the slave will send this data one byte at a time. The master should acknowledge each byte, until the last one. When the master has received all the data it wants it should generate a nack and the slave will stop sending. This nack is essential because it causes the slave to stop driving the SDA line, releasing it back to the master.

6. It is possible to switch direction in a single transfer, using what is known as a repeated start. This involves generating another start condition, sending the 7-bit address again, followed by a new direction bit.

7. At the end of a transfer the master should generate a stop condition, a low-to-high transition on the SDA line while SCL is kept high. Again this signalling does not occur at other times.

There are a number of extensions. The I²C bus supports multiple bus masters and there is an arbitration procedure to allow a master to claim the bus. Some devices can have 10-bit addresses rather than 7-bit addresses. There is a fast mode operating at 400KHz instead of the usual 100KHz, and a high-speed mode operating at 3.4MHz. Currently most I²C-based systems do not involve any of these extensions.

At the hardware level I²C bus master support can be implemented in one of two ways. Some processors provide a dedicated I²C device, with the hardware performing much of the work. On other processors the I²C device is implemented in software, by bit-banging some GPIO pins. The latter approach can consume a significant number of cpu cycles, but is often acceptable because only occasional access to the I²C devices is needed.

eCos Support for I²C

The eCos I²C support for any given platform is spread over a number of different packages:

- This package, `CYGPKG_IO_I2C`, exports a generic API for accessing devices attached to an I²C bus. This API handles issues such as locking between threads. The package does not contain any hardware-specific code. Instead it will use a separate I²C bus driver to handle the hardware, and it defines the interface that such bus drivers should provide. The package only provides support for a bus master, not for acting as a slave device.

  `CYGPKG_IO_I2C` also provides the hardware-independent portion of a bit-banged bus implementation. This needs to be complemented by a hardware-specific function that actually manipulates the SDA and SCL lines.

- If the processor has a dedicated I²C device then there will be a bus driver package for that hardware. The processor may be used on many different platforms and the same bus driver can be used on each one. The actual I²C devices attached to the bus will vary from one platform to the next.

- The generic API depends on cyg_i2c_device data structures. These contain the information needed by a bus driver, for example the device address. Usually the data structures are provided by the platform HAL since it is that package which knows about all the devices on the platform.

  On some development boards the I²C lines are brought out to expansion connectors, allowing end users to add extra devices. In such cases the platform HAL may not know about all the devices on the board. Data structures for the additional devices can instead be supplied by application code.

- If the board uses a bit-banged bus then typically the platform HAL will also instantiate the bus instance, providing the function that handles the low-level SDA and SCL manipulation. Usually this code cannot be shared because each board may use different GPIO pins for driving SCL and SDA, so the code belongs in the platform HAL rather than in a separate package.

- Some types of I²C devices may have their own driver package. For example a common type of I²C device is a battery-backed wallclock, and eCos defines how these devices should be supported. Such an I²C device will have its own wallclock device driver and the device will not be accessed directly by application code. For other types of device eCos does not define an API and there will not be separate device driver packages. Instead application code is expected to use the cyg_i2c_device structures directly to access the hardware.

Typically all appropriate packages will be loaded automatically when you configure eCos for a given platform. If the application does not use any of the I²C I/O facilities, directly or indirectly, then linker garbage collection should eliminate all unnecessary code and data. All necessary initialization should happen automatically. However the exact details may depend on the platform, so the platform HAL documentation should be checked for further details.

There is one important exception to this: if the I²C devices are attached to an expansion connector then the platform HAL will not know about these devices. Instead more work will have to be done by application code.

Name

I²C Functions — allow applications and other packages to access I²C devices

Synopsis

#include <cyg/io/i2c.h>

`cyg_uint32` **`cyg_i2c_tx`**(*`device`*, *`tx_data`*, *`count`*);

`cyg_uint32` **`cyg_i2c_rx`**(*`device`*, *`rx_data`*, *`count`*);

`void` **`cyg_i2c_transaction_begin`**(*`device`*);

`cyg_bool` **`cyg_i2c_transaction_begin_nb`**(*`device`*);

`cyg_uint32` **`cyg_i2c_transaction_tx`**(*`device`*, *`send_start`*, *`tx_data`*, *`count`*, *`send_stop`*);

`cyg_uint32` **`cyg_i2c_transaction_rx`**(*`device`*, *`send_start`*, *`rx_data`*, *`count`*, *`send_nack`*, *`send_stop`*);

`void` **`cyg_i2c_transaction_stop`**(*`device`*);

`void` **`cyg_i2c_transaction_end`**(*`device`*);

Description

All I²C functions take a pointer to a cyg_i2c_device structure as their first argument. These structures are usually provided by the platform HAL. They contain the information needed by the I²C bus driver to interact with the device, for example the device address.

An I²C transaction involves the following stages:

1. Perform thread-level locking on the bus. Only one thread at a time is allowed to access an I²C bus. This eliminates the need to worry about locking at the bus driver level. If a platform involves multiple I²C buses then each one will have its own lock.
2. Generate a start condition, send the address and direction bit, and wait for an acknowledgement from the addressed device.
3. Either transmit data to or receive data from the addressed device.
4. The previous two steps may be repeated several times, allowing data to move in both directions during a single transfer.
5. Generate a stop condition, ending the current data transfer. It is now possible to start another data transfer while the bus is still locked, if desired.
6. End the transaction by unlocking the bus, allowing other threads to access other devices on the bus.

The simple functions `cyg_i2c_tx` and `cyg_i2c_rx` perform all these steps in a single call, making them suitable for many I/O operations. The alternative transaction-oriented functions provide greater control when appropriate, for example if a repeated start is necessary for a bi-directional data transfer.

With the exception of `cyg_i2c_transaction_begin_nb` all the functions will block until completion. The tx routines will return 0 if the specified device does not respond to its address, or the number of bytes actually transferred. This may be less than the number requested if the device sends an early nack, for example because it has run out of buffer space. The rx routines will return 0 or the number of bytes received. Usually this will be the same as the `count` parameter. A slave device has no way of indicating to the master that no more data is available, so the rx operation cannot complete early.

I²C operations should always be performed at thread-level or during system initialization, and not inside an ISR or DSR. This greatly simplifies locking. Also a typical ISR or DSR should not perform a blocking operation such as an I²C transfer.

Simple Transfers

`cyg_i2c_tx` and `cyg_i2c_rx` can be used for simple data transfers. They both go through the following steps: lock the bus, generate the start condition, send the device address and the direction bit, either send or receive the data, generate the stop condition, and unlock the bus. At the end of a transfer the bus is back in its idle state, ready for the next transfer.

`cyg_i2c_tx` returns the number of bytes actually transmitted. This may be 0 if the device does not respond when its address is sent out. It may be less than the number of bytes requested if the device generates an early nack, typically because it has run out of buffer space.

`cyg_i2c_rx` returns 0 if the device does not respond when its address is sent out, or the number of bytes actually received. Usually this will be the number of bytes requested because an I²C slave device has no way of aborting an rx operation early.

Transactions

To allow multiple threads to access devices on the I²C some locking is required. This is encapsulated inside transactions. The `cyg_i2c_tx` and `cyg_i2c_rx` functions implicitly use such transactions, but the functionality is also available directly to application code. Amongst other things transactions can be used for more complicated interactions with I²C devices, in particular ones involving repeated starts.

`cyg_i2c_transaction_begin` must be used at the start of a transaction. This performs thread-level locking on the bus, blocking if it is currently in use by another thread.

`cyg_i2c_transaction_begin_nb` is a non-blocking variant, useful for threads which cannot afford to block for an indefinite period. If the bus is currently locked the function returns false immediately. If the bus is not locked then it acts as `cyg_i2c_transaction_begin` and returns true.

Once the bus has been locked it is possible to perform one or more data transfers by calling `cyg_i2c_transaction_tx`, `cyg_i2c_transaction_rx` and `cyg_i2c_transaction_stop`. Code should ensure that a stop condition has been generated by the end of a transaction.

Once the transaction is complete `cyg_i2c_transaction_end` should be called. This unlocks the bus, allowing other threads to perform I²C I/O to devices on the same bus.

As an example consider reading the registers in an FS6377 programmable clock generator. The first step is to write a byte 0 to the device, setting the current register to 0. Then a repeated start condition should be generated and it is possible to read the 16 byte-wide registers, starting with the current one. Typical code for this might look like:

```
cyg_uint8  tx_data[1];
cyg_uint8  rx_data[16];

cyg_i2c_transaction_begin(&hal_alaia_i2c_fs6377);
tx_data[0] = 0x00;
cyg_i2c_transaction_tx(&hal_alaia_i2c_fs6377,
                       true, tx_data, 1, false);
cyg_i2c_transaction_rx(&hal_alaia_i2c_fs6377,
                       true, rx_data, 16, true, true);
cyg_i2c_transaction_end(&hal_alaia_i2c_fs6377);
```

Here `hal_alaia_i2c_fs6377` is a cyg_i2c_device structure provided by the platform HAL. A transaction is begun, locking the bus. Then there is a transmit for a single byte. This transmit involves generating a start condition and sending the address and direction bit, but not a stop condition. Next there is a receive for 16 bytes. This also involves a start condition, which the device will interpret as a repeated start because it has not yet seen a stop. The start condition will be followed by the address and direction bit, and then the device will start transmitting the register contents. Once all 16 bytes have been received the rx routine will send a nack rather than an ack, halting the transfer, and then a stop condition is generated. Finally the transaction is ended, unlocking the bus.

The arguments to `cyg_i2c_transaction_tx` are as follows:

const cyg_i2c_device* `device`

This identifies the I²C device that should be used.

cyg_bool `send_start`

If true, generate a start condition and send the address and direction bit. If false, skip those steps and go straight to transmitting the actual data. The latter can be useful if the data to be transmitted is spread over several buffers. The first tx call will involve generating the start condition but subsequent tx calls can skip this and just continue from the previous one.

`send_start` must be true if the tx call is the first operation in a transaction, or if the previous call was an rx or stop.

const cyg_uint8* `tx_data`
cyg_uint32 `count`

These arguments specify the data to be transmitted to the device.

cyg_bool `send_stop`

If true, generate a stop condition at the end of the transmit. Usually this is done only if the transmit is the last operation in a transaction.

The arguments to `cyg_i2c_transaction_rx` are as follows:

const cyg_i2c_device* `device`

This identifies the I²C device that should be used.

cyg_bool `send_start`

If true, generate a start condition and send the address and direction bit. If false, skip those steps and go straight to receiving the actual data. The latter can be useful if the incoming data should be spread over several buffers. The first rx call will involve generating the start condition but subsequent rx calls can skip this and just continue from the previous one. Another use is for devices which can send variable length data, consisting of an initial length and then the actual data. The first rx will involve generating the start condition and reading the length, a subsequent rx will then just read the data.

`send_start` must be true if the rx call is the first operation in a transaction, if the previous call was a tx or stop, or if the previous call was an an rx and the `send_nack` flag was set.

cyg_uint8* `rx_data`
cyg_uint32 `count`

These arguments specify how much data should be received and where it should be placed.

cyg_bool `send_nack`

If true generate a nack instead of an ack for the last byte received. This causes the slave to end its transmit. The next operation should either involve a repeated start or a stop. `send_nack` should be set to false only if `send_stop` is also false, the next operation will be another rx, and that rx does not specify `send_start`.

cyg_bool `send_stop`

If true, generate a stop condition at the end of the transmit. Usually this is done only if the transmit is the last operation in a transaction.

The final transaction-oriented function is `cyg_i2c_transaction_stop`. This just generates a stop condition. It should be used if the previous operation was a tx or rx that, for some reason, did not set the `send_stop` flag. A stop condition must be generated before the transaction is ended.

Initialization

The generic package `CYGPKG_IO_I2C` arranges for all I²C bus devices to be initialized via a single prioritized C++ static constructor. This constructor will run early on during system startup, before any application code, with priority `CYG_INIT_BUS_I2C`. Other code should not try to access any of the I²C devices until after the buses have been initialized.

Name

Porting — Adding I²C support to new hardware

Description

Adding I²C support to an eCos port involves a number of steps. The generic I²C package `CYGPKG_IO_I2C` should be included in the appropriate ecos.db target entry or entries. Next cyg_i2c_device structures should be provided for every device on the bus. Usually this is the responsibility of the platform HAL. In the case of development boards where the I²C SDA and SCL lines are accessible via an expansion connector, more devices may have been added and it will be the application's responsibility to provide the structures. Finally there is a need for one or more cyg_i2c_bus structures. Amongst other things these structures provide functions for actually driving the bus. If the processor has dedicated I²C hardware then this structure will usually be provided by a device driver package. If the bus is implemented by bit-banging then the bus structure will usually be provided by the platform HAL.

Adding a Device

The eCos I²C API works in terms of cyg_i2c_device structures, and these provide the information needed to access the hardware. A cyg_i2c_device structure contains the following fields:

cyg_i2c_bus* `i2c_bus`
: This specifies the bus which the slave device is connected to. Most boards will only have a single I²C bus, but multiple buses are possible.

cyg_uint16 `i2c_address`
: For most devices this will be the 7-bit I²C address the device will respond to. There is room for future expansion, for example to support 10-bit addresses.

cyg_uint16 `i2c_flags`
: This field is not used at present. It exists for future expansion, for example to allow for fast mode or high-speed mode, and incidentally pads the structure to a 32-bit boundary.

cyg_uint32 `i2c_delay`
: This holds the clock period which should be used when interacting with the device, in nanoseconds. Usually this will be 10000 ns, corresponding to a 100KHz clock, and the header `cyg/io/i2c.h` provides a `#define` `CYG_I2C_DEFAULT_DELAY` for this. Sometimes it may be desirable to use a slower clock, for example to reduce noise problems.

The normal way to instantiate a `cyg_i2c_device` structure uses the `CYG_I2C_DEVICE` macro, also provided by `cyg/io/i2c.h`:

```
#include <cyg/io/i2c.h>

CYG_I2C_DEVICE(cyg_i2c_wallclock_ds1307,
               &hal_alaia_i2c_bus,
               0x68,
               0x00,
               CYG_I2C_DEFAULT_DELAY);

CYG_I2C_DEVICE(hal_alaia_i2c_fs6377,
               &hal_alaia_i2c_bus,
               0x58,
               0x00,
               CYG_I2C_DEFAULT_DELAY);
```

The arguments to the macro are the variable name, an I²C bus pointer, the device address, the flags field, and the delay field. The above code fragment defines two I²C device variables, `cyg_i2c_wallclock_ds1307` and `hal_alaia_i2c_fs6377`, which can be used for the first argument to the `cyg_i2c_` functions. Both devices are on the same bus. The device addresses are 0x68 and 0x58 respectively, and the devices do not have any special requirements.

When the platform HAL provides these structures it should also export them for use by the application and other packages. Usually this involves an entry in `cyg/hal/plf_io.h`, which gets included automatically via one of the main exported HAL header files cyg/hal/hal_io.h. Unfortunately exporting the structures directly can be problematical because of circular dependencies between the I²C header and the HAL headers. Instead the platform HAL should define a macro HAL_I2C_EXPORTED_DEVICES:

```
# define HAL_I2C_EXPORTED_DEVICES                                   \
    extern cyg_i2c_bus                 hal_alaia_i2c_bus;           \
    extern cyg_i2c_device              cyg_i2c_wallclock_ds1307;    \
    extern cyg_i2c_device              hal_alaia_i2c_fs6377;
```

This macro gets expanded automatically by cyg/io/i2c.h once the data structures themselves have been defined, so application code can just include that header and all the buses and devices will be properly exported and usable.

There is no single convention for naming the I²C devices. If the device will be used by some other package then typically that specifies the name that should be used. For example the DS1307 wallclock driver expects the I²C device to be called cyg_i2c_wallclock_ds1307, so failing to observe that convention will lead to compile-time and link-time errors. If the device will not be used by any other package then it is up to the platform HAL to select the name, and as long as reasonable care is taken to avoid name space pollution the exact name does not matter.

Bit-banged Bus

Some processors come with dedicated I²C hardware. On other hardware the I²C bus involves simply connecting some GPIO pins to the SCL and SDA lines and then using software to implement the I²C protocol. This is usually referred to as bit-banging the bus. The generic I²C package CYGPKG_IO_I2C provides the main code for a bit-banged implementation, requiring one platform-specific function that does the actual GPIO pin manipulation. This function is usually hardware-specific because different boards will use different pins for the I²C bus, so typically it is left to the platform HAL to provide this function and instantiate the I²C bus object. There is no point in creating a separate package for this because the code cannot be re-used for other platforms.

Instantiating a bit-banged I²C bus requires the following:

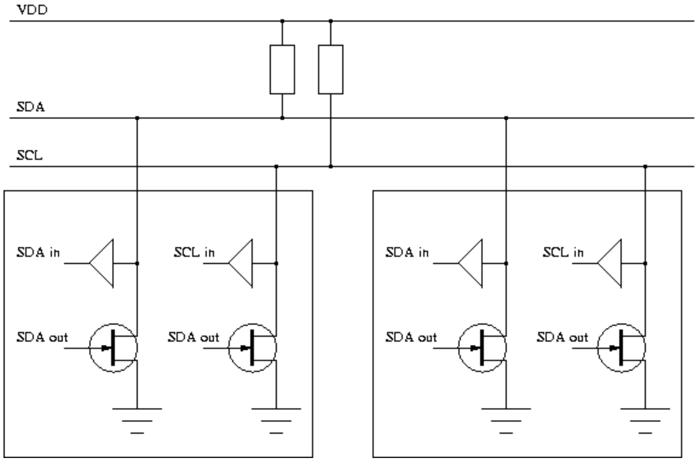
```
#include <cyg/io/i2c.h>

static cyg_bool
hal_alaia_i2c_bitbang(cyg_i2c_bus* bus, cyg_i2c_bitbang_op op)
{
    cyg_bool result    = 0;
    switch(op) {
        …
    }
    return result;
}

CYG_I2C_BITBANG_BUS(hal_alaia_i2c_bus, &hal_alaia_i2c_bitbang);
```

This gives a structure hal_alaia_i2c_bus which can be used when defining the cyg_i2c_device structures. The second argument specifies the function which will do the actual bit-banging. It takes two arguments. The first identifies the bus, which can be useful if the hardware has multiple I²C buses. The second specifies the bit-bang operation that should be performed. To understand these operations consider how I²C devices should be wired up according to the specification:

Figure 75.1. I²C wiring specification



Master and slave devices are interfaced to the bus in exactly the same way. The default state of the bus is to have both lines high via the pull-up resistors. Any device on the bus can lower either line, when allowed to do so by the protocol. Usually the SDA line only changes while SCL is low, but the start and stop conditions involve SDA changing while SCL is high. All devices have the ability to both read and write both lines. In reality not all bit-banged hardware works quite like this. Instead just two GPIO pins are used, and these are switched between input and output mode as required.

The bitbang function should support the following operations:

`CYG_I2C_BITBANG_INIT`

This will be called during system initialization, as a side effect of a prioritized C++ static constructor. The bitbang function should ensure that both SCL and SDA are driven high.

`CYG_I2C_BITBANG_SCL_HIGH`
`CYG_I2C_BITBANG_SCL_LOW`
`CYG_I2C_BITBANG_SDA_HIGH`
`CYG_I2C_BITBANG_SDA_LOW`

These operations simply set the appropriate lines high or low.

`CYG_I2C_BITBANG_SCL_HIGH_CLOCKSTRETCH`

In its simplest form this operation should simply set the SCL line high, indicating that the data on the SDA line is stable. However there is a complication: if a device is not ready yet then it can throttle back the master by keeping the SCL line low. This is known as clock-stretching. Hence for this operation the bitbang function should allow the SCL line to float high, then poll it until it really has become high. If a single pin is used for the SCL line then this pin should be turned back into a high output at the end of the call.

`CYG_I2C_BITBANG_SCL_LOW_SDA_INPUT`

This is used when there is a change of direction and the slave device is about to start driving the SDA line. This can be significant if a single pin is used to handle both input and output of SDA, to avoid a situation where both the master and the slave are driving the SDA line for an extended period of time. The operation combines dropping the SCL line and switching SDA to an input in an atomic or near-atomic operation.

`CYG_I2C_BITBANG_SDA_READ`

The SDA line is currently set as an input and the bitbang function should sample and return the current state.

The bitbang function returns a boolean. For most operations this return value is ignored. For `CYG_I2C_BITBANG_SDA_READ` it should be the current level of the SDA line.

Depending on the hardware some care may have to be taken when manipulating the GPIO pins. Although the I²C subsystem performs the required locking at the bus level, the device registers controlling the GPIO pins may get used by other subsystems or by the application. It is the responsibility of the bitbang function to perform appropriate locking, whether via a mutex or by briefly disabling interrupts around the register accesses.

Full Bus Driver

If the processor has dedicated I²C hardware then usually this will involve a separate device driver package in the `devs/i2c` hierarchy of the eCos component repository. That package should also be included in the appropriate ecos.db target entry or entries. The device driver may exist already, or it may have to be written from scratch.

A new I²C driver basically involves creating an cyg_i2c_bus structure. The device driver should supply the following fields:

`i2c_init_fn`
: This function will be called during system initialization to set up the I²C hardware. The generic I²C code creates a static object with a prioritized constructor, and this constructor will invoke the init functions for the various I²C buses in the system.

`i2c_tx_fn`
`i2c_rx_fn`
`i2c_stop_fn`
: These functions implement the core I²C functionality. The arguments and results are the same as for the transaction functions `cyg_i2c_transaction_tx`, `cyg_i2c_transaction_rx` and `cyg_i2c_transaction_stop`.

void* `i2c_extra`
: This field holds any extra information that may be needed by the device driver. Typically it will be a pointer to some driver-specific data structure.

To assist with instantiating a cyg_i2c_bus object the header file `cyg/io/i2c.h` provides a macro. Typical usage would be:

```
struct xyzzy_data {
    …
} xyzzy_object;

static void
xyzzy_i2c_init(struct cyg_i2c_bus* bus)
{
    …
}

static cyg_uint32
xyzzy_i2c_tx(const cyg_i2c_device* dev,
             cyg_bool send_start,
             const cyg_uint8* tx_data, cyg_uint32 count,
             cyg_bool send_stop)
{
    …
}

static cyg_uint32
xyzzy_i2c_rx(const cyg_i2c_device* dev,
             cyg_bool send_start,
             cyg_uint8* rx_data, cyg_uint32 count,
             cyg_bool send_nack, cyg_bool send_stop)
{
    …
}

static void
xyzzy_i2c_stop(const cyg_i2c_device* dev)
{
    …
}

CYG_I2C_BUS(cyg_i2c_xyzzy_bus,
            &xyzzy_i2c_init,
            &xyzzy_i2c_tx,
            &xyzzy_i2c_rx,
            &xyzzy_i2c_stop,
            (void*) &xyzzy_object);
```

The generic I^{2}C code contains these functions for a bit-banged I^{2}C bus device. It can be used as a starting point for new drivers. Note that the bit-bang code uses the `i2c_extra` field to hold the hardware-specific bitbang function rather than a pointer to some data structure.

Chapter 76. Freescale MCFxxxx ColdFire I^2C Bus Driver

Name

`CYGPKG_DEVS_I2C_MCFxxxx` — eCos Support for the Freescale Coldfire I^{2}C Bus

Description

Several processors in the Freescale ColdFire family come with one or more on-chip I^{2}C bus devices. This package provides an eCos I^{2}C bus driver. It was originally developed on an MCF5280 but should work with any ColdFire processor that uses a compatible bus device. The driver implements the functionality defined by the generic I^{2}C package `CYGPKG_IO_I2C`.

Caution

The hardware does not support DMA or fifos, so usually a transfer will involve an interrupt for every byte transferred. Since the I^{2}C bus typically runs at 100KHz large transfers will consume much of the available cpu time.

This package does not provide any cyg_i2c_bus structures. The number of I^{2}C buses varies between ColdFire processors. If multiple buses are available then exactly which one(s) are in use on a given hardware platform depends entirely on that platform. The desired I^{2}C bus speed also depends on the platform, and there may be other issues such as how the processor pins should be set up. Hence it is left to other code, usually the processor HAL, to instantiate the bus structure(s). This driver package supplies the necessary functions and utility macros. Similarly this package does not provide any cyg_i2c_device structures. Which I^{2}C devices are hooked up to which I^{2}C bus is entirely a characteristic of the hardware platform, so it is up to the platform HAL to instantiate the necessary structures.

The driver will operate in interrupt-driven mode if interrupts are enabled when a transfer is initiated. Otherwise it will operate in polled mode. This allows the driver to be used in a variety of configurations including inside RedBoot.

Configuration Options

The I^{2}C bus driver package should be loaded automatically when selecting a target containing a suitable ColdFire processor, and it should never be necessary to load the package explicitly. If the application does not use any of the I^{2}C functionality, directly or indirectly, then all the I^{2}C code should be removed at link-time and the application does not suffer any overheads.

By default the driver assumes a single I^{2}C bus and optimizes for that case. For example options like the ISR vector and priority are handled by compile-time `#define`'s in the platform HAL's exported header files rather than by per-bus structure fields. This helps to reduce both code and data overheads. If the driver should support multiple I^{2}C buses then `CYGHWR_DEVS_I2C_MCFxxxx_MULTIPLE_BUSES` should be enabled. Typically this will be done by the processor HAL using a CDL requires property. If bus instantiation happens outside the processor HAL and hence the HAL's header files do not provide the appropriate definitions, then this configuration option should also be defined.

The only other configuration options in this package provide control over the compiler flags used to build the driver code.

Defining the Bus and Devices

For most hardware targets the processor HAL will instantiate the cyg_i2c_bus and the platform HAL will instantiate the cyg_i2c_device structures. Between them they will also initialize the hardware so that the I^{2}C-related pins are connected appropriately. Some development boards have no I^{2}C devices, but the I^{2}C bus signals are accessible via an expansion connector and I^{2}C devices can be put on a daughter board. In such cases it may be necessary for the application to instantiate the device structures.

To facilitate bus instantiation the header file `cyg/io/i2c_mcfxxxx.h` provides a utility macro `CYG_MCFxxxx_I2C_BUS`. This takes six parameters:

1. The name of the bus, for example `hal_dnp5280_i2c_bus`. This name will be used when instantiating the I^{2}C devices.

2. An initialization function. If no platform-specific initialization is needed then this can be the `cyg_mcfxxxx_i2c_init` function exported by this driver. Otherwise it can be a platform-specific function which, for example, sets up the relevant pins appropriately and then chains into `cyg_mcfxxxx_i2c_init`.

3. The base address of the I^{2}C bus. For example on an MCF5282 with the IPSBAR set to its usual value of 0x40000000, the I^{2}C bus is at location 0x40000300.

4. The interrupt vector, for example `CYGNUM_HAL_ISR_I2C_IIF` on an MCF5282.

5. The interrupt priority. Typically this will be a configurable option within the platform HAL.

6. A value for the I^{2}C bus's I2FDR register. That register controls the bus speed. Typical bus speeds are 100KHz and 400KHz, depending on the capabilities of the attached devices. There is no simple relationship between the system clock speed, the desired bus speed, and the FDR register. Although the driver could determine the FDR setting using a lookup table and appropriate code, it is better to determine the correct value once during the porting process and avoid unnecessary run-time overheads.

For the common case where only a single I^{2}C bus should be supported (`CYGHWR_DEVS_I2C_MCFxxxx_MULTIPLE_BUSES` is disabled), the last four parameters should be provided by preprocessor `#define`'s, typically in `cyg/hal/plf_io.h` which gets `#include`'d automatically via `cyg/hal/hal_io.h`. This header can also define the `HAL_I2C_EXPORTED_DEVICES` macro as per the generic I^{2}C package:

```
#include <pkgconf/hal_m68k_dnp5280.h>
…
#ifdef CYGHWR_HAL_M68K_DNP5280_I2C
#define HAL_MCFxxxx_I2C_SINGLETON_BASE   (HAL_MCFxxxx_MBAR+HAL_MCF5282_I2C0_BASE)
#define HAL_MCFxxxx_I2C_SINGLETON_ISRVEC CYGNUM_HAL_ISR_I2C_IIF
#define HAL_MCFxxxx_I2C_SINGLETON_ISRPRI CYGNUM_HAL_M68K_DNP5280_I2C_ISRPRI
#define HAL_MCFxxxx_I2C_SINGLETON_FDR    CYGNUM_HAL_M68K_DNP5280_I2C_FDR

#define HAL_I2C_EXPORTED_DEVICES \
    extern cyg_i2c_bus hal_dnp5280_i2c_bus;
#endif
```

On this particular platform the I^{2}C bus is only accessible on an expansion connector so the support is conditional on a configuration option `CYGHWR_HAL_M68K_DNP5280_I2C`. The interrupt priority and I2FDR values are also controlled by configuration options. On other platforms the I^{2}C support may not be conditional and the priority and/or FDR values may be hard-wired.

The I^{2}C bus instantiation should happen in an ordinary C or C++ file, typically in the platform HAL. The corresponding object file should go into `libtarget.a` and the file should only contain I^{2}C-related code to get the maximum benefit of linker garbage collection.

```
#include <cyg/infra/cyg_type.h>
#include <cyg/hal/hal_io.h>
#include <cyg/io/i2c.h>
#include <cyg/io/i2c_mcfxxxx.h>

CYG_MCFxxxx_I2C_BUS(hal_dnp5280_i2c_bus,
                    &cyg_mcfxxxx_i2c_init,
                    HAL_MCFxxxx_I2C_SINGLETON_BASE,
                    HAL_MCFxxxx_I2C_SINGLETON_ISRVEC,
                    HAL_MCFxxxx_I2C_SINGLETON_ISRPRI,
                    HAL_MCFxxxx_I2C_SINGLETON_FDR);
```

Obviously if `CYGHWR_DEVS_I2C_MCFxxxx_MULTIPLE_BUSES` is enabled then the singleton macros may not be defined and the appropriate numbers should be used directly. This example assumes no special initialization is needed. If there are special initialization requirements then a custom function can be used instead of `cyg_mcfxxxx_i2c_init`, and the custom function should chain to the latter.

I^{2}C device structures can be instantiated in the usual way, for example:

```
CYG_I2C_DEVICE(cyg_i2c_wallclock_ds1307,
               &hal_dnp5280_i2c_bus,
               0x68,
               0x00,
               CYG_I2C_DEFAULT_DELAY);
```

Part XXIV. ADC Support

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 77. ADC Support

Name

eCos Support for Analog/Digital Converters — Overview

Introduction

ADC support in eCos is based around the standard character device interface. Hence all device IO function, or file IO functions may be used to access ADC devices.

ADC devices are presented as read-only serial channels that generate samples at a given rate. The size of each sample is hardware specific and is defined by the cyg_adc_sample_t type. The sample rate may be set at runtime by the application. Most ADC devices support several channels which are all sampled at the same rate. Therefore setting the rate for one channel will usually change the rate for all channels on that device.

Examples

The use of the ADC devices is best shown by example. The following is a simple example of using the eCos device interface to access the ADC:

```
int res;
cyg_io_handle_t handle;

// Get a handle for ADC device 0 channel 0
res = cyg_io_lookup( "/dev/adc00", &handle );

if( res != ENOERR )
    handle_error(err);

for(;;)
{
    cyg_adc_sample_t sample;
    cyg_uint32 len = sizeof(sample);

    // read a sample from the channel
    res = cyg_io_read( handle, &sample, &len );

    if( res != ENOERR )
        handle_error(err);

    use_sample( sample );
}
```

In this example, the required channel is looked up and a handle on it acquired. Conventionally ADC devices are named "/dev/adcXY" where X is the device number and Y the channel within that device. Following this, samples are read from the device sequentially.

ADC devices may also be accessed using FILEIO operations. These allow more sophisticated usage. The following example shows `select()` being used to gather samples from several devices.

```
int fd1, fd2;

// open channels, non-blocking
fd1 = open( "/dev/adc01", O_RDONLY|O_NONBLOCK );
fd2 = open( "/dev/adc02", O_RDONLY|O_NONBLOCK );

if( fd1 < 0 || fd2 < 0 )
    handle_error( errno );

for(;;)
{
    fd_set rd;
    int maxfd = 0;
    int err;
    cyg_adc_sample_t samples[128];
    int len;

    FD_ZERO( &rd );

    FD_SET( fd1, &rd );
    FD_SET( fd2, &rd );
    maxfd = max(fd1,fd2);

    // select on available data on each channel.
    err = select( maxfd+1, &rd, NULL, NULL, NULL );

    if( err < 0 )
        handle_error(errno);

    // If channel 1 has data, handle it
    if( FD_ISSET( fd1, &rd ) )
    {
        len = read( fd1, &samples, sizeof(samples) );

        if( len > 0 )
            handle_samples_chan1( &samples, len/sizeof(sample[0]) );
    }

    // If channel 2 has data, handle it
    if( FD_ISSET( fd2, &rd ) )
    {
        len = read( fd2, &samples, sizeof(samples) );

        if( len > 0 )
            handle_samples_chan2( &samples, len/sizeof(sample[0]) );
    }

}
```

This test uses FILEIO operations to access ADC channels. It starts by opening two channels for reading only and with blocking disabled. It then falls into a loop using select to wake up whenever either channel has samples available.

Details

As indicated, the main interface to ADC devices is via the standard character device interface. However, there are a number of aspects that are ADC specific.

Sample Type

Samples can vary in size depending on the underlying hardware and is often a non-standard number of bits. The actual number of bits is defined by the hardware driver package, and the generic ADC package uses this to define a type cyg_adc_sample_t which can contain at least the required number of bits. All reads from an ADC channel should be expressed in multiples of this type, and actual bytes read will also always be a multiple.

Sample Rate

The sample rate of an ADC device can be varied by calling a `set_config` function, either at the device IO API level or at the FILEIO level. The following two functions show how this is done at each:

```
int set_rate_io( cyg_io_handle_t handle, int rate )
{
    cyg_adc_info_t info;
    cyg_uint32 len = sizeof(info);

    info.rate = rate;
    return cyg_io_set_config( handle,
                              CYG_IO_SET_CONFIG_ADC_RATE,
                              &info,
                              &len);
}

int set_rate_fileio( int fd, int rate )
{
    cyg_adc_info_t info;

    info.rate = rate;

    return cyg_fs_fsetinfo( fd,
                            CYG_IO_SET_CONFIG_ADC_RATE,
                            &info,
                            sizeof(info) );
}
```

Enabling a Channel

Channels are initialized in a disabled state and generate no samples. When a channel is first looked up or opened, then it is automatically enabled and samples start to accumulate. A channel may then be disable or re-enabled via a `set_config` function:

```
int disable_io( cyg_io_handle_t handle )
{
    return cyg_io_set_config( handle,
                              CYG_IO_SET_CONFIG_ADC_DISABLE,
                              NULL,
                              NULL);
}

int enable_io( cyg_io_handle_t handle )
{
    return cyg_io_set_config( handle,
                              CYG_IO_SET_CONFIG_ADC_DISABLE,
                              NULL,
                              NULL);
}
```

Flushing a channel

After any run-time channel re-configuration it may desirable (depending on the application) to flush any buffered data that may be present from prior to the channel config update. For example, this can be done at the IO API level by using the `CYG_IO_SET_CONFIG_ADC_FLUSH` config key:

```
int flush_io( cyg_io_handle_t handle )
{
    return cyg_io_set_config( handle,
                              CYG_IO_SET_CONFIG_ADC_FLUSH,
                              NULL,
                              NULL);
}
```

Configuration

The ADC package defines a number of generic configuration options that apply to all ADC implementations:

cdl_component CYGPKG_IO_ADC_DEVICES

> This option enables the hardware device drivers for the current platform. ADC devices will only be enabled if this option is itself enabled.

cdl_option CYGNUM_IO_ADC_SAMPLE_SIZE

> This option defines the sample size for the ADC devices. Given in bits, it will be rounded up to 8, 16 or 32 to define the cyg_adc_sample_t type. This option is usually set by the hardware device driver.

cdl_option CYGPKG_IO_ADC_SELECT_SUPPORT

> This option enables support for the `select()` API function on all ADC devices. This option can be disabled if the `select()` is not used, saving some code and data space.

cdl_component CYGIMP_IO_ADC_INSTRUMENTATION

> If the system instrumentation support is enabled for the active configuration then this option can be used to enable the ADC I/O specific instrumentation support.
>
> Instrumentation records will only be generated if this option is itself enabled, and if the relevant individual event code sub-options are enabled. The default state is for all the instrumentation to be disabled. Some options will generate a lot of instrumentation records in a heavily loaded system and so care may need to be taken regarding the instrumentation enabled vs the instrumentation recording mechanism. Depending on why the ADC I/O driver instrumentation is being enabled (debugging, timing validation, etc.) the user can choose which events they wish to record by enabling the specific CDL option.

In addition to the generic options, each hardware device driver defines some parameters for each device and channel. The exact names of the following option depends on the hardware device driver, but options of this form should be available in all drivers.

cdl_option CYGDAT_IO_ADC_EXAMPLE_CHANNELN_NAME

> This option specifies the name of the device for an ADC channel. Channel names should be of the form "/dev/adcXY" where X is the device number and Y the channel within that device.

cdl_option CYGNUM_IO_ADC_EXAMPLE_CHANNELN_BUFSIZE

> This option specifies the buffer size for an ADC channel. The value is expressed in multiples of cyg_adc_sample_t rather than bytes. The default value is 128.

cdl_option CYGNUM_IO_ADC_EXAMPLE_DEFAULT_RATE

> This option defines the initial default sample rate for all channels. The hardware driver may place constraints on the range of values this option may take.

Name

Overview — ADC Device Drivers

Introduction

This section describes how to write an ADC hardware device. While users of ADC devices do not need to read it, it may provide added insight into how the devices work.

Data Structures

An ADC hardware driver is represented by a number of data structures. These are generic `device` and `channel` data structures, a driver private device data structure, a generic character device table entry and a driver function table. Most of these structures are instantiated using macros, which will be described here.

The data structure instantiation for a typical single device, four channel ADC would look like this:

```
//==========================================================================
// Instantiate data structures

// -------------------------------------------------------------------------
// Driver functions:

CYG_ADC_FUNCTIONS( example_adc_funs,
                   example_adc_enable,
                   example_adc_disable,
                   example_adc_set_rate );

// -------------------------------------------------------------------------
// Device instance:

static example_adc_info example_adc_info0 =
{
    .base               = CYGARC_HAL_EXAMPLE_ADC_BASE,
    .vector             = CYGNUM_HAL_INTERRUPT_ADC
};

CYG_ADC_DEVICE( example_adc_device,
                &example_adc_funs,
                &example_adc_info0,
                CYGNUM_IO_ADC_EXAMPLE_DEFAULT_RATE );

// -------------------------------------------------------------------------
// Channel instances:

#define EXAMPLE_ADC_CHANNEL( __chan )                                    \
CYG_ADC_CHANNEL( example_adc_channel##__chan,                            \
                 __chan,                                                 \
                 CYGNUM_IO_ADC_EXAMPLE_CHANNEL##__chan##_BUFSIZE,        \
                 &example_adc_device );                                  \
                                                                         \
DEVTAB_ENTRY( example_adc_channel##__chan##_device,                      \
              CYGDAT_IO_ADC_EXAMPLE_CHANNEL##__chan##_NAME,              \
              0,                                                         \
              &cyg_io_adc_devio,                                         \
              example_adc_init,                                          \
              example_adc_lookup,                                        \
              &example_adc_channel##__chan );

EXAMPLE_ADC_CHANNEL( 0 );
EXAMPLE_ADC_CHANNEL( 1 );
EXAMPLE_ADC_CHANNEL( 2 );
EXAMPLE_ADC_CHANNEL( 3 );
```

The macro `CYG_ADC_FUNCTIONS()` instantiates a function table called `example_adc_funs` and populates it with the ADC driver functions (see later for details).

Then an instance of the driver private device data structure is instantiated. In addition to the device base address and interrupt vector shown here, this structure should contain the interrupt object and handle for attaching to the vector. It may also contain any other variables needed to manage the device.

The macro `CYG_ADC_DEVICE()` instantiates a cyg_adc_device structure, named `example_adc_device` which will contain pointers to the function table and private data structure. The initial sample rate is also supplied here.

For each channel, an ADC channel structure and a device table entry must be created. The macro `EXAMPLE_ADC_CHANNEL()` is defined to simplify this process. The macro `CYG_ADC_CHANNEL` defines a cyg_adc_channel structure, which contains the channel number, the buffer size, and a pointer to the device object defined earlier. The call to `DEVTAB_ENTRY()` generates a device table entry containing the configured channel name, a pointer to a device function table defined in the generic ADC driver, pointers to init and lookup functions implemented here, and a pointer to the channel data structure just defined.

Finally, four channels, numbered 0 to 3 are created.

Functions

There are several classes of function that need to be defined in an ADC driver. These are those function that go into the channel's device table, those that go into the ADC device's function table, calls that the driver makes into the generic ADC package, and interrupt handling functions.

Device Table Functions

These functions are placed in the standard device table entry for each channel and handle initialization and location of the device within the generic driver infrastructure.

`static bool example_adc_init(struct cyg_devtab_entry *tab)` This function is called from the device IO infrastructure to initialize the device. It should perform any work needed to start up the device, short of actually starting the generation of samples. This function will be called for each channel, so if there is initialization that only needs to be done once, such as creating an interrupt object, then care should be taken to do this. This function should also call `cyg_adc_device_init()` to initialize the generic parts of the driver.

`static Cyg_ErrNo example_adc_lookup(struct cyg_devtab_entry **tab, struct cyg_devtab_entry *sub_tab, const char *name)` This function is called when a client looks up or opens a channel. It should call `cyg_adc_channel_init()` to initialize the generic part of the channel. It should also perform any operations needed to start the channel generating samples.

Driver Functions

These are the functions installed into the driver function table by the `CYG_ADC_FUNCTIONS()` macro.

`static void example_adc_enable( cyg_adc_channel *chan )` This function is called from the generic ADC package to enable the channel in response to a `CYG_IO_SET_CONFIG_ADC_ENABLE` config operation. It should take any steps needed to start the channel generating samples.

`static void example_adc_disable( cyg_adc_channel *chan )` This function is called from the generic ADC package to enable the channel in response to a `CYG_IO_SET_CONFIG_ADC_DISABLE` config operation. It should take any steps needed to stop the channel generating samples.

`static void example_adc_set_rate( cyg_adc_channel *chan, cyg_uint32 rate )` This function is called from the generic ADC package to enable the channel in response to a `CYG_IO_SET_CONFIG_ADC_RATE` config operation. It should take any steps needed to change the sample rate of the channel, or of the entire device.

Generic Package Functions

These functions are called by a hardware ADC device driver to perform operations in the generic ADC package.

`__externC void cyg_adc_device_init( cyg_adc_device *device )` This function is called from the driver's init function and is used to initialize the cyg_adc_device object.

`__externC void cyg_adc_channel_init(cyg_adc_channel *chan)` This function is called from the driver's lookup function and is used to initialize the cyg_adc_channel object.

`__externC cyg_uint32 cyg_adc_receive_sample(cyg_adc_channel *chan, cyg_adc_sample_t sample)` This function is called from the driver's ISR to add a new sample to the buffer. The return value will be either zero, or `CYG_ISR_CALL_DSR` and should be ORed with the return value of the ISR.

`__externC void cyg_adc_wakeup(cyg_adc_channel *chan )` This function is called from the driver's DSR to cause any threads waiting for data to wake up when a new sample is available. It should only be called if the *`wakeup`* field of the channel object is `true`.

Interrupt Functions

These functions are internal to the driver, but make calls on generic package functions. Typically an ADC device will have a single interrupt vector with which it signals available samples on the channels and any error conditions such as overruns.

`static cyg_uint32 example_adc_isr(cyg_vector_t vector, cyg_addrword_t data)` This function is the ISR attached to the ADC device's interrupt vector. It is responsible for reading samples from the channels and passing them on to the generic layer. It needs to check each channel for data, and call `cyg_adc_receive_sample()` for each new sample available, and then ready the device for the next interrupt. It's activities are best explained by example:

```
static cyg_uint32 example_adc_isr(cyg_vector_t vector, cyg_addrword_t data)
{
    cyg_adc_device *example_device = (cyg_adc_device *) data;
    example_adc_info *example_info = example_device->dev_priv;
    cyg_uint32 res = 0;
    int i;

    // Deal with errors if necessary
    DEVICE_CHECK_ERRORS( example_info );

    // Look for all channels with data available
    for( i = 0; i < CHANNEL_COUNT; i++ )
    {
        if( CHANNEL_SAMPLE_AVALIABLE(i) )
        {
            // Fetch data from this channel and pass up to higher
            // level.

            cyg_adc_sample_t data = CHANNEL_GET_SAMPLE(i);

            res |= CYG_ISR_HANDLED | cyg_adc_receive_sample( example_info->channel[i], data );
        }
    }

   // Clear any interrupt conditions
    DEVICE_CLEAR_INTERRUPTS( example_info );

    cyg_drv_interrupt_acknowledge(example_info->vector);

    return res;
}
```

`static void example_adc_dsr(cyg_vector_t vector, cyg_ucount32 count, cyg_addrword_t data)` This function is the DSR attached to the ADC device's interrupt vector. It is called by the kernel if the ISR return value contains the `CYG_ISR_HANDLED` bit. It needs to call `cyg_adc_wakeup()` for each channel that has its *`wakeup`* field set. Again, and example should make it all clear:

```
static void example_adc_dsr(cyg_vector_t vector, cyg_ucount32 count, cyg_addrword_t data)
{
    cyg_adc_device *example_device = (cyg_adc_device *) data;
    example_adc_info *example_info = example_device->dev_priv;
    int i;

    // Look for all channels with pending wakeups
    for( i = 0; i < CHANNEL_COUNT; i++ )
    {
        if( example_info->channel[i]->wakeup )
            cyg_adc_wakeup( example_info->channel[i] );
    }
}
```

Chapter 78. STM32 ADC Driver

Name

STM32 — ADC Driver

Description

This driver supports the ADC devices available in some variants of the ST STM32 family of microprocessors.

Sample Size

The STM32 ADC on F1 series devices produces 12-bit samples. The F2/F4/F7/L4 series devices can produce 12-, 10-, 8- or 6-bit samples and the H7 family can additionally produce 14- and 16-bit samples. The `CYGNUM_DEVS_ADC_CORTEXM_STM32_WIDTH` CDL configuration option allows the sample width to be set for suitable variants. The default is for 12-bit samples, which will cause the generic layer to define cyg_adc_sample_t as a 16-bit value.

Sample Rates

The ADC hardware is limited to a maximum of 2K samples per channel. Since up to 16 channels are sampled on a round-robin basis, this means that the total sample rate can be 16K samples per second.

Configuration

The option `CYGNUM_DEVS_ADC_CORTEXM_STM32_CLOCK_DIV` specifies the divider used to control the ADC system clock supplied by the RCC.

If system instrumentation is enabled then the `CYGIMP_DEVS_ADC_CORTEXM_STM32_INSTRUMENTATION` option is made available, and can be enabled to allow the ADC device driver to generate instrumentation. When enabed the sub-options `CYGDBG_DEVS_ADC_CORTEXM_STM32_INSTRUMENT_CONTROL` and `CYGDBG_DEVS_ADC_CORTEXM_STM32_INSTRUMENT_DMA` control which events are generated.

Each ADC device is controlled by a CDL component, `CYGHWR_DEVS_ADC_CORTEXM_STM32_ADCX` for each device *X*, which must be enabled to initialize the device. For STM32F1 devices only ADC devices 1 and 3 are available, since ADC2 shares GPIO lines and an interrupt with ADC1. For STM32F2/F4/F7/H7 devices ADC devices 1, 2 and 3 are available.

For STM32F2/F4/F7/L4/H7 devices the selection of the timer `TRGO` event to be used for the specific ADC device is controlled by a CDL component, `CYGHWR_DEVS_ADC_CORTEXM_STM32_ADC`*`X`*`_TIM` for each device *X*.

For STM32F2/F4/F7/L4/H7 devices the selection of the DMA stream interrupt to be used for the specific ADC device is controlled by a CDL component, `CYGHWR_DEVS_ADC_CORTEXM_STM32_ADCX_DMA` for each device *X*, which must be configured to avoid clashes with other peripherals that may share the same DMA stream.

The option `CYGNUM_DEVS_ADC_CORTEXM_STM32_ADCX_SAMPLE_TIME` defines the duration over which each sample is taken for each channel, in microseconds.

The option `CYGNUM_DEVS_ADC_CORTEXM_STM32_ADCX_DEFAULT_RATE` defines the default sample rate for all channels attached to device *X*.

The option `CYGNUM_DEVS_ADC_CORTEXM_STM32_ADCX_DMA_INT_PRI` defines the DMA interrupt prioirity for this device. The default of 0x80 sets it in the middle of the prioirity range.

For each channel *X* in ADC device *Y* the CDL script provides the following configuration options:

`cdl_component CYGHWR_DEVS_ADC_CORTEXM_STM32_ADCY_CHANNELX`

> If the application needs to access the on-chip ADC channel X via an eCos ADC driver then this option should be enabled.

`cdl_option CYGDAT_DEVS_ADC_CORTEXM_STM32_ADCT_CHANNELX_NAME`

This option controls the name that an eCos application should use to access this device via cyg_io_lookup(), open(), or similar calls.

`cdl_option CYGDAT_DEVS_ADC_CORTEXM_STM32_ADCY_CHANNELX_BUFSIZE`

This defines the size of the channel's sample buffer, in samples.

Chapter 79. STR7XX ADC Driver

Name

STR7XX — ADC Driver

Description

This driver supports the ADC devices available in some variants of the ST STR7XX family of microprocessors.

Sample Size

The STR7XX ADC produces 12 bit samples. Therefore this driver sets `CYGNUM_IO_ADC_SAMPLE_SIZE` to 12. This will cause the generic layer to define cyg_adc_sample_t as a 16 bit value.

Sample Rates

The ADC hardware is limited to a maximum of 1K samples per channel. Since channels are sampled on a round-robin basis at 4 times this rate, this means that the total sample rate is 4K samples per second.

The option `CYGNUM_DEVS_ADC_ARM_STR7XX_DEFAULT_RATE` defines a default sample rate and is initially set to 500.

Configuration

For each channel *X* supported the CDL script provides the following configuration options:

cdl_component CYGPKG_DEVS_ADC_ARM_STR7XX_CHANNELX

> This defines whether the channel is included.

cdl_option CYGDAT_DEVS_ADC_ARM_STR7XX_CHANNELN_NAME

> This defines the name of the channel.

cdl_option CYGNUM_DEVS_ADC_ARM_STR7XX_CHANNELX_BUFSIZE

> This defines the size of the channel's sample buffer, in samples.

Chapter 80. TSC ADC Driver

Name

TSC — ADC Driver

Description

This driver supports the Touch Screen Controller device available in some variants of the Freescale i.MXxx family of microprocessors.

In addition to the TSC device itself, this driver uses GPT1 to provide the data rate clock.

Sample Size

The TSC ADC produces 12 bit samples. Therefore this driver sets `CYGNUM_IO_ADC_SAMPLE_SIZE` to 12. This will cause the generic layer to define cyg_adc_sample_t as a 16 bit value.

Sample Rates

The ADC collects samples from the inputs sequentially. For the three inputs this driver currently supports (INAUX0, INAUX1 and INAUX2) it takes about 40us to collect all samples. Therefore the hardware is limited to a maximum rate of about 25KHz.

The option `CYGNUM_DEVS_ADC_ARM_TSC_DEFAULT_RATE` defines a default sample rate and is initially set to 500.

Configuration

For each channel *X* supported the CDL script provides the following configuration options:

cdl_component CYGPKG_DEVS_ADC_ARM_TSC_CHANNELX

> This defines whether the channel *N* is included.

cdl_option CYGDAT_DEVS_ADC_ARM_TSC_CHANNELN_NAME

> This defines the name of the channel *N*. By default the channels are named `"/dev/inauxN"`.

cdl_option CYGNUM_DEVS_ADC_ARM_TSC_CHANNELX_BUFSIZE

> This defines the size of the channel's sample buffer, in samples.

Chapter 81. Atmel AFEC (ADC) Driver

Name

Atmel — ADC Driver

Description

This driver supports the AFE (Analog Front-End) Controller available in some Atmel microprocessor variants, e.g. the SAM4E family.

Sample Size

The Atmel AFEC natively supports 12-bit samples, but via digital averaging 13-, 14-, 15- and 16-bit samples are supported. The controller also supports "low-resolution" 10-bit samples, but at the same sampling rate as the native 12-bit samples. When higher resolution, averaged, samples are used the maximum achievable sample rate will be lower than the native resolution. The per-controller `CYGNUM_DEVS_ADC_ATMEL_AFECx_RESOLUTION` configuration option specifies the sample resolution to be used.

This driver left-aligns results so that the full-range of the ADC I/O generic layer defined cyg_adc_sample_t type is used regardless of the resolution configured for this driver. The default generic layer `CYGNUM_IO_ADC_SAMPLE_SIZE` definition of 16 should be sufficient for most applications.

Configuration

If system instrumentation is enabled then the `CYGIMP_DEVS_ADC_ATMEL_AFEC_INSTRUMENTATION` option is made available, and can be enabled to allow the ADC device driver to generate instrumentation. When enabed the sub-options `CYGDBG_DEVS_ADC_ATMEL_AFEC_INSTRUMENT_CONTROL` and `CYGDBG_DEVS_ADC_ATMEL_AFEC_INSTRUMENT_DMA` control which events are generated.

Each ADC device is controlled by a CDL component, `CYGHWR_DEVS_ADC_ATMEL_AFECx` for each device *x*, which must be enabled to initialize the device. The number of channels available to a controller instance is defined by the relevant variant or platform HAL as required.

The option `CYGNUM_DEVS_ADC_ATMEL_AFECx_RESOLUTION` defines the internal sample size.

The option `CYGNUM_DEVS_ADC_ATMEL_AFECx_OFFSET` defines the channel offset compensation applied to all channels..

The option `CYGNUM_DEVS_ADC_ATMEL_AFECx_DEFAULT_RATE` defines the default samples-per-second rate for all channels attached to device *x*. This default can be over-ridden at run-time using the generic ADC I/O layer provided support as required.

For each channel *x* in an AFEC device *y* the CDL script provides the following configuration options:

`CYGHWR_DEVS_ADC_ATMEL_AFECy_CHANNELx`

> If the application needs to access the on-chip ADC channel *x* via an eCos ADC driver then this option should be enabled.

`CYGDAT_DEVS_ADC_ATMEL_AFECy_CHANNELx_NAME`

> This option controls the name that an eCos application should use to access this device via cyg_io_lookup(), open(), or similar calls. This allows meaningful names to be assigned if required, rather than the default "/dev/adc*yx*" style.

`CYGDAT_DEVS_ADC_ATMEL_AFECy_CHANNELx_INPUT`

> By default input channels are configured in single-ended mode, which is the normal acquisition mode. This option allows individual channels to be configured in `Differential` mode, where the input is generated against an adjacent "paired" channel.

`CYGDAT_DEVS_ADC_ATMEL_AFEC`*`y`*`_CHANNEL`*`x`*`_BUFSIZE`

This defines the size of the channel's sample buffer, in cyg_adc_sample_t samples.

Chapter 82. NXP i.MX RT ADC Driver

Name

NXP — ADC Driver

Description

This driver supports the ADC (Analog-to-Digital Converter) Controller of the NXP i.MX RT microprocessor variants, e.g. the i.MX RT105x family.

Sample Size

The i.MX ADC natively supports 12-bit samples. The controller also supports “low-resolution” 10-bit and 8-bit samples. When higher resolution, averaged, samples are used the maximum achievable sample rate will be lower than the native resolution. The per-controller `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_RESOLUTION` configuration option specifies the hardware sample resolution to be used.

This driver left-aligns results so that the full-range of the ADC I/O generic layer defined cyg_adc_sample_t type is used regardless of the resolution configured for this driver. The default generic layer `CYGNUM_IO_ADC_SAMPLE_SIZE` definition of 16 should be sufficient for most applications. However, it should be noted that the underlying cyg_adc_sample_t type is signed, whereas the returned data should be interpreted as an unsigned value (0..MAX) for this controller.

Configuration

Each ADC device is controlled by a CDL component, `CYGHWR_DEVS_ADC_NXP_IMX_ADCx` for each controller device *x*, which must be enabled to initialize the device. The number of channels is currently fixed to 16 for each controller instance, to support the external signals 0..15 as defined by the Processor Reference Manual.

The option `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_RESOLUTION` defines the internal hardware sample size.

The option `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_CLOCK` allows the selection of the conversion clock as either the internal asynchronous `ADACK` clock (default) or the system `IPG` clock. The Processor Reference Manual (PRM) ADC section should be consulted for the pro's and con's of the clock selection, frequency, averaging, etc.

The option `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_SPEED` allows the selection of whether the `Normal` (default) or `High-Speed` internal ADACK clock is used.

The option `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_SAMPLE_PERIOD` defines the sample period for a conversion as the number of ADC clock cycles.

The option `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_AVG` controls whether the hardware averaging is enabled. When enabled the option`CYGNUM_DEVS_ADC_NXP_IMX_ADCx_AVG_SAMPLES` specifies the number of samples that are averaged to provide a single reading.

The option `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_OFFSET` defines the channel offset compensation applied to all channels..

The option `CYGNUM_DEVS_ADC_NXP_IMX_ADCx_DEFAULT_RATE` defines the default samples-per-second rate for all channels attached to device *x*. This default can be over-ridden at run-time using the generic ADC I/O layer provided support as required.

If system instrumentation is enabled then the `CYGIMP_DEVS_ADC_NXP_IMC_ADC_INSTRUMENTATION` option is made available, and can be enabled to allow the ADC device driver to generate instrumentation. When enabed there are sub-options available to further control which events are recorded.

For each channel *x* in an ADC device *y* the CDL script provides the following configuration options:

`CYGHWR_DEVS_ADC_NXP_IMX_ADCy_CHANNELx`

> If the application needs to access the on-chip ADC channel *x* via an eCos ADC driver then this option should be enabled.

`CYGDAT_DEVS_ADC_NXP_IMX_ADCy_CHANNELx_NAME`

This option controls the name that an eCos application should use to access this device via cyg_io_lookup(), open(), or similar calls. This allows meaningful names to be assigned if required, rather than the default “/dev/adc*y*c*x*” style.

`CYGDAT_DEVS_ADC_NXP_IMX_ADCy_CHANNELx_BUFSIZE`

This defines the size of the channel's sample buffer, in multiples of cyg_adc_sample_t samples.

Part XXV. Pulse Width Modulation (PWM) Support

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 83. PWM Support

Name

Overview — eCos Support for PWM, the Inter IC Bus

Synopsis

#include <cyg/io/pwm.h>

```
cyg_pwm_device *cyg_pwm_find(char *name);

int cyg_pwm_set(cyg_pwm_device *device, cyg_uint32 channel, cyg_pwm_period period,
cyg_pwm_period width);

int cyg_pwm_get(cyg_pwm_device *device, cyg_uint32 channel, cyg_pwm_period *period,
cyg_pwm_period *width);

int cyg_pwm_polarity(cyg_pwm_device *device, cyg_uint32 channel, cyg_uint32 polarity);

int cyg_pwm_pin_enable(cyg_pwm_device *device, cyg_uint32 channel, cyg_uint32 pin);

int cyg_pwm_pin_disable(cyg_pwm_device *device, cyg_uint32 channel, cyg_uint32 pin);

int cyg_pwm_start(cyg_pwm_device *device, cyg_uint32 channel);

int cyg_pwm_stop(cyg_pwm_device *device, cyg_uint32 channel);
```

Description

This API provided access to very basic PWM (Pulse Width Modulation) functionality where supported by underlying hardware. The functionality simply allows one or more external pins to be programmed to generate a square wave of a fixed period with a fixed duty cycle. Features of more advanced PWM devices are not supported.

The model for PWM devices allows a single device to contain several independent channels which may be programmed separately. Each channel may have several output pins which may be enabled separately but which all generate the same signal programmed into the channel. Channels within a device, and pins within a channel are all numbered from zero.

The function `cyg_pwm_find()` looks for a PWM device by name and returns a pointer to it. The PWM device is typically defined in the platform HAL and may be given a platform specific name. Typical names may be `"pwm0"` or `"pwm1"`.

The function `cyg_pwm_set()` sets the square wave parameters for the selected channel. Both *`period`* and *`width`* are specified in nanoseconds. For example setting period to 100000 and width to 25000 sets up a square wave with a 100us (10KHz) period and a 25% duty cycle. The function `cyg_pwm_get()` returns the current settings.

The function `cyg_pwm_polarity()` sets the polarity of the signal. By default the width defines the high portion of the wave. Setting polarity to `CYG_PWM_POLARITY_INVERTED` means it defines the low part.

The function `cyg_pwm_pin_enable()` enables the selected channel output pin and `cyg_pwm_pin_disable()` disables it. While is is unusual, it is permitted to enable any number of channel pins.

The function `cyg_pwm_pin_start()` starts the PWM channel generating the square wave and `cyg_pwm_pin_stop()` stops it. The channel configuration functions may all be called before starting the channel, they may also be called after it started and will immediately affect it. If none are called before starting the channel then default values, defined in the platform HAL will be used. There is no need to stop a channel to reconfigure it, unless this is required by the application or attached hardware.

Part XXVI. Framebuffer Support

Table of Contents

Chapter 84. Framebuffer Support

Name

Overview — eCos Support for Framebuffer Devices

Description

Framebuffer devices are the most common way for a computer system to display graphical output to users. There are immense variations in the implementations of such devices. CYGPKG_IO_FRAMEBUF provides an abstraction layer for use by application code and other packages. It defines an API for manipulating framebuffers, mapping this API on to functionality provided by the appropriate device driver. It also defines the interface which such device drivers should implement. For simple hardware it provides default implementations of much of this interface, greatly reducing the effort needed to write a device driver.

This package does not constitute a graphics library. It does not implement functionality like drawing text or arbitrary lines, let alone any kind of windowing system. Instead it operates at the lower level of individual pixels and blocks of pixels, in addition to control operations such as hardware initialization. Some applications may use the framebuffer API directly. Others will instead use a higher-level graphics library, and it is that library which uses the framebuffer API.

It is assumed that users are already familiar with the fundamentals of computer graphics, and no attempt is made here to explain terms like display depth, palette or pixel.

Note

This package is work-in-progress. The support for 1bpp, 2bpp and 4bpp display depths is incomplete. For double-buffered displays the code does not yet maintain a bounding box of the updated parts of the display. The package has also been designed to allow for expansion with new functionality.

Configuration

CYGPKG_IO_FRAMEBUF only contains hardware-independent code. It should be complemented by one or more framebuffer device drivers appropriate for the target platform. These drivers may be specific to the platform, or they may be more generic with platform-specific details such as the framebuffer memory base address provided by the platform HAL. When creating a configuration for a given target the device driver(s) will always be included automatically (assuming one has been written or ported). However by default this driver will be inactive and will not get built, so does not add any unnecessary size overhead for applications which do not require graphics. To activate the device driver CYGPKG_IO_FRAMEBUF must be added explicitly to the configuration, for example using **ecosconfig add framebuf**. After this the full framebuffer API will be available to other packages and to application code.

This package contains very few configuration options. Instead it is left to device drivers or higher-level code to provide appropriate configurability. One option, CYGFUN_IO_FRAMEBUF_INSTALL_DEFAULT_PALETTE, relates to the initialization of paletted displays.

There are a number of calculated and inferred configuration options and a number of interfaces. These provide information such as whether or not there is a backlight. The most important one is CYGDAT_IO_FRAMEBUF_DEVICES, which holds a list of framebuffer identifiers for use with the macro-based API. If there is a single framebuffer device driver which supports one display in either landscape or portrait mode, the configuration option may hold a value like 240x320x8 320x240x8r90.

Application Programmer Interfaces

Framebuffer devices require a difficult choice between flexibility and performance. On the one hand the API should be able to support multiple devices driving separate displays, or a single device operating in different modes at different times. On the other hand graphics tends to involve very large amounts of I/O: even something as simple as drawing a background image can involve setting many thousands of pixels. Efficiency requires avoiding all possible overheads including function calls. Instead the API should make extensive use of macros or inline functions. Ideally details of the framebuffer device such as the stride would be known constants at compile-time, giving the compiler as much opportunity as possible to optimize the code. Clearly this is difficult if multiple framebuffer devices are in use or if the device mode may get changed at run-time.

To meet the conflicting requirements the generic framebuffer package provides two APIs: a fast macro API which requires selecting a single framebuffer device at compile or configure time; and a slower function API without this limitation. The two are very similar, for example:

```
#include <cyg/io/framebuf.h>

void
clear_screen(cyg_fb* fb, cyg_fb_colour colour)
{
    cyg_fb_fill_block(fb, 0, 0,
                      fb->fb_width, fb->fb_height,
                      colour);
}
```

or the equivalent macro version:

```
#include <cyg/io/framebuf.h>

#define FRAMEBUF 240x320x8

void
clear_screen(cyg_fb_colour colour)
{
    CYG_FB_FILL_BLOCK(FRAMEBUF, 0, 0,
                      CYG_FB_WIDTH(FRAMEBUF), CYG_FB_HEIGHT(FRAMEBUF),
                      colour);
}
```

The function-based API works in terms of cyg_fb structures, containing all the information needed to manipulate the device. Each framebuffer device driver will export one or more of these structures, for example `cyg_alaia_fb_240x320x8`, and the driver documentation should list the variable names. The macro API works in terms of identifiers such as `240x320x8`, and by a series of substitutions the main macro gets expanded to the appropriate device-specific code, usually inline. Again the device driver documentation should list the supported identifiers. In addition the configuration option `CYGDAT_IO_FRAMEBUF_DEVICES` will contain the full list. By convention the identifier will be specified by a `#define`'d symbol such as `FRAMEBUF`, or in the case of graphics libraries by a configuration option.

If a platform has multiple framebuffer devices connected to different displays then there will be separate cyg_fb structures and macro identifiers for each one. In addition some devices can operate in multiple modes. For example a PC VGA card can operate in a monochome 640x480 mode, an 8bpp 320x200 mode, and many other modes, but only one of these can be active at a time. The different modes are also represented by different cyg_fb structures and identifiers, effectively treating the modes as separate devices. It is the responsibility of higher-level code to ensure that only one mode is in use at a time.

It is possible to use the macro API with more than one device, basically by compiling the code twice with different values of `FRAMEBUF`, taking appropriate care to avoid identifier name clashes. This gives the higher performance of the macros at the cost of increased code size.

All of the framebuffer API, including exports of the device-specific cyg_fb structures, is available through a single header file `<cyg/io/framebuf.h>`. The API follows a number of conventions. Coordinates (0,0) correspond to the top-left corner of the display. All functions and macros which take a pair of coordinates have x first, y second. For block operations these coordinates are followed by width, then height. Coordinates and dimensions use cyg_ucount16 variables, which for any processor should be the most efficient unsigned data type with at least 16 bits - usually plain unsigned integers. Colours are identified by cyg_fb_colour variables, again usually unsigned integers.

To allow for the different variants of the English language, the API allows for a number of alternate spellings. Colour and color can be used interchangeably, so there are data types cyg_fb_colour and cyg_fb_color, and functions `cyg_fb_make_colour` and `cyg_fb_make_color`. Similarly gray is accepted as a variant of grey so the predefined colours `CYG_FB_DEFAULT_PALETTE_LIGHTGREY` and `CYG_FB_DEFAULT_PALETTE_LIGHTGRAY` are equivalent.

The API is split into the following categories:

parameters
getting information about a given framebuffer device such as width, height and depth. Colours management is complicated so has its own category.

control
operations such as switching the display on and off, and more device-specific ones such as manipulating the backlight.

colours
determining the colour format (monochrome, paletted, …), manipulating the palette, or constructing true colours.

drawing
primitives for manipulating pixels and blocks of pixels.

iteration
efficiently iterating over blocks of pixels.

Thread Safety

The framebuffer API never performs any locking so is not thread-safe. Instead it assumes that higher-level code such as a graphics library performs any locking that may be needed. Adding a mutex lock and unlock around every drawing primitive, including pixel writes, would be prohibitively expensive.

It is also assumed that the framebuffer will only be updated from thread context. With most hardware it will also be possible to access a framebuffer from DSR or ISR context, but this should be avoided in portable code.

Name

Parameters — determining framebuffer capabilities

Synopsis

#include <cyg/io/framebuf.h> typedef struct cyg_fb { cyg_ucount16 fb_depth; cyg_ucount16 fb_format; cyg_ucount16 fb_width; cyg_ucount16 fb_height; #ifdef CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_VIEWPORT cyg_ucount16 fb_viewport_width; cyg_ucount16 fb_viewport_height; #endif void* fb_base; cyg_ucount16 fb_stride; cyg_uint32 fb_flags0; … } cyg_fb;

`cyg_uint32` **`CYG_FB_FLAGS0`**`(`*`FRAMEBUF`*`);`

Description

When developing an application for a specific platform the various framebuffer parameters such as width and height are known, and the code can be written accordingly. However when writing code that should work on many platforms with different framebuffer devices, for example a graphics library, the code must be able to get these parameters and adapt.

Code using the function API can extract the parameters from the cyg_fb structures at run-time. The macro API provides dedicated macros for each parameter. These do not follow the usual eCos convention where the result is provided via an extra argument. Instead the result is returned as normal, and is guaranteed to be a compile-time constant. This allows code like the following:

```
#if CYG_FB_DEPTH(FRAMEBUF) < 8
    …
#else
    …
#endif
```

or alternatively:

```
    if (CYG_FB_DEPTH(FRAMEBUF) < 8) {
        …
    } else {
        …
    }
```

or:

```
    switch (CYG_FB_DEPTH(FRAMEBUF)) {
        case  1 : … break;
        case  2 : … break;
        case  4 : … break;
        case  8 : … break;
        case 16 : … break;
        case 32 : … break;
    }
```

In terms of the code actually generated by the compiler these approaches have much the same effect. The macros expand to a compile-time constant so unnecessary code can be easily eliminated.

The available parameters are as follows:

depth

The number of bits per pixel or bpp. The common depths are 1, 2, 4, 8, 16 and 32.

format

How the pixel values are mapped on to visible colours, for example true colour or paletted or greyscale.

width
height

The number of framebuffer pixels horizontally and vertically.

viewport width
viewport height

With some devices the framebuffer height and/or width are greater than what the display can actually show. The display is said to offer a viewport into the larger framebuffer. The number of visible pixels is determined from the viewport width and height. The position of the viewport is controlled via an `ioctl`. Within a cyg_fb structure these fields are only present if `CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_VIEWPORT` is defined, to avoid wasting data space on fields that are unnecessary for the current platform. For the macro API the viewport macros should only be used if `CYG_FB_FLAGS0_VIEWPORT` is set for the framebuffer:

```
#if (CYG_FB_FLAGS0(FRAMEBUF) & CYG_FB_FLAGS0_VIEWPORT)
    …
#endif
```

base
stride

For linear framebuffers these parameters provide the information needed to access framebuffer memory. The stride is in bytes.

flags0

This gives further information about the hardware capabilities. Some of this overlaps with other parameters, especially when it comes to colour, because it is often easier to test for a single flag than for a range of colour modes. The current flags are:

`CYG_FB_FLAGS0_LINEAR_FRAMEBUFFER`

Framebuffer memory is organized in a conventional fashion and can be accessed directly by higher-level code using the base and stride parameters.

`CYG_FB_FLAGS0_LE`

This flag is only relevant for 1bpp, 2bpp and 4bpp devices and controls how the pixels are organized within each byte. If the flag is set then the layout is little-endian: for a 1bpp device pixel (0,0) occupies bit 0 of the first byte of framebuffer memory. The more common layout is big-endian where pixel (0,0) occupies bit 7 of the first byte.

`CYG_FB_FLAGS0_TRUE_COLOUR`

The framebuffer uses a true colour format where the value of each pixel directly encodes the red, green and blue intensities. This is common for 16bpp and 32bpp devices, and is occasionally used for 8bpp devices.

`CYG_FB_FLAGS0_PALETTE`

The framebuffer uses a palette. A pixel value does not directly encode the colours, but instead acts as an index into a separate table of colour values. That table may be read-only or read-write. Paletted displays are common for 8bpp and some 4bpp displays.

`CYG_FB_FLAGS0_WRITEABLE_PALETTE`

The palette is read-write.

`CYG_FB_FLAGS0_DELAYED_PALETTE_UPDATE`

Palette updates can be synchronized to a vertical blank, in other words a brief time period when the display is not being updated, by using `CYG_FB_UPDATE_VERTICAL_RETRACE` as the last argument to `cyg_fb_write_palette` or `CYG_FB_WRITE_PALETTE`. With some hardware updating the palette in the middle of a screen update may result in visual noise.

`CYG_FB_FLAGS0_VIEWPORT`

The framebuffer contains more pixels than can be shown on the display. Instead the display provides a viewport into the framebuffer. An `ioctl` can be used to move the viewport.

`CYG_FB_FLAGS0_DOUBLE_BUFFER`

The display does not show the current contents of the framebuffer, so the results of drawing into the framebuffer are not immediately visible. Instead higher-level code needs to perform an explicit synch operation to update the display.

`CYG_FB_FLAGS0_PAGE_FLIPPING`

The hardware supports two or more pages, each of width*height pixels, only one of which is visible on the display. This allows higher-level code to update one page without disturbing what is currently visible. An `ioctl` is used to switch the visible page.

`CYG_FB_FLAGS0_BLANK`

The display can be blanked without affecting the framebuffer contents or settings.

`CYG_FB_FLAGS0_BACKLIGHT`

There is a backlight which can be switched on or off. Some hardware provides finer-grained control over the backlight intensity.

`CYG_FB_FLAGS0_MUST_BE_ON`

Often it is desirable to perform some initialization such as clearing the screen or setting the palette before the display is switched on, to avoid visual noise. However not all hardware allows this. If this flag is set then it is possible to access framebuffer memory and the palette before the `cyg_fb_on` or `CYG_FB_ON` operation. It may also be possible to perform some other operations such as activating the backlight, but that is implementation-defined.

To allow for future expansion there are also flags1, flags2, and flags3 fields. These may get used for encoding additional `ioctl` functionality, support for hardware acceleration, and similar features.

Linear Framebuffers

There are drawing primitives for writing and reading individual pixels. However these involve a certain amount of arithmetic each time to get from a position to an address within the frame buffer, plus function call overhead if the function API is used, and this will slow down graphics operations.

When the framebuffer device is known at compile-time and the macro API is used then there are additional macros specifically for iterating over parts of the frame buffer. These should prove very efficient for many graphics operations. However if the device is selected at run-time then the macros are not appropriate and code may want to manipulate framebuffer memory directly. This is possible if two conditions are satisfied:

1. The `CYG_FB_FLAGS0_LINEAR_FRAMEBUFFER` flag must be set. Otherwise framebuffer memory is either not directly accessible or has a non-linear layout.
2. The `CYG_FB_FLAGS0_DOUBLE_BUFFER` flag must be clear. An efficient double buffer synch operation requires knowing what part of the framebuffer have been updated, and the various drawing primitives will keep track of this. If higher-level code then starts manipulating the framebuffer directly the synch operation may perform only a partial update.

The base, stride, depth, width and height parameters, plus the `CYG_FB_FLAGS0_LE` flag for 1bpp, 2bpp and 4bpp devices, provide all the information needed to access framebuffer memory. A linear framebuffer has pixel (0,0) at the base address. Incrementing y means adding stride bytes to the pointer.

The base and stride parameters may be set even if `CYG_FB_FLAGS0_LINEAR_FRAMEBUFFER` is clear. This can be useful if for example the display is rotated in software from landscape to portrait mode. However the meaning of these parameters for non-linear framebuffers is implementation-defined.

Name

Control Operations — managing a framebuffer

Synopsis

#include <cyg/io/framebuf.h>

int **cyg_fb_on**(*fbdev*);

int **cyg_fb_off**(*fbdev*);

int **cyg_fb_ioctl**(*fbdev*, *key*, *data*, *len*);

int **CYG_FB_ON**(*FRAMEBUF*);

int **CYG_FB_OFF**(*FRAMEBUF*);

int **CYG_FB_IOCTL**(*FRAMEBUF*, *key*, *data*, *len*);

Description

The main operations on a framebuffer are drawing and colour management. However on most hardware it is also necessary to switch the display on before the user can see anything, and application code should be able to control when this happens. There are also miscellaneous operations such as manipulating the backlight or moving the viewpoint. These do not warrant dedicated functions, especially since the functionality will only be available on some hardware, so an ioctl interface is used.

Switching the Display On or Off

With most hardware nothing will be visible until there is a call to cyg_fb_on or an invocation of the CYG_FB_ON macro. This will initialize the framebuffer control circuitry, start sending the data signals to the display unit, and switch on the display if necessary. The exact initialization semantics are left to the framebuffer device driver. In some cases the hardware may already be partially or fully initialized by a static constructor or by boot code that ran before eCos.

There are some circumstances in which initialization can fail, and this is indicated by a POSIX error code such as ENODEV. An example would be plug and play hardware where the framebuffer device is not detected at run-time. Another example is hardware which can operate in several modes, with separate cyg_fb structures for each mode, if the hardware is already in use for a different mode. A return value of 0 indicates success.

Some but not all hardware allows the framebuffer memory and, if present, the palette to be manipulated before the device is switched on. That way the user does not see random noise on the screen during system startup. The flag CYG_FB_FLAGS0_MUST_BE_ON should be checked:

```
static void
init_screen(cyg_fb_colour background)
{
    int result;

#if (! (CYG_FB_FLAGS0(FRAMEBUF) & CYG_FB_FLAGS0_MUST_BE_ON))
    CYG_FB_FILL_BLOCK(FRAMEBUF, 0, 0,
                      CYG_FB_WIDTH(FRAMEBUF), CYG_FB_HEIGHT(FRAMEBUF),
                      background);
#endif

    result = CYG_FB_ON(FRAMEBUF);
    if (0 != result) {
        <handle unusual error condition>
    }
#if (CYG_FB_FLAGS0(FRAMEBUF) & CYG_FB_FLAGS0_MUST_BE_ON)
    CYG_FB_FILL_BLOCK(FRAMEBUF, 0, 0,
                      CYG_FB_WIDTH(FRAMEBUF), CYG_FB_HEIGHT(FRAMEBUF),
                      background);
#endif
}
```

Obviously if the application has already manipulated framebuffer memory or the palette but then the `cyg_fb_on` operation fails, the system is left in an undefined state.

It is also possible to switch a framebuffer device off, using the function `cyg_fb_off` or the macro `CYG_FB_OFF`, although this functionality is rarely used in embedded systems. The exact semantics of switching a device off are implementation-defined, but typically it involves shutting down the display, stopping the data signals to the display, and halting the control circuitry. The framebuffer memory and the palette are left in an undefined state, and application code should assume that both need full reinitializing when the device is switched back on. Some hardware may also provide a blank operation which typically just manipulates the display, not the whole framebuffer device. Normally `cyg_fb_on` returns 0. The API allows for a POSIX error code as with `cyg_fb_on`, but switching a device off is not an operation that is likely to fail.

If a framebuffer device can operate in several modes, represented by several cyg_fb structures and macro identifiers, then switching modes requires turning the current device off before turning the next one one.

Miscellaneous Control Operations

Some hardware functionality such as an LCD panel backlight is common but not universal. Supporting these does not warrant dedicated functions. Instead a catch-all `ioctl` interface is provided, with the arguments just passed straight to the device driver. This approach also allows for future expansion and for device-specific operations. `cyg_fb_ioctl` and `CYG_FB_IOCTL` take four arguments: a cyg_fb structure or framebuffer identifier; a key that specifies the operation to be performed; an arbitrary pointer, which should usually be a pointer to a data structure specific to the key; and a length field. Key values from 0 to 0x7fff are generic. Key values from 0x8000 onwards are reserved for the individual framebuffer device drivers, for device-specific functionality. The length field should be set to the size of the data structure, and may get updated by the device driver.

With most ioctl operations the device can indicate whether or not it supports the functionality by one of the flags, for example:

```
void
backlight_off(cyg_fb* fb)
{
    if (fb->fb_flags0 & CYG_FB_FLAGS0_BACKLIGHT) {
        cyg_fb_ioctl_backlight  new_setting;
        size_t                  len = sizeof(cyg_fb_ioctl_backlight);
        int                     result;

        new_setting.fbbl_current = 0;
        result = cyg_fb_ioctl(fb, CYG_FB_IOCTL_BACKLIGHT_SET,
                              &new_setting, &len);
        if (0 != result) {
            …
        }
    }
}
```

The operation returns zero for success or a POSIX error code on failure, for example `ENOSYS` if the device driver does not implement the requested functionality.

Viewport

```
# define CYG_FB_IOCTL_VIEWPORT_GET_POSITION     0x0100
# define CYG_FB_IOCTL_VIEWPORT_SET_POSITION     0x0101

typedef struct cyg_fb_ioctl_viewport {
    cyg_ucount16    fbvp_x;     // position of top-left corner of the viewport within
    cyg_ucount16    fbvp_y;     // the framebuffer
    cyg_ucount16    fbvp_when;  // set-only, now or vert retrace
} cyg_fb_ioctl_viewport;
```

On some targets the framebuffer device has a higher resolution than the display. Only a subset of the pixels, the viewport, is currently visible. Application code can exploit this functionality to achieve certain effects, for example smooth scrolling. Framebuffers which support this functionality will have the `CYG_FB_FLAGS0_VIEWPORT` flag set. The viewport dimensions are available as additional parameters to the normal framebuffer width and height.

The current position of the viewport can be obtained using an `CYG_FB_IOCTL_VIEWPORT_GET_POSITION` ioctl operation. The data argument should be a pointer to a cyg_fb_ioctl_viewport structure. On return the *`fbvp_x`* and *`fbvp_y`* fields will be filled in. To move the viewport use `CYG_FB_IOCTL_VIEWPORT_SET_POSITION` with *`fbvp_x`* and *`fbvp_y`* set to the top left corner of the new viewport within the framebuffer, and *`fbvp_when`* set to either `CYG_FB_UPDATE_NOW` or `CYG_FB_UPDATE_VERTICAL_RETRACE`. If the device driver cannot easily synchronize to a vertical retrace period then this last field is ignored.

```
void
move_viewport(cyg_fb* fb, int dx, int dy)
{
#ifdef CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_VIEWPORT
    cyg_fb_ioctl_viewport viewport;
    int len = sizeof(cyg_fb_ioctl_viewport);
    int result;

    result = cyg_fb_ioctl(fb, CYG_FB_IOCTL_VIEWPORT_GET_POSITION,
                          &viewport, &len);
    if (result != 0) {
        …
    }
    if (((int)viewport.fbvp_x + dx) < 0) {
        viewport.fbvp_x = 0;
    } else if ((viewport.fbvp_x + dx + fb->fb_viewport_width) > fb->fb_width) {
        viewport.fbvp_x = fb->fb_width - fb->fb_viewport_width;
    } else {
        viewport.fbvp_x += dx;
    }
    if (((int)viewport.fbvp_y + dy) < 0) {
        viewport.fbvp_y = 0;
    } else if ((viewport.fbvp_y + dy + fb->fb_viewport_height) > fb->fb_height) {
        viewport.fbvp_y = fb->fb_height - fb->fb_viewport_height;
    } else {
        viewport.fbvp_y += dy;
    }
    result = cyg_fb_ioctl(fb, CYG_FB_IOCTL_VIEWPORT_SET_POSITION,
                            &viewport, &len);
    if (result != 0) {
        …
    }
#else
    CYG_UNUSED_PARAM(cyg_fb*, fb);
    CYG_UNUSED_PARAM(int, dx);
    CYG_UNUSED_PARAM(int, dy);
#endif
}
```

If an attempt is made to move the viewport beyond the boundaries of the framebuffer then the resulting behaviour is undefined. Some hardware may behave reasonably, wrapping around as appropriate, but portable code cannot assume this. The above code fragment is careful to clip the viewport to the framebuffer dimensions.

Page Flipping

```
# define CYG_FB_IOCTL_PAGE_FLIPPING_GET_PAGES   0x0200
# define CYG_FB_IOCTL_PAGE_FLIPPING_SET_PAGES   0x0201
```

```
typedef struct cyg_fb_ioctl_page_flip {
    cyg_uint32      fbpf_number_pages;
    cyg_uint32      fbpf_visible_page;
    cyg_uint32      fbpf_drawable_page;
    cyg_ucount16    fbpf_when;  // set-only, now or vert retrace
} cyg_fb_ioctl_page_flip;
```

On some targets the framebuffer has enough memory for several pages, only one of which is visible at a time. This allows the application to draw into one page while displaying another. Once drawing is complete the display is flipped to the newly drawn page, and the previously displayed page is now available for updating. This technique is used for smooth animation, especially in games. The flag `CYG_FB_FLAGS0_PAGE_FLIPPING` indicates support for this functionality.

`CYG_FB_IOCTL_PAGE_FLIPPING_GET_PAGES` can be used to get the current settings of the page flipping support. The data argument should be a pointer to a cyg_fb_ioctl_page_flip structure. The resulting *`fbpf_number_pages`* field indicates the total number of pages available: 2 is common, but more pages are possible. *`fbpf_visible_page`* gives the page that is currently visible to the user, and will be between 0 and (*`fbpf_number_pages`* - 1). Similarly *`fbpf_drawable_page`* gives the page that is currently visible. It is implementation-defined whether or not the visible and drawable page can be the same one.

`CYG_FB_IOCTL_PAGE_FLIPPING_SET_PAGES` can be used to change the visible and drawable page. The *`fbpf_number_pages`* field is ignored. *`fbpf_visible_page`* and *`fbpf_drawable_page`* give the new settings. *`fbpf_when`* should be one of `CYG_FB_UPDATE_NOW` or `CYG_FB_UPDATE_VERTICAL_RETRACE`, but may be ignored by some device drivers.

```
#if !(CYG_FB_FLAGS0(FRAMEBUF) & CYG_FB_FLAGS0_PAGE_FLIPPING)
# error Current framebuffer device does not support page flipping
#endif

static cyg_uint32 current_visible = 0;

static void
page_flip_init(cyg_fb_colour background)
{
    cyg_fb_ioctl_page_flip flip;
    size_t len = sizeof(cyg_fb_ioctl_page_flip);

    flip.fbpf_visible_page  = current_visible;
    flip.fbpf_drawable_page = 1 - current_visible;
    flip.fbpf_when          = CYG_FB_UPDATE_NOW;
    CYG_FB_IOCTL(FRAMEBUF, CYG_FB_IOCTL_PAGE_FLIPPING_SET_PAGES,
                 &flip, &len);
    CYG_FB_FILL_BLOCK(FRAMEBUF, 0, 0,
                      CYG_FB_WIDTH(FRAMEBUF), CYG_FB_HEIGHT(FRAMEBUF),
                      background);
    flip.fbpf_visible_page  = 1 - current_visible;
    flip.fbpf_drawable_page = current_visible;
    CYG_FB_IOCTL(FRAMEBUF, CYG_FB_IOCTL_PAGE_FLIPPING_SET_PAGES,
                 &flip, &len);
    CYG_FB_FILL_BLOCK(FRAMEBUF, 0, 0,
                      CYG_FB_WIDTH(FRAMEBUF), CYG_FB_HEIGHT(FRAMEBUF),
                      background);
    current_visible = 1 - current_visible;
}

static void
page_flip_toggle(void)
{
    cyg_fb_ioctl_page_flip flip;
    size_t len = sizeof(cyg_fb_ioctl_page_flip);

    flip.fbpf_visible_page  = 1 - current_visible;
    flip.fbpf_drawable_page = current_visible;
    CYG_FB_IOCTL(FRAMEBUF, CYG_FB_IOCTL_PAGE_FLIPPING_SET_PAGES,
                 &flip, &len);
    current_visible = 1 - current_visible;
}
```

A page flip typically just changes a couple of pointers within the hardware and device driver. No attempt is made to synchronize the contents of the pages, that is left to higher-level code.

Blanking the Screen

```
# define CYG_FB_IOCTL_BLANK_GET                   0x0300
# define CYG_FB_IOCTL_BLANK_SET                   0x0301

typedef struct cyg_fb_ioctl_blank {
    cyg_bool        fbbl_on;
} cyg_fb_ioctl_blank;
```

Some hardware allows the display to be switched off or blanked without shutting down the entire framebuffer device, greatly reducing power consumption. The current blanking state can be obtained using `CYG_FB_IOCTL_BLANK_GET` and the state can be updated using `CYG_FB_IOCTL_BLANK_SET`. The data argument should be a pointer to a cyg_fb_ioctl_blank structure. Support for this functionality is indicated by the `CYG_FB_FLAGS0_BLANK` flag.

```
static cyg_bool
display_blanked(cyg_fb_* fb)
{
    cyg_fb_ioctl_blank blank;
    size_t len = sizeof(cyg_fb_ioctl_blank);

    if (! (fb->fb_flags0 & CYG_FB_FLAGS0_BLANK)) {
        return false;
    }
    (void) cyg_fb_ioctl(fb, CYG_FB_IOCTL_BLANK_GET, &blank, &len);
    return !blank.fbbl_on;
}
```

Controlling the Backlight

```
# define CYG_FB_IOCTL_BACKLIGHT_GET               0x0400
# define CYG_FB_IOCTL_BACKLIGHT_SET               0x0401

typedef struct cyg_fb_ioctl_backlight {
    cyg_ucount32    fbbl_current;
    cyg_ucount32    fbbl_max;
} cyg_fb_ioctl_backlight;
```

Many LCD panels provide some sort of backlight, making the display easier to read at the cost of increased power consumption. Support for this is indicated by the `CYG_FB_FLAGS0_BACKLIGHT` flag. `CYG_FB_IOCTL_BACKLIGHT_GET` can be used to get both the current setting and the maximum value. If the maximum is 1 then the backlight can only be switched on or off. Otherwise it is possible to control the intensity.

```
static void
set_backlight_50_percent(void)
{
#if (CYG_FB_FLAGS0(FRAMEBUF) & CYG_FB_FLAGS0_BACKLIGHT)
    cyg_fb_ioctl_backlight backlight;
    size_t len = sizeof(cyg_fb_ioctl_backlight);

    CYG_FB_IOCTL(FRAMEBUF, CYG_FB_IOCTL_BACKLIGHT_GET, &backlight, &len);
    backlight.fbbl_current = (backlight.fbbl_max + 1) >> 1;
    CYG_FB_IOCTL(FRAMEBUF, CYG_FB_IOCTL_BACKLIGHT_SET, &backlight, &len);
#endif
}
```

Description

Managing colours can be one of the most difficult aspects of writing graphics code, especially if that code is intended to be portable to many different platforms. Displays can vary from 1bpp monochrome, via 2bpp and 4bpp greyscale, through 4bpp and 8bpp paletted, and up to 16bpp and 32bpp true colour - and those are just the more common scenarios. The various drawing primitives like `cyg_fb_write_pixel` work in terms of cyg_fb_colour values, usually an unsigned integer. Exactly how the hardware interprets a cyg_fb_colour depends on the format.

Colour Formats

There are a number of ways of finding out how these values will be interpreted by the hardware:

1. The `CYG_FB_FLAGS0_TRUE_COLOUR` flag is set for all true colour displays. The format parameter can be examined for more details but this is not usually necessary. Instead code can use `cyg_fb_make_colour` or `CYG_FB_MAKE_COLOUR` to construct a cyg_fb_colour value from red, green and blue components.

2. If the `CYG_FB_FLAGS0_WRITEABLE_PALETTE` flag is set then a cyg_fb_colour value is an index into a lookup table known as the palette, and this table contains red, green and blue components. The size of the palette is determined by the display depth, so 16 entries for a 4bpp display and 256 entries for an 8bpp display. Application code or a graphics library can install its own palette so can control exactly what colour each cyg_fb_colour value corresponds to. Alternatively there is support for installing a default palette.

3. If `CYG_FB_FLAGS0_PALETTE` is set but `CYG_FB_FLAGS0_WRITEABLE_PALETTE` is clear then the hardware uses a fixed palette. There is no easy way for portable software to handle this case. The palette can be read at run-time, allowing the application's desired colours to be mapped to whichever palette entry provides the best match. However normally it will be necessary to write code specifically for the fixed palette.

4. Otherwise the display is monochrome or greyscale, depending on the depth. There are still variations, for example on a monochrome display colour 0 can be either white or black.

As an alternative or to provide additional information, the exact colour format is provided by the *`fb_format`* field of the cyg_fb structure or by the `CYG_FB_FORMAT` macro. It can be one of the following (more entries may be added in future):

`CYG_FB_FORMAT_1BPP_MONO_0_BLACK`

simple 1bpp monochrome display, with 0 as black or the darker of the two colours, and 1 as white or the ligher colour.

`CYG_FB_FORMAT_1BPP_MONO_0_WHITE`

simple 1bpp monochrome display, with 0 as white or the lighter of the two colours, and 1 as black or the darker colour.

`CYG_FB_FORMAT_1BPP_PAL888`

a 1bpp display which cannot easily be described as monochrome. This is unusual and not readily supported by portable code. It can happen if the framebuffer normally runs at a higher depth, for example 4bpp or 8bpp paletted, but is run at only 1bpp to save memory. Hence only two of the palette entries are used, but can be set to arbitrary colours. The palette may be read-only or read-write.

`CYG_FB_FORMAT_2BPP_GREYSCALE_0_BLACK`

a 2bpp display offering four shades of grey, with 0 as black or the darkest of the four shades, and 3 as white or the lightest.

`CYG_FB_FORMAT_2BPP_GREYSCALE_0_WHITE`

a 2bpp display offering four shades of grey, with 0 as white or the lightest of the four shades, and 3 as black or the darkest.

`CYG_FB_FORMAT_2BPP_PAL888`

a 2bpp display which cannot easily be described as greyscale, for example providing black, red, blue and white as the four colours. This is unusual and not readily supported by portable code. It can happen if the framebuffer normally runs at a higher depth, for example 4bpp or 8bpp paletted, but is run at only 2bpp to save memory. Hence only four of the palette entries are used, but can be set to arbitrary colours. The palette may be read-only or read-write.

`CYG_FB_FORMAT_4BPP_GREYSCALE_0_BLACK`

a 4bpp display offering sixteen shades of grey, with 0 as black or the darkest of the 16 shades, and 15 as white or the lighest.

`CYG_FB_FORMAT_4BPP_GREYSCALE_0_WHITE`

a 4bpp display offering sixteen shades of grey, with 0 as white or the lightest of the 16 shades, and 15 as black or the darkest.

`CYG_FB_FORMAT_4BPP_PAL888`

a 4bpp paletted display, allowing for 16 different colours on screen at the same time. The palette may be read-only or read-write.

`CYG_FB_FORMAT_8BPP_PAL888`

an 8bpp paletted display, allowing for 256 different colours on screen at the same time. The palette may be read-only or read-write.

`CYG_FB_FORMAT_8BPP_TRUE_332`

an 8bpp true colour display, with three bits (eight levels) of red and green intensity and two bits (four levels) of blue intensity.

`CYG_FB_FORMAT_16BPP_TRUE_565`

a 16bpp true colour display with 5 bits each for red and blue and 6 bits for green.

`CYG_FB_FORMAT_16BPP_TRUE_555`

a 16bpp true colour display with five bits each for red, green and blue, and one unused bit.

`CYG_FB_FORMAT_32BPP_TRUE_0888`

a 32bpp true colour display with eight bits each for red, green and blue and eight bits unused.

For the true colour formats the format does not define exactly which bits in the pixel are used for which colour. Instead the `cyg_fb_make_colour` and `cyg_fb_break_colour` functions or the equivalent macros should be used to construct or decompose pixel values.

Paletted Displays

Palettes are the common way of implementing low-end colour displays. There are two variants. A read-only palette provides a fixed set of colours and it is up to application code to use these colours appropriately. A read-write palette allows the application to select its own set of colours. Displays providing a read-write palette will have the `CYG_FB_FLAGS0_WRITEABLE_PALETTE` flag set in addition to `CYG_FB_FLAGS0_PALETTE`.

Even if application code can install its own palette, many applications do not exploit this functionality and instead stick with a default. There are two standard palettes: the 16-entry PC EGA for 4bpp displays; and the 256-entry PC VGA, a superset of the EGA one, for 8bpp displays. This package provides the data for both, in the form of arrays `cyg_fb_palette_ega` and `cyg_fb_palette_vga`, and 16 `#define`'s such as `CYG_FB_DEFAULT_PALETTE_BLACK` for the EGA colours and the first 16 VGA colours. By default device drivers for read-write paletted displays will install the appropriate default palette, but this can be suppressed using configuration option `CYGFUN_IO_FRAMEBUF_INSTALL_DEFAULT_PALETTE`. If a custom palette will be used then installing the default palette involves wasting 48 or 768 bytes of memory.

It should be emphasized that displays vary widely. A colour such as `CYG_FB_DEFAULT_PALETTE_YELLOW` may appear rather differently on two different displays, although it should always be recognizable as yellow. Developers may wish to fine-tune the palette for specific hardware.

The current palette can be retrieved using `cyg_fb_read_palette` or `CYG_FB_READ_PALETTE`. The *`first`* and *`count`* arguments control which palette entries should be retrieved. For example, to retrieve just palette entry 12 *`first`* should be set to 12 and *`count`* should be set to 1. To retrieve all 256 entries for an 8bpp display, *`first`* should be set to 0 and *`count`* should be set to 256. The *`data`* argument should point at an array of bytes, allowing three bytes for every entry. Byte 0 will contain the red intensity for the first entry, byte 1 green and byte 2 blue.

For read-write palettes the palette can be updated using `cyg_fb_write_palette` or `CYG_FB_WRITE_PALETTE`. The *`first`* and *`count`* arguments are the same as for `cyg_fb_read_palette`, and the *`data`* argument should point at a suitable byte array packed in the same way. The *`when`* argument should be one of `CYG_FB_UPDATE_NOW` or `CYG_FB_UPDATE_VERTICAL_RETRACE`. With some displays updating the palette in the middle of an update may result in visual noise, so synchronizing to the vertical retrace avoids this. However not all device drivers will support this.

There is an assumption that palette entries use 8 bits for each of the red, green and blue colour intensities. This is not always the case, but the device drivers will perform appropriate adjustments. Some hardware may use only 6 bits per colour, and the device driver will ignore the bottom two bits of the supplied intensity values. Occasionally hardware may use more than 8 bits, in which case the supplied 8 bits are shifted left appropriately and zero-padded. Device drivers for such hardware may also provide device-specific routines to manipulate the palette in a non-portable fashion.

True Colour displays

True colour displays are often easier to manage than paletted displays. However this comes at the cost of extra memory. A 16bpp true colour display requires twice as much memory as an 8bpp paletted display, yet can offer only 32 or 64 levels of intensity for each colour as opposed to the 256 levels provided by a palette. It also requires twice as much video memory bandwidth to send all the pixel data to the display for every refresh, which may impact the performance of the rest of the system. A 32bpp true colour display offers the same colour intensities but requires four times the memory and four times the bandwidth.

Exactly how the colour bits are organized in a cyg_fb_colour pixel value is not defined by the colour format. Instead code should use the `cyg_fb_make_colour` or `CYG_FB_MAKE_COLOUR` primitives. These take 8-bit intensity levels for red, green and blue, and return the corresponding cyg_fb_colour. When using the macro interface the arithmetic happens at compile-time, for example:

```
#define BLACK        CYG_FB_MAKE_COLOUR(FRAMEBUF,   0,   0,   0)
#define WHITE        CYG_FB_MAKE_COLOUR(FRAMEBUF, 255, 255, 255)
#define RED          CYG_FB_MAKE_COLOUR(FRAMEBUF, 255,   0,   0)
#define GREEN        CYG_FB_MAKE_COLOUR(FRAMEBUF,   0, 255,   0)
#define BLUE         CYG_FB_MAKE_COLOUR(FRAMEBUF,   0,   0, 255)
#define YELLOW       CYG_FB_MAKE_COLOUR(FRAMEBUF, 255, 255,  80)
```

Displays vary widely so the numbers may need to be adjusted to give the exact desired colours.

For symmetry there are also `cyg_fb_break_colour` and `CYG_FB_BREAK_COLOUR` primitives. These take a cyg_fb_colour value and decompose it into its red, green and blue components.

Description

The eCos framebuffer infrastructure defines a small number of drawing primitives. These are not intended to provide full graphical functionality like multiple windows, drawing text in arbitrary fonts, or anything like that. Instead they provide building blocks for higher-level graphical toolkits. The available primitives are:

1. Manipulating individual pixels.
2. Drawing horizontal and vertical lines.
3. Block fills.
4. Moving blocks between the framebuffer and main memory.

5. Moving blocks within the framebuffer.

6. For double-buffered devices, synchronizing the framebuffer contents with the actual display.

There are two versions for each primitive: a macro and a function. The macro can be used if the desired framebuffer device is known at compile-time. Its first argument should be a framebuffer identifier, for example `320x240x16`, and must be one of the entries in the configuration option `CYGDAT_IO_FRAMEBUF_DEVICES`. In the examples below it is assumed that `FRAMEBUF` has been `#define`'d to a suitable identifier. The function can be used if the desired framebuffer device is selected at run-time. Its first argument should be a pointer to the appropriate cyg_fb structure.

The pixel, line, and block fill primitives take a cyg_fb_colour argument. For details of colour handling see Framebuffer Colours. This argument should have no more bits set than are appropriate for the display depth. For example on a 4bpp only the bottom four bits of the colour may be set, otherwise the behaviour is undefined.

None of the primitives will perform any run-time error checking, except possibly for some assertions in a debug build. If higher-level code provides invalid arguments, for example trying to write a block which extends past the right hand side of the screen, then the system's behaviour is undefined. It is the responsibility of higher-level code to perform clipping to the screen boundaries.

Manipulating Individual Pixels

The primitives for manipulating individual pixels are very simple: a pixel can be written or read back. The following example shows one way of drawing a diagonal line:

```
void
draw_diagonal(cyg_fb* fb,
              cyg_ucount16 x, cyg_ucount16 y, cyg_ucount16 len,
              cyg_fb_colour colour)
{
    while ( len-- ) {
        cyg_fb_write_pixel(fb, x++, y++, colour);
    }
}
```

The next example shows how to draw a horizontal XOR line on a 1bpp display.

```
void
draw_horz_xor(cyg_ucount16 x, cyg_ucount16 y, cyg_ucount16 len)
{
    cyg_fb_colour colour;
    while ( len--) {
        colour = CYG_FB_READ_PIXEL(FRAMEBUF, x, y);
        CYG_FB_WRITE_PIXEL(FRAMEBUF, x++, y, colour ^ 0x01);
    }
}
```

The pixel macros should normally be avoided. Determining the correct location within framebuffer memory corresponding to a set of coordinates for each pixel is a comparatively expensive operation. Instead there is direct support for iterating over parts of the display, avoiding unnecessary overheads.

Drawing Simple Lines

Higher-level graphics code often needs to draw single-pixel horizontal and vertical lines. If the application involves multiple windows then these will usually have thin borders around them. Widgets such as buttons and scrollbars also often have thin borders.

`cyg_fb_draw_hline` and `CYG_FB_DRAW_HLINE` draw a horizontal line of the specified *`colour`*, starting at the *`x`* and *`y`* coordinates and extending to the right (increasing x) for a total of *`len`* pixels. A 50 pixel line starting at (100,100) will end at (149,100).

`cyg_fb_draw_vline` and `CYG_FB_DRAW_VLINE` take the same arguments, but the line extends down (increasing y).

These primitives do not directly support drawing lines more than one pixel thick, but block fills can be used to achieve those. There is no generic support for drawing arbitrary lines, instead that is left to higher-level graphics toolkits.

Block Fills

Filling a rectangular part of the screen with a solid colour is another common requirement for higher-level code. The simplest example is during initialization, to set the display's whole background to a known value. Block fills are also often used when creating new windows or drawing the bulk of a simple button or scrollbar widget. `cyg_fb_fill_block` and `CYG_FB_FILL_BLOCK` provide this functionality.

The *`x`* and *`y`* arguments specify the top-left corner of the block to be filled. The *`width`* and *`height`* arguments specify the number of pixels affected, a total of `width * height`. The following example illustrates part of the process for initializing a framebuffer, assumed here to have a writeable palette with default settings.

```
int
display_init(void)
{
    int result = CYG_FB_ON(FRAMEBUF);
    if ( result ) {
        return result;
    }
    CYG_FB_FILL_BLOCK(FRAMEBUF, 0, 0,
                      CYG_FB_WIDTH(FRAMEBUF), CYG_FB_HEIGHT(FRAMEBUF),
                      CYG_FB_DEFAULT_PALETTE_WHITE);
    …
}
```

Copying Blocks between the Framebuffer and Main Memory

The block transfer primitives serve two main purposes: drawing images. and saving parts of the current display to be restored later. For simple linear framebuffers the primitives just implement copy operations, with no data conversion of any sort. For non-linear ones the primitives act as if the framebuffer memory was linear. For example, consider a 2bpp display where the two bits for a single pixel are split over two separate bytes in framebuffer memory, or two planes. For a block write operation the source data should still be organized with four full pixels per byte, as for a linear framebuffer of the same depth. and the block write primitive will distribute the bits over the framebuffer memory as required. Similarly a block read will combine the appropriate bits from different locations in framebuffer memory and the resulting memory block will have four full pixels per byte.

Because the block transfer primitives perform no data conversion, if they are to be used for rendering images then those images should be pre-formatted appropriately for the framebuffer device. For small images this would normally happen on the host-side as part of the application build process. For larger images it will usually be better to store them in a compressed format and decompress them at run-time, trading off memory for cpu cycles.

The *`x`* and *`y`* arguments specify the top-left corner of the block to be transferred, and the *`width`* and *`height`* arguments determine the size. The *`data`*, *`offset`* and *`stride`* arguments determine the location and layout of the block in main memory:

`data`

The source or destination for the transfer. For 1bpp, 2bpp and 4bpp devices the data will be packed in accordance with the framebuffer device's endianness as per the `CYG_FB_FLAGS0_LE` flag. Each row starts in a new byte so there may be some padding on the right. For 16bpp and 32bpp the data should be aligned to the appropriate boundary.

`offset`

Sometimes only part of an image should be written to the screen. A vertical offset can be achieved simply by adjusting *`data`* to point at the appropriate row within the image instead of the top row. For 8bpp, 16bpp and 32bpp displays an additional horizontal offset can also be achieved by adjusting *`data`*. However for 1bpp, 2bpp and 4bpp displays the starting position within the image may be in the middle of a byte. Hence the horizontal pixel offset can instead be specified with the *`offset`* argument.

stride This indicates the number of bytes between rows. Usually it will be related to the *width*, but there are exceptions such as when drawing only part of an image.

The following example fills a 4bpp display with an image held in memory and already in the right format. If the image is smaller than the display it will be centered. If the image is larger then the center portion will fill the entire display.

```
void
draw_image(const void* data, int width, int height)
{
    cyg_ucount16 stride;
    cyg_ucount16 x, y, offset;

#if (4 != CYG_FB_DEPTH(FRAMEBUF))
# error This code assumes a 4bpp display
#endif

    stride = (width + 1) >> 1;  // 4bpp to byte stride

    if (width < CYG_FB_WIDTH(FRAMEBUF)) {
        x      = (CYG_FB_WIDTH(FRAMEBUF) - width) >> 1;
        offset = 0;
    } else {
        x      = 0;
        offset = (width - CYG_FB_WIDTH(FRAMEBUF)) >> 1;
        width  = CYG_FB_WIDTH(FRAMEBUF);
    }
    if (height < CYG_FB_HEIGHT(FRAMEBUF)) {
        y      = (CYG_FB_HEIGHT(FRAMEBUF) - height) >> 1;
    } else {
        y      = 0;
        data   = (const void*)((const cyg_uint8*)data +
                 (stride * ((height - CYG_FB_HEIGHT(FRAMEBUF)) >> 1));
        height = CYG_FB_HEIGHT(FRAMEBUF);
    }
    CYG_FB_WRITE_BLOCK(FRAMEBUF, x, y, width, height, data, offset, stride);
}
```

Moving Blocks with the Framebuffer

Sometimes it is necessary to move a block of data around the screen, especially when using a higher-level graphics toolkit that supports multiple windows. Block moves can be implemented by a read into main memory followed by a write block, but this is expensive and imposes an additional memory requirement. Instead the framebuffer infrastructure provides a generic block move primitive. It will handle all cases where the source and destination positions overlap. The *x* and *y* arguments specify the top-left corner of the block to be moved, and *width* and *height* determine the block size. *new_x* and *new_y* specify the destination. The source data will remain unchanged except in areas where it overlaps the destination.

Synchronizing Double-Buffered Displays

Some framebuffer devices are double-buffered: the framebuffer memory that gets manipulated by the drawing primitives is separate from what is actually displayed, and a synch operation is needed to update the display. In some cases this may be because the actual display memory is not directly accessible by the processor, for example it may instead be attached via an SPI bus. Instead drawing happens in a buffer in main memory, and then this gets transferred over the SPI bus to the actual display hardware during a synch. In other cases it may be a software artefact. Some drawing operations, especially ones involving complex curves, can take a very long time and it may be considered undesirable to have the user see this happening a few pixels at a time. Instead the drawing happens in a separate buffer in main memory and then a double buffer synch just involves a block move to framebuffer memory. Typically that block move is much faster than the drawing operation. Obviously there is a cost: an extra area of memory, and the synch operation itself can consume many cycles and much of the available memory bandwidth.

It is the responsibility of the framebuffer device driver to provide the extra main memory. As far as higher-level code is concerned the only difference between an ordinary and a double-buffered display is that with the latter changes do not become visible until a synch operation has been performed. The framebuffer infrastructure provides support for a bounding box, keeping track of what has been updated since the last synch. This means only the updated part of the screen has to be transferred to the display hardware.

The synch primitives take two arguments. The first identifies the framebuffer device. The second should be one of `CYG_FB_UPDATE_NOW` for an immediate update, or `CYG_FB_UPDATE_VERTICAL_RETRACE`. Some display hardware involves a lengthy vertical retrace period every 10-20 milliseconds during which nothing gets drawn to the screen, and performing the synch during this time means that the end user is unaware of the operation (assuming the synch can be completed in the time available). When the hardware supports it, specifying `CYG_FB_UPDATE_VERTICAL_RETRACE` means that the synch operation will block until the next vertical retrace takes place and then perform the update. This may be an expensive operation, for example it may involve polling a bit in a register. In a multi-threaded environment it may also be unreliable because the thread performing the synch may get interrupted or rescheduled in the middle of the operation. When the hardware does not involve vertical retraces, or when there is no easy way to detect them, the second argument to the synch operation will just be ignored and the update will always happen immediately.

It is up to higher level code to determine when a synch operation is appropriate. One approach for typical event-driven code is to perform the synch at the start of the event loop, just before waiting for an input or timer event. This may not be optimal. For example if there two small updates to opposite corners of the screen then it would be better to make two synch calls with small bounding boxes, rather than a single synch call with a a large bounding box that requires most of the framebuffer memory to be updated.

Leaving out the synch operations leads to portability problems. On hardware which does not involve double-buffering the synch operation is a no-op, usually eliminated at compile-time, so invoking synch does not add any code size or cpu cycle overhead. On double-buffered hardware, leaving out the synch means the user cannot see what has been drawn into the framebuffer.

Name

Pixel Manipulation — iterating over the display

Synopsis

#include <cyg/io/framebuf.h>

void **CYG_FB_PIXEL0_SET**(*FRAMEBUF*, *x*, *y*);

void **CYG_FB_PIXEL0_GET**(*FRAMEBUF*, *x*, *y*);

void **CYG_FB_PIXEL0_ADDX**(*FRAMEBUF*, *incr*);

void **CYG_FB_PIXEL0_ADDY**(*FRAMEBUF*, *incr*);

void **CYG_FB_PIXEL0_WRITE**(*FRAMEBUF*, *colour*);

cyg_fb_colour **CYG_FB_PIXEL0_READ**(*FRAMEBUF*);

void **CYG_FB_PIXEL0_FLUSHABS**(*FRAMEBUF*, *x0*, *y0*, *width*, *height*);

void **CYG_FB_PIXEL0_FLUSHREL**(*FRAMEBUF*, *x0*, *y0*, *dx*, *dy*);

Description

A common requirement for graphics code is to iterate over parts of the framebuffer. Drawing text typically involves iterating over a block of pixels for each character, say 8 by 8, setting each pixel to either a foreground or background colour. Drawing arbitrary lines typically involves moving to the start position and then adjusting the x and y coordinates until the end position is reached, setting a single pixel each time around the loop. Drawing images which are not in the frame buffer's native format typically involves iterating over a block of pixels, from top to bottom and left to right, setting pixels as the image is decoded.

Functionality like this can be implemented in several ways. One approach is to use the pixel write primitive. Typically this involves some arithmetic to get from the x and y coordinates to a location within framebuffer memory so it is fairly expensive compared with a loop which just increments a pointer. Another approach is to write the data first to a separate buffer in memory and then use a block write primitive to move it to the framebuffer, but again this involves overhead. The eCos framebuffer support provides a third approach: a set of macros specifically for iterating over the frame buffer. Depending on the operation being performed and the details of the framebuffer implementation, these macros may be optimal or near-optimal. Obviously there are limitations. Most importantly the framebuffer device must be known at compile-time: the compiler can do a better job optimizing the code if information such as the frame buffer width are constant. Also each iteration must be performed within a single variable scope: it is not possible to do some of the iteration in one function, some in another.

The Pixel Macros

All the pixel macros take a framebuffer identifier as their first argument. This is the same identifier that can be used with the other macros like `CYG_FB_WRITE_HLINE` and `CYG_FB_ON`, one of the entries in the configuration option `CYGDAT_IO_FRAMEBUF_DEVICES`. Using an invalid identifier will result in numerous compile-time error messages which may bear little resemblance to the original code. In the examples below it is assumed that `FRAMEBUF` has been `#define`'d to a suitable identifier.

Typical use of the pixel macros will look like this:

```
    CYG_FB_PIXEL0_VAR(FRAMEBUF);
    …
    CYG_FB_PIXEL0_FLUSHABS(FRAMEBUF, x, y, width, height);
```

The VAR macro will define one or more local variables to keep track of the current pixel position, as appropriate to the framebuffer device. The other pixel macros will then use these variables. For a simple 8bpp linear framebuffer there will be just a byte pointer. For a 1bpp display there may be several variables: a byte pointer, a bit index within that byte, and possibly a cached byte; using a cached value means that the framebuffer may only get read and written once for every 8 pixels, and the compiler may well allocate a register for the cached value; on some platforms framebuffer access will bypass the processor's main cache, so reading from or writing to framebuffer memory will be slow; reducing the number of framebuffer accesses may greatly improve performance.

Because the VAR macro defines one or more local variables it is normally placed at the start of a function or block, alongside other local variable definitions.

One the iteration has been completed there should be a FLUSHABS or FLUSHREL macro. This serves two purposes. First, if the local variables involve a dirty cached value or similar state then this will be written back. Second, for double-buffered displays the macro sets a bounding box for the part of the screen that has been updated. This allows the double buffer synch operation to update only the part of the display that has been modified, without having to keep track of the current bounding box for every updated pixel. For FLUSHABS the *x0* and *y0* arguments specify the top-left corner of the bounding box, which extends for *width* by *height* pixels. For FLUSHREL *x0* and *y0* still specify the top-left corner, but the bottom-right corner is now determined from the current pixel position offset by *dx* and *dy*. More specifically, *dx* should move the current horizontal position one pixel to the right of the right-most pixel modified, such that (x + dx) - x0 gives the width of the bounding box. Similarly *dy* should move the current vertical position one pixel below the bottom-most pixel modified. In typical code the current pixel position will already correspond in part or in whole to the bounding box corner, as a consequence of iterating over the block of memory.

If a pixel variable has been used only for reading framebuffer memory, not for modifying it, then it should still be flushed. A FLUSHABS with a width and height of 0 can be used to indicate that the bounding box is empty. If it is known that the framebuffer device being used does not support double-buffering then again it is possible to specify an empty bounding box. Otherwise portable code should specify a correct bounding box. If the framebuffer device that ends up being used does not support double buffering then the relevant macro arguments are eliminated at compile-time and do not result in any unnecessary code. In addition if there is no cached value or other state then the whole flush operation will be a no-op and no code will be generated.

Failure to perform the flush may result in strange drawing artefacts on some displays which can be very hard to debug. A FLUSHABS or FLUSHREL macro only needs to be invoked once, at the end of the iteration.

The SET macro sets the current position within the framebuffer. It can be used many times within an iteration. However it tends to be somewhat more expensive than ADDX or ADDY, so usually SET is only executed once at the start of an iteration.

```
    CYG_FB_PIXEL0_VAR(FRAMEBUF);
    CYG_FB_PIXEL0_SET(FRAMEBUF, x, y);
    …
    CYG_FB_PIXEL0_FLUSHREL(FRAMEBUF, x, y, 0, 0);
```

The GET macro retrieves the x and y coordinates corresponding to the current position. It is provided mainly for symmetry, but can prove useful for debugging.

```
    CYG_FB_PIXEL0_VAR(FRAMEBUF);
    CYG_FB_PIXEL0_SET(FRAMEBUF, x, y);
    …
#ifdef DEBUG
    CYG_FB_PIXEL0_GET(FRAMEBUF, new_x, new_y);
    diag_printf("Halfway through: x now %d, y now %d\n", new_x, new_y);
#endif
    …
    CYG_FB_PIXEL0_FLUSHREL(FRAMEBUF, x, y, 0, 0);
```

The ADDX and ADDY macros adjust the current position. The most common increments are 1 and -1, moving to the next or previous pixel horizontally or vertically, but any increment can be used.

```
    CYG_FB_PIXEL0_VAR(FRAMEBUF);
    CYG_FB_PIXEL0_SET(FRAMEBUF, x, y);
    for (rows = height; rows; rows--) {
        for (columns = width; columns; columns--) {
            <perform operation>
            CYG_FB_PIXEL0_ADDX(FRAMEBUF, 1);
        }
        CYG_FB_PIXEL0_ADDX(FRAMEBUF, -1 * width);
        CYG_FB_PIXEL0_ADDY(FRAMEBUF, 1);
    }
    CYG_FB_PIXEL0_FLUSHREL(FRAMEBUF, x, y, width, 0);
```

Here the current position is moved one pixel to the right each time around the inner loop. In the outer loop the position is first moved back to the start of the current row, then moved one pixel down. For the final flush the current x position is off by `width`, but the current y position is already correct.

The final two macros `READ` and `WRITE` can be used to examine or update the current pixel value.

```
    CYG_FB_PIXEL0_VAR(FRAMEBUF);
    CYG_FB_PIXEL0_SET(FRAMEBUF, x, y);
    for (rows = height; rows; rows--) {
        for (columns = width; columns; columns--) {
            cyg_fb_colour colour = CYG_FB_PIXEL0_READ(FRAMEBUF);
            if (colour == colour_to_replace) {
                CYG_FB_PIXEL0_WRITE(FRAMEBUF, replacement);
            }
            CYG_FB_PIXEL0_ADDX(FRAMEBUF, 1);
        }
        CYG_FB_PIXEL0_ADDX(FRAMEBUF, -1 * width);
        CYG_FB_PIXEL0_ADDY(FRAMEBUF, 1);
    }
    CYG_FB_PIXEL0_FLUSHREL(FRAMEBUF, x, y, width, 0);
```

Concurrent Iterations

Although uncommon, in some cases application code may need to iterate over two or more blocks. An example might be an advanced block move where each copied pixel requires some processing. To support this there are `PIXEL1`, `PIXEL2` and `PIXEL3` variants of all the `PIXEL0` macros. For example:

```
    CYG_FB_PIXEL0_VAR(FRAMEBUF);
    CYG_FB_PIXEL1_VAR(FRAMEBUF);

    CYG_FB_PIXEL0_SET(FRAMEBUF, dest_x, dest_y_);
    CYG_FB_PIXEL1_SET(FRAMEBUF, source_x, source_y);
    for (rows = height; rows; rows--) {
        for (columns = width; columns; columns--) {
            colour = CYG_FB_PIXEL1_READ(FRAMEBUF);
            <do some processing on colour>
            CYG_FB_PIXEL0_WRITE(FRAMEBUF, colour);
            CYG_FB_PIXEL0_ADDX(FRAMEBUF, 1);
            CYG_FB_PIXEL1_ADDX(FRAMEBUF, 1);
        }
        CYG_FB_PIXEL0_ADDX(FRAMEBUF, -100);
        CYG_FB_PIXEL0_ADDY(FRAMEBUF, 1);
        CYG_FB_PIXEL1_ADDX(FRAMEBUF, -100);
        CYG_FB_PIXEL1_ADDY(FRAMEBUF, 1);
    }

    CYG_FB_PIXEL0_FLUSHABS(FRAMEBUF, source_x, source_y, width, height);
    CYG_FB_PIXEL1_FLUSHABS(FRAMEBUF, 0, 0, 0, 0);  // Only used for reading
```

The `PIXEL0`, `PIXEL1`, `PIXEL2` and `PIXEL3` macros all use different local variables so there are no conflicts. The variable names also depend on the framebuffer device. If the target has two displays and two active framebuffer devices then the pixel macros can be used with the two devices without conflict:

```
    CYG_FB_PIXEL0_VAR(FRAMEBUF0);
    CYG_FB_PIXEL0_VAR(FRAMEBUF1);
    …
```

Name

Porting — writing a new framebuffer device driver

Description

As with most device drivers, the easiest way to write a new framebuffer package is to start with an existing one. Suitable ones include the PC VGA mode13 driver, an 8bpp paletted display, and the ARM iPAQ driver, a 16bpp true colour display. This document only outlines the process.

Before writing any code it is necessary to decide how many framebuffer devices should be provided by the device driver. Each such device requires a cyg_fb structure and appropriate functions, and an identifier for use with the macro API plus associated macros. There are no hard rules here. Some device drivers may support just a single device, others may support many devices which drive the hardware in different modes or orientations. Optional functionality such as viewports and page flipping may be supported by having different cyg_fb devices, or by a number of configuration options which affect a single cyg_fb device. Usually providing multiple cyg_fb structures is harmless because the unused ones will get eliminated at link-time.

Configuration

The CDL for a framebuffer package is usually straightforward. A framebuffer package should be a hardware package and reside in the `devs/framebuf` hierarchy, further organized by architecture. Generic framebuffer packages, if any, can go into a `generic` subdirectory, and will normally rely on the platform HAL to provide some platform-specific information such as base addresses. The package should be part of the target definition and hence loaded automatically, but should be `active_if CYGPKG_IO_FRAMEBUF` so that the driver only gets built if the generic framebuffer support is explicitly added to the configuration.

The configuration option `CYGDAT_IO_FRAMEBUF_DEVICES` should hold all the valid identifiers which can be used as the first argument for the macro API. This helps application developers to select the appropriate identifier, and allows higher-level graphics library packages to check that they have been configured correctly. This is achieved using something like the following, where `mode13_320x200x8` is a valid identifier for the PC VGA driver:

```
  requires { is_substr(CYGDAT_IO_FRAMEBUF_DEVICES, " mode13_320x200x8 ") }
```

The spaces ensure that the CDL inference engine keeps the identifiers separate.

`CYGPKG_IO_FRAMEBUF` contains a number of interfaces which should be implemented by individual device drivers when appropriate. This is used to eliminate some code or data structure fields at compile-time, keeping down memory requirements. The interfaces are `CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_32BPP`, `CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_TRUE_COLOUR`, `CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_PALETTE`, `CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_WRITEABLE_PALETTE`, `CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_DOUBLE_BUFFER`, and `CYGHWR_IO_FRAMEBUF_FUNCTIONALITY_VIEWPORT`. For example if a device driver provides a true colour display but fails to implement the relevant interface then functions like `cyg_fb_make_colour` will be no-ops.

Device drivers for paletted displays should observe the generic configuration option `CYGFUN_IO_FRAMEBUF_INSTALL_DEFAULT_PALETTE` and install either `cyg_fb_palette_ega` or `cyg_fb_palette_vga` as part of their `cyg_fb_on` implementation.

Exported Header File(s)

Each framebuffer device driver should export one or more header files to `cyg/io/framebufs`. A custom build step in `CYGPKG_IO_FRAMEBUF` ensures that application code can just `#include cyg/io/framebuf.h` and this will automatically include the device-specific headers. Drivers may export one header per cyg_fb device or a single header for all devices, without affecting any code outside the device driver.

Each exported header serves two purposes. First it defines the parameters, drawing primitive macros, and iteration macros for each device. Second it declares the cyg_fb structure.

Parameters

The parameter section should resemble the following:

```
#define CYG_FB_320x240x16_STRUCT            cyg_ipaq_fb_320x240x16
#define CYG_FB_320x240x16_DEPTH             16
#define CYG_FB_320x240x16_FORMAT            CYG_FB_FORMAT_16BPP_TRUE_565
#define CYG_FB_320x240x16_WIDTH             320
#define CYG_FB_320x240x16_HEIGHT            240
#define CYG_FB_320x240x16_VIEWPORT_WIDTH    320
#define CYG_FB_320x240x16_VIEWPORT_HEIGHT   240
#define CYG_FB_320x240x16_FLAGS0            (CYG_FB_FLAGS0_LINEAR_FRAMEBUFFER | \
                                             CYG_FB_FLAGS0_TRUE_COLOUR        | \
                                             CYG_FB_FLAGS0_BLANK              | \
                                             CYG_FB_FLAGS0_BACKLIGHT)
#define CYG_FB_320x240x16_FLAGS1            0
#define CYG_FB_320x240x16_FLAGS2            0
#define CYG_FB_320x240x16_FLAGS3            0
#define CYG_FB_320x240x16_BASE              ((void*)0x01FC0020)
#define CYG_FB_320x240x16_STRIDE            640
```

Here `320x240x16` is the framebuffer identifier for use with the macro API. Application code like:

```
#define FRAMEBUF 320x240x16
cyg_ucount16 width = CYG_FB_WIDTH(FRAMEBUF);
```

will end up using the `CYG_FB_320x240x16_WIDTH` definition. To allow for efficient portable code all parameters must be compile-time constants. If the hardware may allow some of the parameters to be varied, for example different resolutions, then this should be handled either by defining separate devices for each resolution or by configuration options.

The viewport width and height should always be defined. If the device driver does not support a viewport then these will be the same as the standard width and height.

To allow for future expansion there are `FLAGS1`, `FLAGS2` and `FLAGS3` parameters. No flags are defined for these at present, but device drivers should still define the parameters.

Drawing Primitives

For each device the exported header file should define macros for the drawing primitives, using the same naming convention as for parameters. In the case of true colour displays there should also be macros for the make-colour and break-colour primitives:

```
#define CYG_FB_320x240x16_WRITE_PIXEL(_x_, _y_, _colour_) …
#define CYG_FB_320x240x16_READ_PIXEL(_x_, _y_) …
#define CYG_FB_320x240x16_WRITE_HLINE(_x_, _y_, _len_, _colour_) …
#define CYG_FB_320x240x16_WRITE_VLINE(_x_, _y_, _len_, _colour_) …
#define CYG_FB_320x240x16_FILL_BLOCK(_x_, _y_, _w_, _h_, _colour_) …
#define CYG_FB_320x240x16_WRITE_BLOCK(_x_, _y_, _w_, _h_, _data_, _off_, _s_) …
#define CYG_FB_320x240x16_READ_BLOCK(_x_, _y_, _w_, _h_, _data_, _off_, _s_) …
#define CYG_FB_320x240x16_MOVE_BLOCK(_x_, _y_, _w_, _h_, _new_x_, _new_y_) …
#define CYG_FB_320x240x16_MAKE_COLOUR(_r_, _g_, _b_) …
#define CYG_FB_320x240x16_BREAK_COLOUR(_colour_, _r_, _g_, _b_) …
```

For typical linear framebuffers there are default implementations of all of these primitives in the generic framebuffer package, held in the exported header `cyg/io/framebuf.inl`. Hence the definitions will typically look something like:

```
#include <cyg/io/framebuf.inl>
…
#define CYG_FB_320x240x16_WRITE_PIXEL(_x_, _y_, _colour_)         \
    CYG_MACRO_START                                               \
    cyg_fb_linear_write_pixel_16_inl(CYG_FB_320x240x16_BASE,      \
                                     CYG_FB_320x240x16_STRIDE,    \
                                     _x_, _y_, _colour_);         \
    CYG_MACRO_END
```

```
#define CYG_FB_320x240x16_READ_PIXEL(_x_, _y_)                    \
    ({ cyg_fb_linear_read_pixel_16_inl(CYG_FB_320x240x16_BASE,    \
                                       CYG_FB_320x240x16_STRIDE,  \
                                       _x_, _y_); })
…
```

All of the drawing primitives have variants for the common display depths and layouts: 1le, 1be, 2le, 2be, 4le, 4be, 8, 16 and 32. The inlines take the framebuffer memory base address as the first argument, and the stride in bytes as the second. Similarly there are default definitions of the true colour primitives for `8BPP_TRUE_332`, `16BPP_TRUE_565`, `16BPP_TRUE_555`, and `32BPP_TRUE_0888`:

```
#define CYG_FB_320x240x16_MAKE_COLOUR(_r_, _g_, _b_)             \
    ({  CYG_FB_MAKE_COLOUR_16BPP_TRUE_565(_r_, _g_, _b_); })
#define CYG_FB_320x240x16_BREAK_COLOUR(_colour_, _r_, _g_, _b_)  \
    CYG_MACRO_START                                              \
    CYG_FB_BREAK_COLOUR_16BPP_TRUE_565(_colour_, _r_, _g_, _b_); \
    CYG_MACRO_END
```

These default definitions assume the most common layout of colours within a pixel value, so for example `CYG_FB_MAKE_COLOUR_16BPP_TRUE_565` assumes bits 0 to 4 hold the blue intensity, bits 5 to 10 the green, and bits 11 to 15 the red.

If the hardware does not implement a linear framebuffer then obviously writing the device driver will be significantly more work. The macros will have to perform the operations themselves instead of relying on generic implementations. The required functionality should be obvious, and the generic implementations can still be consulted as a reference. For complicated hardware it may be appropriate to map the macros onto function calls, rather than try to implement everything inline.

Note

At the time of writing the support for linear framebuffers is incomplete. Only 8bpp, 16bpp and 32bpp depths have full support. There may also be future extensions, for example `r90`, `r180` and `r270` variants to support rotation in software, and `db` variants to support double-buffered displays.

Iteration Macros

In addition to the drawing primitives the exported header file should define iteration macros:

```
#define CYG_FB_320x240x16_PIXELx_VAR(  _fb_, _id_) …
#define CYG_FB_320x240x16_PIXELx_SET(  _fb_, _id_, _x_, _y_) …
#define CYG_FB_320x240x16_PIXELx_GET(  _fb_, _id_, _x_, _y_) …
#define CYG_FB_320x240x16_PIXELx_ADDX( _fb_, _id_, _incr_) …
#define CYG_FB_320x240x16_PIXELx_ADDY( _fb_, _id_, _incr_) …
#define CYG_FB_320x240x16_PIXELx_WRITE(_fb_, _id_, _colour_) …
#define CYG_FB_320x240x16_PIXELx_READ( _fb_, _id_)…
#define CYG_FB_320x240x16_PIXELx_FLUSHABS( _fb_, _id_, _x0_, _y0_, _w_, _h_) …
#define CYG_FB_320x240x16_PIXELx_FLUSHREL( _fb_, _id_, _x0_, _y0_, _dx_, _dy_) …
```

The *`_fb_`* argument will be the identifier, in this case `320x240x16`, and the *`_id_`* will be a small number, 0 for a `PIXEL0` iteration, 1 for `PIXEL1`, and so on. Together these two should allow unique local variable names to be constructed. Again there are default definitions of the macros in `cyg/io/framebuf.inl` for linear framebuffers:

```
#define CYG_FB_320x240x16_PIXELx_VAR(  _fb_, _id_) \
    CYG_FB_PIXELx_VAR_16(  _fb_, _id_)
#define CYG_FB_320x240x16_PIXELx_SET(  _fb_, _id_, _x_, _y_)    \
    CYG_MACRO_START                                             \
    CYG_FB_PIXELx_SET_16( _fb_, _id_,                           \
                          CYG_FB_320x240x16_BASE,               \
                          320, _x_, _y_);                       \
    CYG_MACRO_END
```

The linear `SET` and `GET` macros take base and stride information. The `ADDX` and `ADDY` macros only need the stride. By convention most of the macros are wrapped in `CYG_MACRO_START`/`CYG_MACRO_END` or `({`/`})` pairs, allowing debug code to be inserted if necessary. However the _VAR macro must not be wrapped in this way: its purpose is to define one or more local variables; wrapping the macro would declare the variables in a new scope, inaccessible to the other macros.

Again for non-linear framebuffers it will be necessary to implement these macros fully rather than rely on generic implementations, but the generic versions can be consulted as a reference.

The cyg_fb declaration

Finally there should be an export of the cyg_fb structure or structures. Typically this uses the _STRUCT parameter, reducing the possibility of an accidental mismatch between the macro and function APIs:

```
extern cyg_fb   CYG_FB_320x240x16_STRUCT;
```

Driver-Specific Source Code

Exporting parameters and macros in a header file is not enough. It is also necessary to actually define the cyg_fb structure or structures, and to provide hardware-specific versions of the control operations. For non-linear framebuffers it will also be necessary to provide the drawing functions. There is a utility macro CYG_FB_FRAMEBUFFER for instantiating a cyg_fb structure. Drivers may ignore this macro and do the work themselves, but at an increased risk of compatibility problems with future versions of the generic code.

```
CYG_FB_FRAMEBUFFER(CYG_FB_320x240x16_STRUCT,
                   CYG_FB_320x240x16_DEPTH,
                   CYG_FB_320x240x16_FORMAT,
                   CYG_FB_320x240x16_WIDTH,
                   CYG_FB_320x240x16_HEIGHT,
                   CYG_FB_320x240x16_VIEWPORT_WIDTH,
                   CYG_FB_320x240x16_VIEWPORT_HEIGHT,
                   CYG_FB_320x240x16_BASE,
                   CYG_FB_320x240x16_STRIDE,
                   CYG_FB_320x240x16_FLAGS0,
                   CYG_FB_320x240x16_FLAGS1,
                   CYG_FB_320x240x16_FLAGS2,
                   CYG_FB_320x240x16_FLAGS3,
                   0, 0, 0, 0,   // fb_driver0 -> fb_driver3
                   &cyg_ipaq_fb_on,
                   &cyg_ipaq_fb_off,
                   &cyg_ipaq_fb_ioctl,
                   &cyg_fb_nop_synch,
                   &cyg_fb_nop_read_palette,
                   &cyg_fb_nop_write_palette,
                   &cyg_fb_dev_make_colour_16bpp_true_565,
                   &cyg_fb_dev_break_colour_16bpp_true_565,
                   &cyg_fb_linear_write_pixel_16,
                   &cyg_fb_linear_read_pixel_16,
                   &cyg_fb_linear_write_hline_16,
                   &cyg_fb_linear_write_vline_16,
                   &cyg_fb_linear_fill_block_16,
                   &cyg_fb_linear_write_block_16,
                   &cyg_fb_linear_read_block_16,
                   &cyg_fb_linear_move_block_16,
                   0, 0, 0, 0 // fb_spare0 -> fb_spare3
);
```

The first 13 arguments to the macro correspond to the device parameters. The next four are arbitrary CYG_ADDRWORD values for use by the device driver. Typically these are used to share on/off/ioctl functions between multiple cyg_fb structure. They are followed by function pointers: on/off/ioctl control; double buffer synch; palette management; true colour support; and the drawing primitives. nop versions of the on, off, ioctl, synch, palette management and true colour functions are provided by the generic framebuffer package, and often these arguments to the CYG_FB_FRAMEBUFFER macro will be discarded at compile-time because the relevant CDL interface is not implemented. The final four arguments are currently unused and should be 0. They are intended for future expansion, with a value of 0 indicating that a device driver does not implement non-core functionality.

As with the macros there are default implementations of the true colour primitives for `8bpp_true_332`, `16bpp_true_565`, `16bpp_true_555` and `32bpp_true_0888`, assuming the most common layout for these colour modes. There are also default implementations of the drawing primitives for linear framebuffers, with variants for the common display depths and layouts. Obviously non-linear framebuffers will need rather more work.

Typically a true colour or grey scale framebuffer device driver will have to implement just three hardware-specific functions:

```
int
cyg_ipaq_fb_on(cyg_fb* fb)
{
    …
}

int
cyg_ipaq_fb_off(cyg_fb* fb)
{
    …
}

int
cyg_ipaq_fb_ioctl(cyg_fb* fb, cyg_ucount16 key, void* data, size_t* len)
{
    int result;

    switch(key) {
        case CYG_FB_IOCTL_BLANK_GET: …
        …
        default: result = ENOSYS; break;
    }
    return result;
}
```

These control operations are entirely hardware-specific and cannot be implemented by generic code. Paletted displays will need two more functions, again hardware-specific:

```
void
cyg_pcvga_fb_read_palette(cyg_fb* fb, cyg_ucount32 first, cyg_ucount32 len,
                          void* data)
{
    …
}

void
cyg_pcvga_fb_write_palette(cyg_fb* fb, cyg_ucount32 first,  cyg_ucount32 len,
                           const void* data, cyg_ucount16 when)
{
    …
}
```

Future Expansion

As has been mentioned before framebuffer hardware varies widely. The design of a generic framebuffer API requires complicated trade-offs between efficiency, ease of use, ease of porting, and still supporting a very wide range of hardware. To some extent this requires a lowest common denominator approach, but the design allows for some future expansion and optional support for more advanced features like hardware acceleration.

The most obvious route for expansion is the `ioctl` interface. Device drivers can define their own keys, values `0x8000` and higher, for any operation. Alternatively a device driver does not have to implement just the interface provided by the generic framebuffer package: additional functions and macros can be exported as required.

Currently there are only a small number of `ioctl` operations. Additional ones may get added in future, for example to support a hardware mouse cursor, but only in cases where the functionality is likely to be provided by a significant number of framebuffer devices. Adding new generic functionality adds to the maintenance overhead of both code and documentation. When a new generic ioctl operation is added there will usually also be one or more new flags, so that device drivers can indicate they support the functionality. At the time of writing only 12 of the 32 FLAGS0 flags are used, and a further 96 are available in FLAGS1, FLAGS2 and FLAGS3.

Another route for future expansion is the four spare arguments to the CYG_FB_FRAMEBUFFER macro. As an example of how these may get used in future, consider support for 3d hardware acceleration. One of the spare fields would become another table of function pointers to the various accelerators, or possibly a structure. A FLAGS0 flag would indicate that the device driver implements such functionality.

Other forms of expansion such as defining a new standard drawing primitive would be more difficult, since this would normally involve changing the CYG_FB_FRAMEBUFFER macro. Such expansion should not be necessary because the existing primitives provide all reasonable core functionality. Instead other packages such as graphics libraries can work on top of the existing primitives.

Chapter 85. CSB337/900 Framebuffer Device Driver

Name

CYGPKG_DEVS_FRAMEBUF_ARM_CSB337900 — eCos framebuffer support for a CSB337/900

Description

This package provides an eCos framebuffer device driver for a Cogent CSB337 board with a CSB900 add-on to provide the LCD panel. It has dependencies on both pieces of hardware so cannot be used with any other combination. The driver is a hardware package and is loaded automatically when configuring eCos for a csb337900 target, but not when configuring for a vanilla csb337 target. By default it is inactive and does not add any code size or data overheads. To activate the driver the generic framebuffer package CYGPKG_IO_FRAMEBUF should be added to the configuration. The driver's functionality is only accessible via the API defined by the generic package.

There are a number of design issues with this hardware combination. The framebuffer memory cannot be accessed in the conventional linear way, Instead the driver contains custom drawing code which will be significantly slower than the equivalent linear framebuffer routines. There are also problems with the colour handling: only three bits of control are available for each of red, green and blue intensity,

The driver supports four cyg_fb structures: cyg_csb337900_fb_240x320x8, cyg_csb337900_fb_320x240x8r90, cyg_csb337900_fb_240x320x8r180, and cyg_csb337900_fb_320x240x8r270. These all run the hardware in the same resolution but in the four different orientations, using hardware to perform the rotation. The corresponding identifiers for the macro API are 240x320x8, 320x240x8r90, 240x320x8r180 and 320x240x8r270. Obviously only one of these framebuffer devices can be used at a time. All the devices implement 8bpp non-linear displays with a writeable palette. The supported ioctl operations are CYG_FB_IOCTL_BLANK_GET, CYG_FB_IOCTL_BLANK_SET, CYG_FB_IOCTL_BACKLIGHT_GET and CYG_FB_IOCTL_BACKLIGHT_SET. The backlight can only be switched on or off, there is no support for different levels of intensity.

Chapter 86. i.MXxx Framebuffer Device Driver

Name

CYGPKG_DEVS_FRAMEBUF_ARM_IMX — eCos Support for the i.MXxx framebuffer

Description

CYGPKG_DEVS_FRAMEBUF_ARM_IMX provides an eCos framebuffer device driver for the LCD panel on the i.MXxx family of processors. The driver is a hardware package and is loaded automatically when configuring eCos for an i.MXxx target. By default it is inactive and does not add any code size or data overheads. To activate the driver the generic framebuffer package CYGPKG_IO_FRAMEBUF should be added to the configuration. The driver's functionality is only accessible via the API defined by the generic package.

The driver supports a single framebuffer device, driving the LCD panel in 565 true colour mode with a resolution of 640x480 pixels at 16bpp. The cyg_fb structure for this is cyg_imx_fb_640x480x16, and the identifier for use with the framebuffer macro API is 640x480x16. The ioctl operations supported are CYG_FB_IOCTL_BLANK_GET, CYG_FB_IOCTL_BLANK_SET, CYG_FB_IOCTL_BACKLIGHT_GET and CYG_FB_IOCTL_BACKLIGHT_SET. The backlight supports 256 levels of intensity.

The driver must be configured for the LCD panel attached using the CYGPKG_DEVS_FRAMEBUF_ARM_IMX_LCD option. Normally this would be set by the platform HAL package using a requires statement. At present only one panel type is supported: the Chunghwa CLAA057VA01CT.

Chapter 87. iPAQ Framebuffer Device Driver

Name

CYGPKG_DEVS_FRAMEBUF_ARM_IPAQ — eCos Support for the iPAQ framebuffer

Description

CYGPKG_DEVS_FRAMEBUF_ARM_IPAQ provides an eCos framebuffer device driver for the LCD panel on an iPAQ. The driver is a hardware package and is loaded automatically when configuring eCos for an iPAQ target. By default it is inactive and does not add any code size or data overheads. To activate the driver the generic framebuffer package CYGPKG_IO_FRAMEBUF should be added to the configuration. The driver's functionality is only accessible via the API defined by the generic package.

The driver supports a single framebuffer device, driving the LCD panel in 565 true colour mode with a resolution of 320x240 pixels at 16bpp. The cyg_fb structure for this is cyg_ipaq_fb_320x240x16, and the identifier for use with the framebuffer macro API is 320x240x16. The ioctl operations supported are CYG_FB_IOCTL_BLANK_GET, CYG_FB_IOCTL_BLANK_SET, CYG_FB_IOCTL_BACKLIGHT_GET and CYG_FB_IOCTL_BACKLIGHT_SET. The backlight supports 32 levels of intensity.

Chapter 88. PC VGA Framebuffer Device Driver

Name

CYGPKG_DEVS_FRAMEBUF_I386_PCVGA — eCos Support for PC VGA Cards

Description

This package provides an eCos framebuffer device driver for a VGA graphics card in a standard PC. Although VGA is now very old technology, more recent PC graphics hardware usually still provides compatibility. The device driver works by interacting directly with the hardware, not via the video BIOS, so the level of compatibility must be very high. Hence the driver cannot be guaranteed to work with all PC graphics cards and should be used with care.

CYGPKG_DEVS_FRAMEBUF_I386_PCVGA is a hardware package and is loaded automatically when configuring eCos for a PC target. By default it is inactive and does not add any code size or data overheads. To activate the driver the generic framebuffer package CYGPKG_IO_FRAMEBUF should be added to the configuration. The driver's functionality is only accessible via the API defined by the generic package.

The driver supports just one of the VGA graphics modes, mode 13. This provides an 8bpp linear framebuffer with a resolution of 320x200 pixels, and uses a writeable palette for colour management. The cyg_fb structure for this is cyg_pcvga_fb_mode13_320x200x8, and the identifier for use with the framebuffer macro API is mode13_320x200x8. The only ioctl operations supported are CYG_FB_IOCTL_BLANK_GET and CYG_FB_IOCTL_BLANK_SET.

There is one configuration option specific to the PC VGA hardware. Some of the documentation for these cards recommends a delay after every VGA register access because not all graphics cards can keep up with full-speed I/O. By default the driver implements such a delay, but obviously this slows down certain operations. If the graphics card actually being used does not require this delay then the configuration option CYGHWR_DEVS_FRAMEBUF_I386_PCVGA_REGISTER_ACCESS_DELAY can be disabled.

Chapter 89. Synthetic Target Framebuffer Device

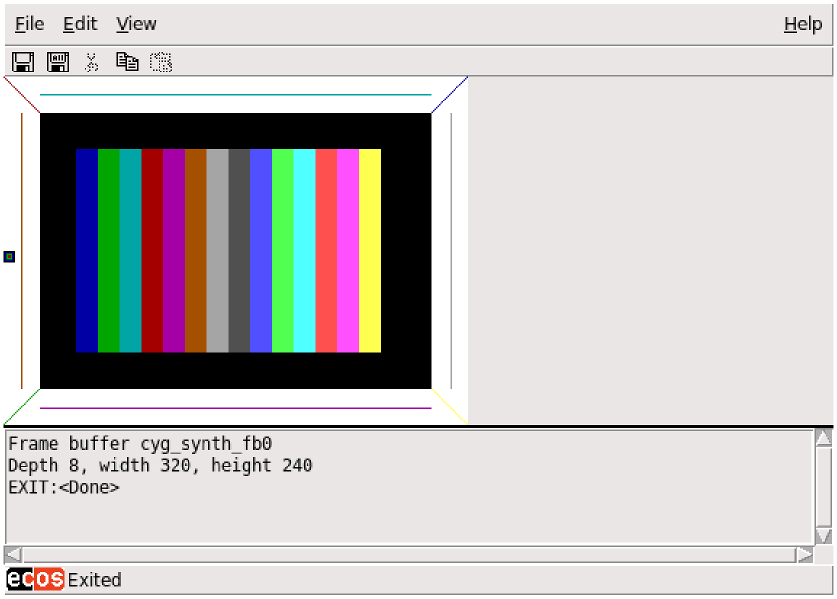
Name

Synthetic Target Framebuffer Device — Emulate framebuffer hardware in the synthetic target

Overview

This package CYGPKG_DEVS_FRAMEBUF_SYNTH provides a framebuffer device driver for the eCos synthetic target.

Figure 89.1. Synthetic Target Framebuffer X Window



```
Frame buffer cyg_synth_fb0
Depth 8, width 320, height 240
EXIT:<Done>
```

The driver supports up to four framebuffer devices fb0, fb1, fb2 and fb3. The width, height, depth, and display format of each framebuffer can be controlled via configuration options. It is also possible to set a viewport for each device and to enable page flipping.

To use the framebuffer support the eCos application must run inside an X session, not from the console, and it must be started with *--io* to enable the I/O auxiliary. The I/O auxiliary will start a separate instance of a host-side utility framebuf for each target-side framebuffer device. The framebuf utility can access the eCos framebuffer data via a shared memory region and draw it to the screen using X library calls. It needs the X server to run with a TrueColor visual and a display of depth of 24 or 32 bits per pixel.

Installation

The synthetic target framebuffer driver depends on host-side support which must be built and installed. The relevant code resides in the host subdirectory of the synthetic target framebuffer package, and building it involves the standard **configure**, **make** and **make install** steps. This will build and install a utility program framebuf that does the actual drawing of the eCos framebuffer contents to the host-side X display. It will also install a Tcl script and some support files. framebuf is an X11 application so can only be built on Linux systems with the appropriate X11 development package or packages.

There are two main ways of building the host-side software. It is possible to build both the generic host-side software and all package-specific host-side software, including the framebuffer support, in a single build tree. This involves using the **configure** script at the toplevel of the eCos repository. For more information on this, see the README.host file at the top of the repository. Note that if you have an existing build tree which does not include the synthetic target framebuffer support then it will be necessary to rerun the toplevel configure script: the search for appropriate packages happens at configure time.

The alternative is to build just the host-side for this package. This requires a separate build directory, building directly in the source tree is disallowed. The **configure** options are much the same as for a build from the toplevel, and the README.host file can be consulted for more details. It is essential that the framebuffer support be configured with the same `--prefix` option as other eCos host-side software, especially the I/O auxiliary provided by the architectural synthetic target HAL package, otherwise the I/O auxiliary will be unable to locate the framebuffer support.

Configuration

The package is loaded automatically when creating a configuration for the synthetic target. However it is inactive unless the generic framebuffer support `CYGPKG_IO_FRAMEBUF` is also added to the configuration, for example by `ecosconfig add framebuf`.

By default the package enables a single framebuffer device `fb0` with a corresponding cyg_fb data structure `cyg_synth_fb0`. The default settings for this device are 320 by 240 pixels, a depth of 8 bits per pixel, a paletted display, no viewport support, and no page flipping. All of these settings can be changed by configuration options inside the CDL component `CYGPKG_DEVS_FRAMEBUF_SYNTH_FB0`. The supported display formats are: 8 bpp paletted; 8bpp true colour 332; 16bpp true 565; 16bpp true 555; and 32bpp 0888. This allows the synthetic target to match the actual display capabilities of the hardware that is being emulated. If the actual hardware has more than one framebuffer device then this can be emulated by enabling additional components `CYGPKG_DEVS_FRAMEBUF_SYNTH_FB1` …, and setting the appropriate options.

Customization

In addition to the target-side configurability it is possible to customize the host-side behaviour. For example, the default behaviour is for `fb0` to be drawn inside the I/O auxiliary's main window, if it is not too large. `fb1`, `fb2` and `fb3` will be drawn inside separate toplevel windows, as will `fb0` if that has been configured too large for embedding in the main window. This behaviour can be changed by providing a custom Tcl/Tk procedure that creates the containing frame for the framebuffer device.

Customization involves adding a synth_device `framebuf` section to the `.tdf` target definition file, usually `default.tdf` or `~/.ecos/synth/default.tdf`.

```
proc my_framebuf_create_frame { … } {
    …
}

synth_device framebuf {
    fb2_magnification   2
    create_frame_proc   my_framebuf_create_frame
}
```

The pixel size on the host display may be rather smaller than on the final hardware, causing a serious mismatch between the application's appearance when using synthetic target emulation and when using real hardware. To reduce this problem the host-side can magnify the target-side framebuffer devices. In the example above each target-side pixel in device `fb2` will be drawn using 2*2 pixels on the host side. Valid magnifications are 1, 2, 3 and 4. With a magnification of 4 an eCos framebuffer device of 320*240 pixels will be drawn in an X window of 1280*960 pixels.

The *`create_frame_proc`* entry can be used to specify a custom Tcl/Tk procedure that will create the containing Tk frames for the host-side displays. This procedure can be written for a specific configuration, but it is supplied with all the parameters associated with the framebuffer device so can be more generic. An example is supplied in the package's `misc` subdirectory:

1. Create a configuration for the synthetic target with the default template.
2. Import the `example.ecm` configuration fragment from the `misc` subdirectory. This will add the generic framebuffer support package, enable all four framebuffer devices, and configure each device. Build the resulting configuration.
3. Compile the `example.c` program and link it against the eCos configuration.
4. Incorporate the `example.tdf` fragment into the appropriate target definition file, typically `default.tdf` or `~/.ecos/synth/default.tdf`.

5. Run the example executable. The four framebuffer devices should get instantiated in a separate window in a single column. `FB0` just contains a static display. `FB1` supports two pages, one with vertical stripes and one with horizontal stripes, and the two pages are flipped at regular intervals. `FB2` has a static display similar to `FB0`, but is drawn in a viewport of only 160x120 pixels. However `example.tdf` magnifies this by 2 so it appears the same size as the other devices. The application moves the viewport around the underlying framebuffer device. `FB3` is also a static display, a simple set of vertical stripes. However this framebuffer is paletted and the palette is changed at regular intervals, causing apparent movement.

Part XXVII. CAN Support

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Important

The eCosPro-CAN package and its associated device drivers are STRICTLY LICENSED FOR INTERNAL EVALUATION AND TESTING PURPOSES ONLY for a maximum period of THREE months from the initial delivery of your eCosPro release. It may not be used for production purposes nor redistributed in full or in part in any format, including source code, binary code and object code format. Shipment of prototypes, hardware or products containing the package in any format is STRICTLY PROHIBITED.

A separate COMMERCIAL LICENSE for this package from eCosCentric is required to receive technical support for the package as well as permit distribution of binary forms of this package.

Some releases of eCosPro may not include evaluation copies of this package. In this case, please contact eCosCentric for licensing and availability. You must obtain written permission from eCosCentric to exceed the evaluation period.

Table of Contents

Chapter 90. CAN Support

⚠

Important

This eCosPro-CAN Middleware package is STRICTLY LICENSED FOR NON-COMMERCIAL PURPOSES ONLY. It may not be used for Commercial purposes in full or in part in any format, including source code, binary code and object code format.

A Commercial eCosPro License version 3 (or above) which explicity includes this Middleware Package is required for Commercial use.

Name

Overview — eCos Support for CAN, the Controller Area Network

Description

The Controller Area Network, CAN, was originally designed for use in automotive systems where many small sensors report small values frequently. Consequently, CAN uses small messages of up to 8 bytes payload, which permits many messages to be passed each second and also reduces packet transmission latency.

CAN is a simple broadcast network carried on a twisted pair. It uses CSMA/CD, like Ethernet, to access the medium, however the signal levels and messages format are designed to resolve collisions in favour of the highest priority packet, rather than the jam and random retry of Ethernet. This yields a priority-based approach to contention that is better suited to real time applications.

CAN messages contain an 11 bit message ID, up to 8 bytes of data, a 15 data, a 15 bit CRC and assorted control bits. The message ID is also the priority used to resolve collisions, and has to be unique. Since the network is broadcast, and there are no fixed node addresses, receivers need to have hardware acceptance filters to avoid having to process every packet.

There are two very distinct operational modes for CAN devices. The first of these is BasicCAN. This is the approach familiar from Ethernet controllers. Packets to be transmitted are fed one at a time into an output FIFO and are sent on the wire when it appears to be idle. Received packets are pulled off the wire and are compared against one or more acceptance filters. If they match they are placed into an input FIFO ready for the CPU to collect them.

The second approach is FullCAN. Here, the controller contains a number of packet buffers which are used for transmission or reception. To transmit, the packet is put into a buffer and the buffer state changed to "transmit" and the packet goes out when the controller and the line are ready. Received packets are compared against an acceptance filter on each buffer that is marked "receive" and copied into whichever buffer matches first. The clear intention here is that specific buffers are statically dedicated to particular communication channels.

The eCos CAN subsystem currently supports the BasicCAN mode only. FullCAN devices are driven in such a way as to provide BasicCAN functionality. FullCAN functionality can always be emulated using software.

You can find more information at the CAN in Automation website.

eCos Support for CAN

The eCos CAN support for any given platform is spread over a number of different packages:

- This package, `CYGPKG_IO_CAN`, exports a generic API for accessing devices attached to a CAN network. This API handles issues such as locking between threads. The package does not contain any hardware-specific code. Instead it uses a separate CAN device driver to handle the hardware and defines the interface that such network drivers should provide.
- Each CAN device has its own device driver, which is implemented as a separate package. For devices that may be attached to a variety of different boards, the device driver will be generic and a second platform specific package will be used to customize it to each platform. For devices that are associated with a specific chipset, only a single package may be present.

Typically all appropriate packages will be loaded automatically when you configure eCos for a given platform. If the application does not use any of the CAN I/O facilities, directly or indirectly, then linker garbage collection should eliminate all unnecessary code and data. All necessary initialization should happen automatically. However the exact details may depend on the platform, so the platform HAL documentation should be checked for further details.

There is an important exception to this: if the CAN devices are attached to an expansion connector, such as PCI, then the platform HAL will not know about these devices. Instead the necessary packages will need to be added explicitly during configuration.

Support for CAN-FD

The eCos CAN subsystem also provides support for CAN-FD messages. CAN-FD messages mainly looks similar to standard CAN messages except that the length field can specify packet sizes up to 64 bytes, and there is an option to transmit the data part of a message at a higher baud rate than the rest.

CAN-FD support is only enabled if a driver capable of supporting the protocol is present. Otherwise CAN-FD is not present.

CAN-FD support mainly consist of some extra fields in the CAN message structure and some additional API functions. Both standard CAN and CAN-FD messages may be sent and received using the common structure.

Name

CAN Functions — allow applications and other packages to access CAN devices

Synopsis

#include <cyg/io/can.h>

```
int cyg_can_init();

int cyg_can_open(devname, dev);

int cyg_can_close(dev);

cyg_can_msg* cyg_can_msg_alloc();

void cyg_can_msg_free(msg);

int cyg_can_send(dev, msg);

int cyg_can_send_nowait(dev, msg);

int cyg_can_recv(dev, msg);

int cyg_can_recv_poll(dev, msg);

int cyg_can_recv_timeout(dev, msg, timeout);

void cyg_can_poll();

int cyg_can_filter_set(dev, ide, match, mask);

int cyg_can_filter_get(dev, ide, match, mask);

int cyg_can_filter_ext_set(dev, *filters, len);

int cyg_can_filter_ext_get(dev, *filters, *len);

int cyg_can_baud_set(dev, baud);

int cyg_can_baud_get(dev, baud);

int cyg_can_baud_fd_set(dev, baud);

int cyg_can_baud_fd_get(dev, baud);

int cyg_can_autobaud(dev);

const char cyg_can_error_string(code);
```

Initialization and Device Access

Before performing any CAN system operations, the application must call `cyg_can_init()`. This function initializes the CAN subsystem and causes all the configured devices to initialize themselves. Only the first call to this function will initialize the subsystem, subsequent calls will do nothing, so libraries and independent systems may call it in their initialization routines without needing to ensure it is called only once.

To gain access to a specific CAN channel, the application must call `cyg_can_open()`. Channel names are defined in the configuration and are typically "can0" "can1" and so on. If the channel is not found this function will return `CYG_CAN_NOTFOUND`; it may also return errors generated by the device driver. If the channel is found the call will return `CYG_CAN_NOERROR` and the location pointed to by the *`dev`* parameter will be initialized with a handle on the channel. This handle must be used in all subsequent calls to access this channel.

When the application has finished with a channel it must call `cyg_can_close()` on the handle.

Buffer Management

The CAN subsystem uses buffers to pass messages between the application and the CAN subsystem. These buffers are allocated and managed by the CAN subsystem. The exact number of buffers is controllable in the configuration.

Each buffer contains the following fields:

cyg_can_msg * `next`

This field is used within the CAN subsystem to link this message buffer into lists. When the buffer is in the possession of the user (`state` is `CYG_CAN_MSG_STATE_USER`) then this may be used for application purposes.

unsigned int `rtr`

Remote Transmission Request. If this field is set in a transmitted message buffer, then the RTR bit on the message will be set and the `data` field will be ignored. On reception this field reflects the state of the RTR bit in the received message.

unsigned int `ide`

Extended ID. If this field is set then the `id` field contains a 29 bit extended ID. If it is clear then the ID is 11 bits.

unsigned int `state`

This field is used within the CAN subsystem to track the current state of the buffer. The following states are supported:

CYG_CAN_MSG_STATE_FREE

The message buffer is not currently being used and is on the CAN subsystem's free list.

CYG_CAN_MSG_STATE_USER

The message buffer is currently in the possession of the application code and is outside the control of the CAN subsystem.

CYG_CAN_MSG_STATE_TX

The message buffer is either currently being transmitted, or is in a queue of buffers awaiting transmission.

CYG_CAN_MSG_STATE_RX

The message buffer is the current pending receive buffer for a CAN channel. The next message from that channel will be received into this buffer.

CYG_CAN_MSG_STATE_RXQ

The message buffer is currently on a channel's receive queue. A message has been received into it but not yet been passed on to the user.

unsigned int `len`

The length of the data carried in the message. This can range from zero to 8. In a message with the RTR field set, this indicates the size of data being requested.

int `result`

An error code. For normal successful receptions of messages this will be `CYG_CAN_NOERROR`. Message buffers are also used to report special events on the channel such as transitions to passive error and bus off states. In these cases, the event will be reported using a message buffer with this field set to the appropriate error code.

cyg_uint32 `timestamp`
: Some CAN channels contain a timer that can be used to timestamp received packets. If that is the case, then the timestamp will be stored in this field. If the channel does not have any hardware timing facility, this field will not be used. This field is used for internal purposes during message transmission.

cyg_uint32 `id`
: Message ID. This is the ID to be transmitted with the message, or the ID received. If the `ide` field is set, then this will contain a 29 bit ID, otherwise it will contain an 11 bit ID.

cyg_uint8 `data[8]`
: Message data. Only the first `len` bytes of data are valid. If the `rtr` field is set, then the contents of this field are ignored.

A message buffer may be allocated by calling `cyg_can_msg_alloc()` and freed by calling `cyg_can_msg_free()`.

CAN-FD Buffers

When CAN-FD is enabled the message buffer contains some extra and modified fields:

unsigned int `fdf`
: FD Format. This marks a message as being in FD format. If this field is set in a transmitted message then it will be sent in CAN-FD format. A message with a `len` value of more than 8 will also be considered to be in FD format regardless of the state of this field. On reception this field reflects the state of the FDF bit in the received message.

unsigned int `brs`
: Bit Rate Switch. This indicates whether the message is transmitted with a higher bit rate for the data portion. This field is only valid for FD format messages. If this field is set in a transmitted message then its data bytes will be transmitted at the FD bit rate. On reception this field reflects the state of the BRS bit in the received message.

unsigned int `esi`
: Error State Indicator. This field indicates the error state of the transmitting node, 0 for error active and 1 for error passive. This field is only valid for FD format messages. If this field is set in a transmitted message then the ESI bit on the message will be set. On reception this field reflects the state of the ESI bit in the received message.

unsigned int `len`
: This field is expanded for FD messages to permit any value between 0 and 64. The CAN-FD protocol only permits a limited selection of message sizes: 0 to 8, 12, 16, 20, 24, 32, 48 and 64, encoded into a 4 bit field. This encoding is not used in this field, instead the actual number of bytes are used, with the translation being done in the device driver.

: On transmission if this value is greater than 8 then the message is sent in FD format, regardless of the value of `fdf`. If the supplied value is not one of the protocol-permitted sizes it will be increased to the next greater size.

: On reception this field will be translated from the protocol encoding into the correct number of bytes.

cyg_uint8 `data[64]`
: When CAN-FD is enabled, this field is increased to 64 bytes. Only the first `len` bytes will be valid. If, on transmission, the length has been increased to the next supported size, some extra bytes at the end of the supplied data in the buffer may be sent. On reception, bytes beyond the end of the specified length may have been written by the driver.

Transmit and Receive

To transmit a message an application must acquire a message buffer from the CAN subsystem, fill it in with the message to be sent and call `cyg_can_send()`. Following a successful call the buffer becomes the property of the CAN subsystem and will be returned to the free pool when the message has been transmitted. If an error is detected then the call will return an error code and the message buffer will be returned to the user for reuse or retransmission.

To send a message without waiting for it to complete, the application can call `cyg_can_send_nowait()`.

To receive a message the application calls `cyg_can_recv()`. If there is a message waiting, then a pointer to the message buffer will be installed in the location pointed to by the *`msg`* argument and `CYG_CAN_NOERROR` is returned.

If the application does no want to wait for a message to arrive, it can call `cyg_can_recv_poll()` which will just test for a message and return. If a message is present then `CYG_CAN_NOERROR` is returned and the *`msg`* filled in with a pointer to a message buffer. If no message is present then the function will return `CYG_CAN_AGAIN`.

The application can also wait for a defined length of time for a message to arrive by calling `cyg_can_recv_timeout()`. The additional *`timeout`* argument supplies an *absolute* timeout in system ticks. If a message is present then `CYG_CAN_NOERROR` is returned and the *`msg`* filled in with a pointer to a message buffer. If no message arrives before the timeout expires then the function will return `CYG_CAN_TIMEOUT`.

Regardless of which receive function is used, a successful return results in a message buffer being passed back to the caller. The `result` field of this message buffer will either contain `CYG_CAN_NOERROR` for a normal message, or it will contain an error code indicating an event that has occurred on the channel. When the application has finished with the buffer it must return it to the CAN subsystem by calling `cyg_can_msg_free()`.

The function `cyg_can_poll()` may be called to force all channels to check for transmission completion or pending receptions. When using interrupt driven devices it is unnecessary to call this. However, if there are any polled devices, this is the only way to ensure timely processing of received messages. This function should therefore be called from the application main loop, or from a separate timer driven thread, or by any other appropriate means to ensure communication proceeds in a timely fashion.

Basic Filtering

The functions `cyg_can_filter_set()` and `cyg_can_filter_get()` allow the basic hardware filter to be set and queried. The basic filter model consists of a match value, such that if an ID when bitwise ANDed with the mask equals mask equals the match value ANDed with the mask, then the message is accepted. If the hardware does not support a filter that conforms to this model then no hardware filtering is done, but the filter will still be applied by the CAN subsystem to all incoming packets.

In `cyg_can_filter_set()`, the *`match`* and *`mask`* arguments define the filter. The *`ide`* indicates whether the filter is for normal or extended IDs. It is hardware dependent what happens when the filter ID size does not match the ID size being used on the network.

Extended Filtering

The functions `cyg_can_filter_ext_set()` and `cyg_can_filter_ext_get()` implement an extended filtering mechanism. In this case the application can submit an array of filters which will accept a message if any one of them matches the received ID. If it is possible, extended filtering will be implemented in the CAN controller hardware. Otherwise it will be implemented in software. Setting the extended filters will invalidate the basic filter and vice versa.

The filters are an array of cyg_can_filter structures. Each filter consists of a mask and a match field. For each filter, if the received ID bitwise ANDed with the mask equals the match field ANDed with the mask, then the message is accepted. In addition to the 11 or 29 bits of the ID, the mask and match fields can contain two extra bits: CYG_CAN_FILTER_IDE matches the message IDE bit for 29 bit addressing, and CYG_CAN_FILTER_RTR matches the message RTR bit.

Some care should be taken in setting the IDE and RTR bits in the filters. In general, if the intention is to match on either bit, then it should be set in both fields. Setting the bit only in the mask field will match packets that have the bit clear, which is unlikely to be what it wanted. Incoming message IDs are only matched against similarly sized filters: a message with a 29 bit ID is only matched against filters that have the IDE bits set, and 11 bit ID are only matched against filters with IDE clear. This approach is to ensure consistency between software and hardware filters, and between different hardware filters.

In `cyg_can_filter_ext_set()` the *`filters`* argument is the address of the filter array, and *`len`* defines the number of elements. An error will be returned if the filters are invalid or the list is too long. In `cyg_can_filter_ext_get()`, the *`*len`* argument is a pointer to the length; it should be set to the size of the *filters* array before the call and will be updated with the number of actual filters returned. If the *filters* argument is NULL, the number of filters set will be returned in **len*. If the number of filters set is larger than the value of **len*, or if no extended filters are set, then an error will be returned.

The configuration option CYGNUM_IO_CAN_FILTER_MAX describes the maximum number of extended filters than can be stored. Usually controller drivers will set this value according to the amount of hardware resource available in the filter system.

Baud Rate

The functions cyg_can_baud_set() and cyg_can_baud_get() allow the channel baud rate to be set and queried. Baud rates from 10kb/s to 1Mb/s may be set, although not all device drivers will necessarily support all rates, many will only support a subset. Also, due to interactions between the input clock to the device and the divider granularity, it may not be possible to set some baud rates accurately at some system clock rates; it may be necessary to alter the system clock speed to enable communication.

The functions cyg_can_baud_fd_set() and cyg_can_baud_fd_get() allow the channel FD baud rate to be set and queried. When an FD format message is sent or received, the data bytes will be transmitted at this rate rather than the standard rate.

Autobaud Support

The function cyg_can_autobaud() supports automatic baud rate detection. This will only be present if the controller driver supports autobaud or listen-only mode. It indicates this by implementing the CYGINT_IO_CAN_AUTOBAUD interface. If the driver does no support this feature then this function will not be defined.

The approach for baud detection is to switch the controller to listen-only mode, where it cannot affect the bus state. Each of a set of candidate baud rates are set and the function waits for a period of time for a valid packet to arrive. If no packet is seen, then attention moves to the next baud rate. If a packet is received, then that baud rate is selected and set in the controller in non-listen-mode. If no packets are seen at any baud rate, the original rate is restored to the controller.

There are two configuration options that control the behaviour of the autobaud mechanism:

CYGPKG_IO_CAN_AUTOBAUD_RATES

> This is the set of baud rates tested when autobaud is enabled. It is a comma separated list of rates used to initialize an array in the CAN subsystem. The default value contains all the standard CANOpen rates, but for specific applications only the subset of rates that might be used should be listed.

CYGNUM_IO_CAN_AUTOBAUD_TIMEOUT

> Maximum time in ticks that the autobaud code will wait for bus activity at each baud rate. If no packet is received or an error reported in this time, it will move on to the next baud rate. The default 50 ticks equals half a second at the default 100Hz clock frequency. If this option is set to zero, then the autobaud code will wait indefinitely at each baud rate for either a packet or an error. This is useful during testing when traffic is initiated by hand.

Autobaud support comes with a number of caveats. Baud detection depends on traffic being present on the CAN bus and being frequent enough for packets to be seen during the timeout period for each candidate baud rate. Some baud rates may not be supportable by the controller. If there is only one other node in the network sending packets, the lack of acknowledgements may cause it to move into Error Passive or Bus Off mode and stop transmitting. Consequently autobaud detection cannot be considered to be a fully reliable operation and it is quite possible for cyg_can_autobaud() to terminate without detecting the baud rate. The length of time taken to detect the baud rate may be as long as the number of candidate rates multiplied by the timeout period.

Errors

Many of the CAN API calls return error codes. The result field of the message buffer structure may also contain an error code from this set. The following error codes may be returned by API calls:

CYG_CAN_NOERROR

No error, the operation completed successfully.

CYG_CAN_NOTFOUND

When returned from `cyg_can_open()` this error code means that the named CAN channel could not be found.

CYG_CAN_INVALID

When returned from `cyg_can_filter_set()` this error code means that the filter is invalid. When returned from `cyg_can_baud_get()` this error code means that the baud rate is invalid, or the hardware cannot support it with sufficient accuracy in the current system configuration.

CYG_CAN_TIMEOUT

When returned from `cyg_can_recv_timeout()` this error code means that the timeout has expired with no message being received.

The following error codes may be passed back in the result field of a message buffer acquired from one of the receive functions. Refer to the CAN specification for details of what these events actually mean.

CYG_CAN_NOERROR

The message buffer contains a CAN message that was received from the channel.

CYG_CAN_WARN_TX

This error code indicates that the CAN channel's transmit error counter has exceeded its warning limit, which is usually 96.

CYG_CAN_WARN_RX

This error code indicates that the CAN channel's receive error counter has exceeded its warning limit, which is usually 96.

CYG_CAN_PASSIVE

This error code indicates that the CAN channel has gone into "error passive" mode.

CYG_CAN_BUSOFF

This error code indicates that the CAN channel had gone into "bus off" mode.

CYG_CAN_OVERRUN

This error code indicates that the CAN channel has lost one or more CAN messages due to all the hardware buffers being full.

CYG_CAN_RXERROR

This error code indicates that the controller has detected one or more low level error conditions. Support for detecting these errors may only be enabled when driver autobaud support is enabled. It may not be generated during normal operation.

The `cyg_can_error_string()` function translates these error codes into strings for diagnostic purposes.

Name

Configuration — CAN subsystem configuration

Description

The CAN subsystem has a number of configuration options:

cdl_interface CYGINT_IO_CAN_DRIVER

> This CDL interface counts the number of CAN channels present in the system. Each driver must have an **implements** command for this interface for each channel it supports.

cdl_option CYGNUM_IO_CAN_MSG_COUNT_BASE

> This CDL option defines the base number of message buffers allocated regardless of the number of channels available.
>
> Default value: 10

cdl_option CYGNUM_IO_CAN_MSG_COUNT_DRIVER

> This CDL option defines the number of message buffers allocated per CAN channel. The total number of message buffers allocated is `CYGNUM_IO_CAN_MSG_COUNT_BASE` plus `CYGNUM_IO_CAN_MSG_COUNT_DRIVER` times `CYGINT_IO_CAN_DRIVER`.
>
> Default value: 10

cdl_option CYGNUM_IO_CAN_FILTER_MAX

> This option defines the number of extended filters that can be stored. Drivers may use a requires statement to increase this number to reflect the availability of hardware filters. If hardware filtering is not supported, then this defines the number of software filters that can be stored.
>
> Default value: 10

cdl_option CYGDBG_IO_CAN_DEBUG

> This CDL option enables diagnostic output to be generated by the CAN subsystem. This is mostly useful in debugging problems with the CAN subsystem or in the development of device drivers.
>
> Default value: 0

Name

Device Drivers — Writing new CAN device drivers

Description

Adding CAN support for a new device to eCos involves a number of steps. First a new package for the driver must be created and added to ecos.db. This package must contain CDL, headers and sources for implementing the driver. If the driver can apply to devices on different platforms, then a further package that configures the generic device to each platform will also be needed.

Device Driver Data Structures

Each CAN device is represented by a cyg_can_device structure. Most of the fields of this structure are private to the CAN subsystem and it needs to be defined in such a way that it is included in a table of all the CAN devices. To make this simple for the driver writer a macro has been defined to create this structure for each channel.

```
CYG_CAN_DEVICE( tag, chan, name, priv );
```

The arguments to this macro are:

tag
: This is a general name for the device driver as a whole, it should usually be the name of the device chip or interface type. Typical values might be `sja1000` or `flexcan`. This tag is used to ensure that the data structures declared by this macro are unique to this driver.

chan
: This distinguishes between separate channels supported by the driver. Typical values might be `can0` or `can1`.

name
: This is the name of the channel as used in the `cyg_can_open()` function. It is a string constant and is usually defined by the driver's CDL. Typical CAN channel names are "can0" and "can1". However this argument will usually be a CDL option such as `CYGPKG_DEVS_CAN_CHANNEL0_NAME` or `CYGPKG_DEVS_CAN_CHANNEL1_NAME`.

priv
: This is a pointer to a private data structure that contains device specific information such as its base address and interrupt vector. The CAN subsystem does not interpret the contents of this in any way. Typical values for this might be `cyg_can_flexcan_drv_0` or `cyg_can_sja1000_drv[1]`.

The interface to each driver is via a table of function calls that is pointed to by the cyg_can_device structure. This structure has the following definition:

```
struct cyg_can_device_calls {
       int (*init)  (cyg_can_device *dev);
       int (*open)  (cyg_can_device *dev);
       int (*close) (cyg_can_device *dev);
       int (*send)  (cyg_can_device *dev, cyg_can_msg *msg);
       int (*poll)  (cyg_can_device *dev);
       int (*filter)(cyg_can_device *dev, cyg_bool ide, cyg_uint32 match, cyg_uint32 mask);
       int (*baud)  (cyg_can_device *dev, cyg_uint32 baud);
       int (*filter_ext)(cyg_can_device *dev, cyg_can_filter *filters, int len);
};
```

`init()`
: This is called to initialize the channel when `cyg_can_init()` is called. It should locate the channel and initialize it ready for communication. It should also install any interrupts and initialize the fields of the private data structure.

`open()`
: This is called if the name of this channel matches the device name passed to `cyg_can_open()`. There is no requirement for the driver to do anything here, but possible things it might do is to allocate per-client resources in the hardware, or just keep count of the number of users.

`close()`
: This is called when `cyg_can_close()` is called. As with the `open()` function, there is no required behaviour here, but if `open()` allocated resources, then this is where they should be released.

`send()`
: This function is called to transmit a message by `cyg_can_send()` and is passed a pointer to a message buffer. This function should return one of several return codes depending on the state of the channel:

  CYG_CAN_BUSY

  > The channel is busy and cannot transmit the message at this point. The CAN subsystem will add the message to its pending queue until the channel is available, at which point the buffer will be passed back to the driver by the `cyg_can_tx_done()` function.

  CYG_CAN_WAIT

  > The channel has started the transmission of the message, but it is not yet complete. The CAN subsystem will cause the sending thread to wait until the driver calls `cyg_can_tx_done()`. This is usually used by interrupt driven drivers to make the sender wait for the transmit completion interrupt.

  CYG_CAN_NOERROR

  > The channel has transmitted the message immediately, and has also called `cyg_can_tx_done()` to complete the process. This is mainly used by polled drivers, which don't use interrupts.

  CYG_CAN_*

  > Any other error code indicates a hardware error of some sort and will be passed back to the caller by the CAN subsystem.

`poll()`
: This is usually called from the driver's DSR routine to handle any events that have occurred on the channel. It may also be called from the CAN subsystem at various times, and may be called from application code calling `cyg_can_poll()`.

`filter()`
: This function is called to set the hardware ID filter. Not all hardware supports a filter mechanism that matches the model implemented by the CAN subsystem. This function should return `CYG_CAN_NOERROR` whether it can set the hardware filter or not. The CAN subsystem will always apply the filter in software to all received messages, so setting the hardware filter is an optimization to reduce the number of messages received. There is no function to return the filter since the CAN subsystem records the filter itself.

`baud()`
: This function is called to set the network baud rate. The driver is at liberty to support only a subset of the possible baud rates, and return `CYG_CAN_INVALID` for those it cannot. It is also possible for certain baud rates not be supported for certain system clock speeds due to limitations in the clock divider. It may not be possible for the driver to detect this.

`filter_ext()`
: This function is called to set the extended hardware ID filters. Not all hardware supports the extended filter mechanism and this function pointer may be NULL, in which case the CAN subsystem will apply the filters in software. If not NULL then the driver should return `CYG_CAN_NOERROR` if all the extended filters can be handled, and `CYG_CAN_INVALID` if not. Partial implementation of the filters is not supported; either all the filters are installed into the hardware or none are.

The CAN subsystem defines a macro to create this function table:

```
CYG_CAN_DEVICE_CALLS( tag );
```

That macro creates a function table with `filter_ext()` set to NULL. If extended filters are supported, the driver should use the following macro:

```
CYG_CAN_DEVICE_CALLS_EXT( tag );
```

The *`tag`* argument should match the *`tag`* argument of the `CYG_CAN_DEVICE()` macro. This macro does two things. First it declares static function prototypes for all the driver functions of the form `cyg_can_<tag>_<function>` (e.g. `cyg_can_sja1000_init()` or `cyg_can_flexcan_send()`). Second, it defines a function table called cyg_can_<tag>_calls. The `CYG_CAN_DEVICE()` macro assumes that a function table of this name is defined.

Device Driver API Calls

In addition to the standard device driver API calls defined by the kernel, there are a number of additional CAN specific API calls that a device driver must use to interact with the CAN subsystem. These functions may only be called from thread level with the DSR lock claimed, or from a DSR. They cannot be called from an ISR.

```
cyg_can_msg *cyg_can_tx_done( cyg_can_device *can_dev, cyg_can_msg *msg );
```

This must be called when a transmission is completed. For polled drivers it should be called from the `send()` function while for interrupt driven drivers it should be called from the *`poll()`* routine invoked from the driver's DSR. The function is called with a pointer to the transmitted message buffer and following this call the message buffer will become the property of the CAN subsystem and may be returned to the free pool. The return value from this function will a pointer be another message buffer to transmit, or NULL. The driver should use the resources recently freed by the completion of the previous transmission to start transmission of this message.

```
cyg_can_msg *cyg_can_rx_buffer( void );
```

This is called by the driver to acquire a message buffer in to which a message will be received. The normal approach is to allocate a buffer during driver initialization and to keep at least one pending buffer available at all times. New buffers will usually be passed back to the running driver by the `cyg_can_rx_done()` function.

```
cyg_can_msg *cyg_can_rx_done( cyg_can_device *can_dev, cyg_can_msg *msg );
```

This must be called when a driver has a completed message buffer to return to the user. This buffer may either contain a received message, or may be reporting a channel event. This call is made with a pointer to the message buffer to be returned. Following this call the message buffer becomes the property of the CAN subsystem. The return value of this function will be a pointer to a message buffer to replace the one just passed back. Thus with one call the driver both gives up an old buffer and gets a new one to use in its place.

It is possible for `cyg_can_rx_done()` to return a NULL pointer if there are currently no more buffers available. The driver must therefore be able to handle this. The usual approach is to check, just before it is needed, for a current pending buffer. If no buffer is present then call `cyg_can_rx_buffer()` and if this returns NULL then take action to, for example, throw the message away.

```
typedef struct
{
    cyg_uint8           tseg1_min;      // Time segment 1 = prop+phase1
    cyg_uint8           tseg1_max;
    cyg_uint8           tseg2_min;      // Time segment 2 = phase2
    cyg_uint8           tseg2_max;
    cyg_uint16          divider_min;    // Clock quantum divider
    cyg_uint16          divider_max;
} cyg_can_bitrate_param;

typedef struct
{
    // Input parameters
    cyg_uint32          clock;          // System input clock in Hz
    // Input/Output parameters
    cyg_uint32          bitrate;        // Target bit rate in Hz
                                        // Must be set on input
                                        // Updated with actual rate set

    cyg_uint16          sample;         // Sample point in tenths of a percent
                                        // If zero, CIA recommended value used
                                        // Updated with actual sample point

    // Output calculated values
    cyg_uint8           prop;           // Propogation segment in quanta
    cyg_uint8           phase1;         // Phase segment 1 in quanta
    cyg_uint8           phase2;         // Phase segment 2 in quanta
    cyg_uint16          divider;        // Clock divider

} cyg_can_bitrate;

int cyg_can_calculate_bitrate(  const cyg_can_bitrate_param *param,
                                cyg_can_bitrate             *bitrate );
```

The function `cyg_can_calculate_bitrate` may be called from the driver to calculate the timing values for a given bit rate.

The *`param`* argument contains details of the bit timing hardware in the device, mainly derived from the field widths in the timing register(s). These details comprise minimum and maximum values for *`tseg1`* (propogation segment plus phase segment one), *`tseg2`* (phase segment two) and the quantum clock *`divider`*.

The *`bitrate`* argument must have the input *`clock`* and target *`bitrate`* set. The *`sample`* point must either be set, or zeroed for a CIA recommended value to be chosen. On return the fields *`prop`*, *`phase1`* and *`phase2`* will be set to the quantum counts calculated for each segment. The *`divider`* field will set to the calculated divider. The *`bitrate`* and *`sample`* fields will be updated with the actual bit rate and sample point.

This function will either return `CYG_CAN_NOERROR` if a valid set of timing values have been calculated, or `CYG_CAN_INVALID` if no values could be found. The routine will attempt to find values that give the closest match to the bitrate and sample point requested. If an exact match is found for both, that setting is returned. If no exact match is found, success is only reported if the calculated bitrate is within 5% of the requested rate.

Most drivers should be able to use the values returned by this routine directly. Most CAN devices have one or two registers that contain fields that are directly analogous to these values. All that is needed is for them to be shifted in to position. Quanta are divided more or less equally between *`prop`* and *`phase1`*. However, some hardware may combine these values into a single field or have different sized fields for each. In these cases then the driver may need to add them together, or move some quanta from one to another to match the hardware.

Configuration

The only direct configuration requirement on device drivers is that for each channel supported, the driver should have an "implements CYGINT_IO_CAN_DRIVER" statement to ensure that the correct number of message buffers are available. The name of the channels should also be defined in the CDL. A minimal CDL file for the XYZZY driver would be as follows:

```
cdl_package CYGPKG_DEVS_CAN_XYZZY {
    display       "XYZZY CAN driver"
    description   "XYZZY CAN driver."

    parent        CYGPKG_IO_CAN
    active_if     CYGPKG_IO_CAN

    include_dir   cyg/devs/can

    compile -library=libextras.a xyzzy.c

    cdl_component CYGPKG_DEVS_CAN_CHANNEL0 {
        display   "CAN channel 0 configuration"
        default_value 1
        implements    CYGINT_IO_CAN_DRIVER

       cdl_option CYGPKG_DEVS_CAN_CHANNEL0_NAME {
            display       "CAN channel 0 name"
            flavor        data
            default_value { "\"can0\"" }
            description   "Name of CAN channel 0"
        }
    }

    cdl_component CYGPKG_DEVS_CAN_CHANNEL1 {
        display   "CAN channel 1 configuration"
        default_value 1
        implements    CYGINT_IO_CAN_DRIVER

        cdl_option CYGPKG_DEVS_CAN_CHANNEL1_NAME {
            display       "CAN channel 1 name"
            flavor        data
            default_value { "\"can1\"" }
            description   "Name of CAN channel 1"
        }

    }

    # Further entries for extra channels would go here

}
```

If the driver is multi-platform, then the channel configurations should go into the second platform specific package which may also need to define suitable configuration options to customize the generic driver.

Driver Template

The following example show the general structure of a CAN device driver for a fictional XYZZY device.

The first thing we need to do is to define the data structures that interface the device to the CAN subsystem:

```
#include <pkgconf/hal.h>
#include <pkgconf/io_can.h>
#include <pkgconf/devs_can_xyzzy.h>

#include <cyg/io/can_dev.h>

//=============================================================================
// Define private data structure. At the very least this needs to
// contain the base address of the device and the interrupt vector.
// If this is an interrupt driven device, then it will also need to
// contain the data structures to manage the interrupt.

struct cyg_can_xyzzy_priv
{
    cyg_uint32                  devno;          // device number
    CYG_ADDRESS                 base;           // base address
    cyg_vector_t                vector;         // vector number

    cyg_can_msg                 *tx_msg;        // current tx message buffer
    cyg_can_msg                 *rx_msg;        // pending rx message buffer

    cyg_handle_t                interrupt_handle;
    cyg_interrupt               interrupt_object;

    // Further device fields here
};
```

```
//=============================================================================
// Define device function call table. This should be done before the
// CYG_CAN_DEVICE() macro is called.

CYG_CAN_DEVICE_CALLS( xyzzy );

//=============================================================================
// Define driver-private structures for each of the channels. For this
// example we define just two.

#ifdef CYGPKG_DEVS_CAN_CHANNEL0
struct cyg_can_xyzzy_priv cyg_can_xyzzy_drv_0 =
    { 0, CYGARC_HAL_XYZZY_BASE_CAN_0, CYGNUM_HAL_INTERRUPT_CAN_0 };
#endif
#ifdef CYGPKG_DEVS_CAN_CHANNEL1
struct cyg_can_xyzzy_priv cyg_can_xyzzy_drv_1 =
    { 1, CYGARC_HAL_XYZZY_BASE_CAN_1, CYGNUM_HAL_INTERRUPT_CAN_1 };
#endif

//=============================================================================
// Define CAN device table entries.

#ifdef CYGPKG_DEVS_CAN_CHANNEL0
CYG_CAN_DEVICE( xyzzy, can0, CYGPKG_DEVS_CAN_CHANNEL0_NAME, cyg_can_xyzzy_drv_0 );
#endif
#ifdef CYGPKG_DEVS_CAN_CHANNEL1
CYG_CAN_DEVICE( xyzzy, can1, CYGPKG_DEVS_CAN_CHANNEL1_NAME, cyg_can_xyzzy_drv_1 );
#endif
```

The first thing that needs writing is the initialization routine:

```
static int cyg_can_xyzzy_init(cyg_can_device *dev)
{
    int result = CYG_CAN_NOERROR;
    struct cyg_can_xyzzy_priv *priv = (struct cyg_can_xyzzy_priv *)dev->private;

    // Locate, validate and initialize the channel hardware. This
    // may include setting up the acceptance filter to accept all IDs
    // and setting the baud rate to a default (100kHz say).

    // Install interrupt handlers

    cyg_drv_interrupt_create( priv->vector,
                              0,
                              (CYG_ADDRWORD)dev,
                              cyg_can_xyzzy_isr,
                              cyg_can_xyzzy_dsr,
                              &priv->interrupt_handle,
                              &priv->interrupt_object );
    cyg_drv_interrupt_attach( priv->interrupt_handle );
    cyg_drv_interrupt_unmask( priv->vector );

    // Perform any final initialization, for example clearing and then
    // enabling interrupts in the channel.

    // Allocate a pending buffer for message receive.
    priv->rx_msg = cyg_can_rx_buffer();

    return result;
}
```

The open and close routines come next. Most drivers don't need to do much here so these examples are the minimum necessary:

```
static int cyg_can_xyzzy_open(cyg_can_device *dev)
{
    return CYG_CAN_NOERROR;
}

static int cyg_can_xyzzy_close(cyg_can_device *dev)
{
    return CYG_CAN_NOERROR;
}
```

The send routine is responsible for actually transmitting a message:

```
static int cyg_can_xyzzy_send(cyg_can_device *dev, cyg_can_msg *msg)
{
    struct cyg_can_xyzzy_priv *priv = (struct cyg_can_xyzzy_priv *)dev->private;

    // If there is still a current tx message or the transmit hardware
    // is still busy, return busy so that the upper levels will
    // queue this request.
    if( priv->tx_msg != NULL || xyzzy_tx_busy( priv ) )
        return CYG_CAN_BUSY;

    // Record current transmit packet
    priv->tx_msg = msg;

    // Write the message header and ID to be sent into the channel
    // transmit buffer, ensuring that the length and the IDE bit is
    // set correctly, and the ID is correct.

    // If the RTR flag is not set, install the data in the transmit
    // buffer. If the RTR flag is set, do not install the data and set
    // the RTR bit in the frame info.

    // Start the transmission.

    // Return CYG_CAN_WAIT to cause the sending thread to wait for completion.

    return CYG_CAN_WAIT;
}
```

The following routine is internal to the driver, it is called from the `poll()` routine to actually receive a message into a buffer:

```
static int cyg_can_xyzzy_recv(cyg_can_device *dev, cyg_can_msg *msg)
{
    int result = CYG_CAN_NOERROR;
    struct cyg_can_xyzzy_priv *priv = (struct cyg_can_xyzzy_priv *)dev->private;
    cyg_ucount8 ide, rtr, len;
    cyg_uint32 id = 0;

    // Get the message frame header and decode it into some locals:
    // ide, rtr, len and id.

    // If we have a message buffer, move the message out into it.

    if( msg != NULL )
    {
        msg->ide = ide;
        msg->rtr = rtr;
        msg->len = len;
        msg->id  = id;

        if( !rtr )
        {
            // Copy data from receive frame into message buffer.
        }
    }
    else
    {
            // Do whatever is needed to throw the message away since
            // there is no buffer available.
    }

    // Do whatever is needed to release the receive buffer and ready
    // it for a new message and/or cancel the interrupt.

    return result;
}
```

The `poll()` handles most of the asynchronous events:

```
static int cyg_can_xyzzy_poll(cyg_can_device *dev)
{
    int result = CYG_CAN_NOERROR;
    struct cyg_can_xyzzy_priv *priv = (struct cyg_can_xyzzy_priv *)dev->private;

    // If there is a pending transmission and the hardware channel
    // indicates that it is finished, then call cyg_can_tx_done().

    if( priv->tx_msg != NULL && xyzzy_tx_done( priv ) )
    {
        cyg_can_msg *msg = priv->tx_msg;

        priv->tx_msg = NULL;
        msg = cyg_can_tx_done( dev, msg );

        // If we have been passed a new message to transmit, send it.
        if( msg != NULL )
            cyg_can_xyzzy_send( dev, msg );
    }

    // While there are messages available in the receive buffer or
    // FIFO, pull them out and pass them back to the CAN subsystem.

    while( xyzzy_rx_done( priv ) )
    {
        // If there is no current rx buffer, try to allocate one here.
        if( priv->rx_msg == NULL )
            priv->rx_msg = cyg_can_rx_buffer();

        // Either receive the message, or clear the channel.
        cyg_can_xyzzy_recv( dev, priv->rx_msg );

        // If we have a buffer, pass it back.
        if( priv->rx_msg != NULL )
            priv->rx_msg = cyg_can_rx_done( dev, priv->rx_msg );
    }

    // See if any other CAN channel events have occurred.

    if( xyzzy_event( priv ) )
    {
        // Decode the event and set result to an appropriate error
        // code.

        // Return a message buffer recording this event. As above, we
        // may need to allocate a fresh buffer if none is available.

        if( result != CYG_CAN_NOERROR )
        {
            if( priv->rx_msg == NULL )
                priv->rx_msg = cyg_can_rx_buffer();

            if( priv->rx_msg != NULL )
            {
                priv->rx_msg->result = result;
                priv->rx_msg = cyg_can_rx_done( dev, priv->rx_msg );
            }
            result = CYG_CAN_NOERROR;
        }
    }

    return result;
}
```

The simplest form for the ISR is for it to just mask the channel's interrupt vector and cause the DSR to run. The DSR can then simply call `cyg_can_xyzzy_poll()` to handle the channel events. Alternatively, the ISR could handle the hardware, but the DSR still needs to be run to call `cyg_can_tx_done()`, `cyg_can_rx_done()` and `cyg_can_rx_buffer()`.

```
static cyg_uint32 cyg_can_xyzzy_isr(cyg_vector_t    vector,
                                    cyg_addrword_t  data)
{
    cyg_can_device *dev = (cyg_can_device *)data;

    // Block interrupts from this device until the DSR is run
    cyg_drv_interrupt_mask( vector );

    // Ack the interrupt in the system interrupt controller
    cyg_drv_interrupt_acknowledge( vector );

    // Pass handling on to DSR
    return (CYG_ISR_HANDLED|CYG_ISR_CALL_DSR);
}

static void cyg_can_xyzzy_dsr(cyg_vector_t    vector,
                              cyg_ucount32    count,
                              cyg_addrword_t  data)
{
    cyg_can_device *dev = (cyg_can_device *)data;

    // Poll hardware for pending events
    cyg_can_xyzzy_poll( dev );

    // Re-allow device interrupts
    cyg_drv_interrupt_unmask( vector );
}
```

Finally, the filter and baud rate functions are very simple:

```
static int cyg_can_xyzzy_filter(cyg_can_device  *dev,
                                cyg_bool        ide,
                                cyg_uint32      match,
                                cyg_uint32 mask)
{
    int result = CYG_CAN_NOERROR;
    struct cyg_can_xyzzy_priv *priv = (struct cyg_can_xyzzy_priv *)dev->private;

    // Set the hardware filter to match the parameters. If the
    // hardware filter cannot be used, return CYG_CAN_NOERROR anyway,
    // since filtering will also be done in the CAN subsystem.

    return result;
}

static int cyg_can_xyzzy_filter_ext(cyg_can_device  *dev,
                                    cyg_can_filter  *filter,
                                    int             len)
{
    int result = CYG_CAN_NOERROR;
    struct cyg_can_xyzzy_priv *priv = (struct cyg_can_xyzzy_priv *)dev->private;

    // Set the extended filters to match the parameters. If the
    // hardware filter cannot be used, return CYG_CAN_INVALID, only
    // return CYG_CAN_NOERROR if all filters can be installed.
    return result;
}

static int cyg_can_xyzzy_baud(cyg_can_device  *dev,
                              cyg_uint32      baud)
{
    int result = CYG_CAN_NOERROR;
    struct cyg_can_xyzzy_priv *priv = (struct cyg_can_xyzzy_priv *)dev->private;

    // Set the baud rate, which may involve checking that the
    // requested rate is supported. If not the return
    // CYG_CAN_INVALID.

    result = cyg_can_xyzzy_set_baudrate( priv, baud );

    return result;
}
```

Chapter 91. NXP FlexCAN CAN Driver

Name

FlexCAN — CAN Driver

Description

This driver supports the FlexCAN CAN devices available in some NXP i.MXRT microprocessors.

Filter

The device provides filtering support that is compatible with the filter model defined by the CAN subsystem, and therefore hardware filtering is employed.

Baud Rates

The following baud rates are supported: 1Mb/s, 500kb/s, 250kb/s, 125kb/s, 100kb/s, 50kb/s, and 20kb/s.

Configuration

This driver requires an external package to configure it for the particular microcontroller, normally the platform (`PLF`) or variant (`VAR`) HAL. Each CAN channel is then implemented by a controller instance as specified.

For each channel # supported the CDL script in this package will provide the following configuration options:

cdl_component CYGPKG_DEVS_CAN_CHANNEL#

> This defines whether the channel is included. It depends on the associated `FLEXCAN` controller being implemented for the platform.
>
> ### Note
>
> The CAN channels are numbered logically from 0, whereas the physical FLEXCAN controllers are numbered from 1. So if the platform supports the `FLEXCAN2` controller the correspoding CAN channel device name will be *`"can1"`* by default.

cdl_option CYGPKG_DEVS_CAN_CHANNEL#_NAME

> This defines the name of the channel. This is the name that an eCos application should use to access the device via the I/O API.

cdl_option CYGPKG_DEVS_CAN_CHANNEL#_INTERRUPT_PRI

> This option defines the interrupt priority for the `FLEXCAN` controller interrupts.

cdl_option CYGPKG_DEVS_CAN_CHANNEL#_MB_RX

> This option defines the number of MailBox (MB) slots available for use as RX buffers. The minimum acceptable setting allowed being 2 dedicated RX buffers. However, for normal application configurations it is expected that more RX buffers will be required than TX buffers, so the default reflects such “normal” ratio.
>
> The number of available TX mailboxes (CYGPKG_DEVS_CAN_CHANNEL#_MB_TX) is calculated as the number of remaining mailboxes after the RX allocation.

cdl_option CYGPKG_DEVS_CAN_CHANNEL#_BITRATE

> This option defines the start-of-day (default) bitrate for the CAN channel.

Chapter 92. FlexCAN CAN Driver

Name

FlexCAN — CAN Driver

Description

This driver supports the FlexCAN CAN devices available in some Freescale Coldfire and PowerPC microprocessors.

Filter

The device provides filtering support that is compatible with the filter model defined by the CAN subsystem, and therefore hardware filtering is employed.

Baud Rates

The following baud rates are supported: 1Mb/s, 800kb/s, 500kb/s, 250kb/s, 125kb/s, 100kb/s, 50kb/s, 20kb/s, 10kb/s.

Configuration

This driver requires an additional package to configure it to the particular microcontroller. For each channel *X* supported the CDL script in this package must provide the following configuration options:

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is included.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

cdl_option CYGNUM_DEVS_CAN_CHANNELX_BASE

> This defines the base address of the CAN channel controller in the memory map. It will typically be an expression involving HAL-defined constants which resolves to the address of the the device.

cdl_option CYGNUM_DEVS_CAN_CHANNELX_VECTOR

> This defines the interrupt vector associated with buffer 0. It is assumed that the vectors for buffers 1..15 follow this, and that the error and bus off interrupt vectors follow these. This will typically be a HAL-defined constant.

Chapter 93. MSCAN CAN Driver

Name

Mscan — CAN Driver

Description

This driver supports the MSCAN CAN devices available in some Freescale Coldfire and PowerPC microprocessors.

Filter

The device provides filtering support that is compatible with the filter model defined by the CAN subsystem, and therefore hardware filtering is employed.

Baud Rates

The following baud rates are supported: 500kb/s, 250kb/s, 125kb/s, 100kb/s, 50kb/s, 20kb/s, 10kb/s.

Configuration

This driver requires an additional package to configure it to the particular microcontroller. For each channel *X* supported the CDL script in this package must provide the following configuration options:

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is included.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

cdl_option CYGNUM_DEVS_CAN_CHANNELX_BASE

> This defines the base address of the CAN channel controller in the memory map. It will typically be an expression involving HAL-defined constants which resolves to the address of the the device.

cdl_option CYGNUM_DEVS_CAN_CHANNELX_VECTOR

> This defines the interrupt vector associated with buffer 0. It is assumed that the vectors for buffers 1..15 follow this, and that the error and bus off interrupt vectors follow these. This will typically be a HAL-defined constant.

Chapter 94. LPC2XXXX CAN Driver

Name

LPC2XXX — CAN Driver

Description

This driver supports the CAN devices available in some variants of the Philips LPC2XXX family of microprocessors. The device itself is similar to the the SJA1000, but is sufficiently different that the drivers cannot be shared.

Filter

The filter mechanism present in the LPC2XXX CAN devices is not compatible with the filter model adopted by the CAN subsystem. Consequently the hardware filter is not used and only software filtering is applied.

Baud Rates

The following baud rates are supported: 1Mb/s, 800kb/s, 500kb/s, 250kb/s, 125kb/s, 100kb/s, 50kb/s, 20kb/s, 10kb/s.

Configuration

For each channel *X* supported the CDL script provides the following configuration options:

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is included. For channels 2 and 3 the default value is conditional on the LPC2XXX variant.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

Chapter 95. Atmel SAM CAN Driver

Name

Atmel SAM — CAN Driver

Description

This driver supports the CAN devices available in some variants of Atmel's SAM4, SAM7, SAM9 and SAMA5 microprocessor families.

Filter

The filter mechanism present in the SAM4/7/9 and SAMA5 CAN devices is not compatible with the filter model adopted by the CAN subsystem. Consequently the hardware filter is not used and only software filtering is applied.

Baud Rates

The following baud rates are supported: 1Mb/s, 800kb/s, 500kb/s, 250kb/s, 125kb/s, 100kb/s, 50kb/s, 20kb/s and 10kb/s. However, the accuracy of baud rates that can be supported at any particular MCLK frequency depend on the resolution of the baud rate divisor.

Configuration

For each channel *X* supported the CDL script provides the following configuration options:

cdl_interface CYGINT_DEVS_CAN_CHANNELX

> This determines whether the given channel is available on the board. It is usually implemented by the platform HAL.

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is active. It will default to active for all channels whose corresponding interface is implemented, but may be disabled by the user.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_MBOX_COUNT

> This defines the number of mailboxes supported by the device. This is usually eight or sixteen. The HAL for the microprocessor variant will usually set this value during configuration.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_EXT

> If set this option configures this channel to receive extended, 29 bit, identifiers as well as standard, 11 bit, identifiers. Otherwise it receives only 11 bit identifiers. The default is to receive both message types.

At present there is support for up to two channels.

Chapter 96. Atmel MCAN CAN Driver

Name

Atmel MCAN — CAN Driver

Description

This driver supports the CAN devices available in some variants of Atmel's SAMX70 microprocessor families.

In addition to standard CAN messages, this device is capable of handling CAN-FD messages.

Filter

At present the hardware filter is not used and only software filtering is applied.

Baud Rates

All standard baud rates are supported. However, the accuracy of baud rates that can be supported at any particular MCLK frequency depend on the resolution of the baud rate divisor.

At present autobaud is not supported.

Configuration

For each channel *X* supported the CDL script provides the following configuration options:

cdl_interface CYGINT_DEVS_CAN_CHANNELX

> This determines whether the given channel is available on the board. It is usually implemented by the platform HAL.

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is active. It will default to active for all channels whose corresponding interface is implemented, but may be disabled by the user.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_BITRATE

> This defines the default bitrate at which the channel will start.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_BITRATE_FD

> This defines the default fast data bitrate at which the channel will start.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_RX_FIFO_SIZE

> This defines the number of receive buffers in RX FIFO 0. Only FIFO 0 is currently used.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_TX_BUF_COUNT

> This defines the number of transmit buffers and the number of entries in the transmit event FIFO.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_

cdl_option CYGPKG_DEVS_CAN_CHANNELX_EXT

> If set this option configures this channel to receive extended, 29 bit, identifiers as well as standard, 11 bit, identifiers. Otherwise it receives only 11 bit identifiers. The default is to receive both message types.

At present there is support for up to two channels.

Chapter 97. SJA1000 CAN Driver

Name

SJA1000 — CAN Driver

Description

This driver supports the Philips SJA1000 CAN device. As a stand-alone device, the SJA1000 may be connected to the target system by a variety of mechanisms, including direct connection, PCI bus, ISA bus or USB. This driver is structured to support any of these methods, although not all are currently implemented.

Access Methods

At present only Peak PCAN-PCI boards are supported by this driver. As a consequence only the PCI access method is currently implemented and within that, only PCAN-PCI boards are recognised and initialized. New access methods and boards will be added as they become available.

Filter

The device provides filtering support that is compatible with the filter model defined by the CAN subsystem, and therefore hardware filtering is employed.

Baud Rates

The following baud rates are supported: 1Mb/s, 500kb/s, 250kb/s, 125kb/s, 100kb/s, 50kb/s, 20kb/s, 10kb/s.

Configuration

This driver requires an additional package to configure it to the particular microcontroller. For each channel *X* supported the CDL script in this package must provide the following configuration options:

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is included. For channels 2 and 3 the default value is conditional on the SJA1000 variant.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

In addition to the above options, each channel should contain the following **implements** or **requires** commands, as appropriate:

implements CYGINT_DEVS_CAN_SJA1000_REQUIRED

> This adds to the count of SJA1000 devices implemented by the driver.

implements CYGINT_DEVS_CAN_SJA1000_PCI

> This adds to the count of SJA1000 PCI-based devices implemented by the driver. If the SJA1000 is accessed through a PCI device then this interface should be implemented.

Chapter 98. BXCAN CAN Driver

Name

BXCAN — CAN Driver

Description

This driver supports the BXCAN devices available in some variants of the ST STM32 family of microprocessors.

Filter

Hardware filtering is used to provide the standard CAN subsystem filtering semantics.

Baud Rates

The following baud rates are supported: 1Mb/s, 500kb/s, 250kb/s, 125kb/s, 100kb/s, 50kb/s. However, the accuracy of baud rates that can be supported at any particular PCLK1 frequency depend on the resolution of the baud rate divisor.

Configuration

For each channel *X* supported the CDL script provides the following configuration options:

cdl_component CYGINT_DEVS_CAN_CHANNELX

> This interface should be implemented by the platform HAL for each channel that is connected to a CAN bus or socket on the board.

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is initialized. By default this depends on `CYGINT_DEVS_CAN_CHANNELX`.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

Chapter 99. STR7XX CAN Driver

Name

STR7XX — CAN Driver

Description

This driver supports the CAN devices available in some variants of the ST STR7XX family of microprocessors.

Filter

The filter mechanism present in the STR7XX CAN devices is not compatible with the filter model adopted by the CAN subsystem. Consequently the hardware filter is not used and only software filtering is applied.

Baud Rates

The following baud rates are supported: 1Mb/s, 500kb/s, 250kb/s, 125kb/s, 100kb/s. However, the accuracy of baud rates that can be supported at any particular PCLK1 frequency depend on the resolution of the baud rate divisor.

Configuration

For each channel *X* supported the CDL script provides the following configuration options:

cdl_component CYGPKG_DEVS_CAN_CHANNELX

> This defines whether the channel is included. For channels 2 and 3 the default value is conditional on the STR7XX variant.

cdl_option CYGPKG_DEVS_CAN_CHANNELX_NAME

> This defines the name of the channel.

At present, only one channel, 0, is supported.

Part XXVIII. Coherent Connection Bus

Table of Contents

Chapter 100. Coherent Connection Bus overview

Introduction

The CYGPKG_COHERENT_CCB package implements support for Coherent Connection Bus (CCB) communications. This enables eCos-based systems to communicate with and control compatible members of Coherent's range of laser products.

The package provides an API for applications to send and receive messages from an eCos-based master to slave devices over the CCB. Familiarity with CCB and the relevant specifications is assumed in the following documentation.

The implementation is based on the relevant sections of the Coherent's “Integrator's Guide Coherent OBIS“ document (Part No. 1215508 Rev. AB - CoherentOBIS_IntegratorsGuide_1215508RevAB.pdf).

The CCB package features:

- CCB packet driver interface support
- Master device support
- Example applications

The eCos CCB backend interface is transport agnostic, though CCB is normally routed over an RS-485 connection. The configured target must provide a suitable platform/variant hardware package implementing the necessary low-level hardware I/O support. The CCB support relies on the platform specific CDL forcing any per-device configuration to ensure a 921600 baud 8N1 connection for the underlying serial (RS-485) communications.

Chapter 101. Configuration

This chapter shows how to incorporate the CCB support into an eCos configuration, and how to configure it once included.

Configuration Overview

The CCB support is contained in a single eCos package `CYGPKG_IO_CCB`. However, it depends on the services of a collection of other packages for complete functionality. For example, the `CYGPKG_KERNEL`, `CYGPKG_ERROR` and `CYGPKG_IO_FILEIO` packages.

Quick Start

Incorporating the CCB support into your application is straightforward. The essential starting point is to incorporate the CCB eCos package (`CYGPKG_COHERENT_CCB`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Depending on the CCB package configuration other packages may be required (e.g. UART device driver support). The package requires that the `CYGPKG_KERNEL` and `CYGPKG_ERROR` packages are included in the eCos application configuration.

It is recommended to include the `CYGPKG_IO_FILEIO` package for `select()` functionality to allow client-applications to avoid having to use a busy message read loop.

Configuring the CCB memory footprint

CYGNUM_IO_CCB_SIZE_MSG

This option defines the maximum size of message that can be received, and should include space for the standard message header. The default value caters for the maximum possible message size. For low-memory targets or where the maximum message sizes are fixed and known for all bus nodes, then this option can be tuned to minimise the memory footprint. Any messages that exceed this configured size will be dropped.

The value of this option is used to define the buffer sizes required by the low-level I/O driver to accept packets.

CYGNUM_IO_CCB_RECV_PKTS

This option defines the maximum number of pending received messages that can be queued for the client application. As per the Coherent Connection Bus Protocol “Only complete messages are buffered; if there is not enough buffer space remaining for a new message, the message will be discarded”. This option can be tuned to reflect the ability of the client application to read and process messages, against the memory footprint required for each descriptor.

Configuring the CCB control thread

CYGNUM_COHERENT_CCB_CONTROL_STACK_SIZE

The CCB subsystem uses an internal thread to handle asynchronous actions and to process packet reception. This option defines the *ADDITIONAL* size that is added to the variant `CYGNUM_HAL_STACK_SIZE_TYPICAL` setting to define the stack size for this thread.

CYGNUM_COHERENT_CCB_CONTROL_PRIORITY

The CCB subsystem uses an internal thread to handle asynchronous actions. This option defines the priority at which this thread is scheduled. To avoid resource starvation issues it should normally be a higher priority than the thread implementing the CCB client-application.

Configuring the CCB master server

The common CCB server support is enabled by the CYGPKG_IO_CCB_MASTER option. When enabled it provides access to the following relevant options.

CYGNUM_IO_CCB_MASTER_NUM_SLAVES

> This option specifies the maximum number of slave devices supported across all of the physical CCB ports present. This is used to avoid the need for dynamic allocation, but does mean that the value may need to be tuned to reflect the application and variant/platform usage. The maximum of 253 reflects the total unit bus limit. The master will ignore address acquisition requests when the pool of slave descriptors is exhausted.
>
> The default value of 1 reflects the expected use case of a single physical interface (port) with only a single slave device connected to that RS-485 bus. If the implementation provides multiple hardware ports, or expects multiple slaves per hardware port then this configuration option should be updated accordingly.

CYGNUM_IO_CCB_MASTER_MAX_SLAVEID_LEN

> This option specifies the maximum length of the per-slave unique identifiers supported. The default is to accept all slaves by using the maximum possible length (this option includes space for the NUL-terminator). For targets with limited memory resources, or where the application is limited to a known set of device identifier lengths, this value can be tuned to save on the run-time memory footprint. Slave devices with identifiers longer than this option will be ignored.

CYGNUM_IO_CCB_MASTER_SLAVE_POLL

> If a message has not been received from an assigned address for the period of time (in seconds) specified by this option then the master CCB stack will issue a PING request to the slave. After the fixed number of retries (CYGNUM_IO_CCB_MASTER_SLAVE_POLL_ATTEMPTS) without a response a slave is considered disconnected.

Note

An eCos CCB package extension disables the slave polling if this option is set to zero (0). Such a configuration would not be conformant with the CCB protocol definition.

CYGNUM_IO_CCB_MASTER_SLAVE_POLL_WAIT

> This option defines the period (in seconds) that the master CCB stack will wait between PING requests. A slave is declared disconnected if no response is received after CYGNUM_IO_CCB_MASTER_SLAVE_POLL_ATTEMPTS.

Chapter 102. API Overview

The main client-application access to CCB functionality is via the common named device /dev/ccb. It is the responsibility of the client-application to open a handle onto this common device, and then to read and write messages as appropriate.

The common layer will automatically start the protocol control thread and use the standard eCos cyg_io interface connection to the specific CCB interface (hardware port) device drivers.

For CYGPKG_IO_FILEIO configurations the client-application can use the open(), write(), read() and select() functions. If CYGPKG_IO_FILEIO is not configured then the standard cyg_io_lookup(), cyg_io_read() and cyg_io_write() function interface is used.

Note

The client-application writes to the CCB are *always* blocking. The read operations can be configured as non-blocking if required, and if CYGPKG_FILEIO select() support is configured will default to non-blocking operation.

The common and driver-specific CCB packages also provide access to some GET/SET operations that can be accessed via the relevant cyg_fs_fgetinfo/cyg_fs_fsetinfo or cyg_io_get_config/cyg_io_set_config functions. The “*key*” values supported are:

CYG_IO_GET_CONFIG_PENDING_MESSAGES

This *key* allows a snapshot view of the number of pending client-application RX messages.

Note

As packet reception might occur during calls to this config operation, the information returned may already be stale. If the thread reading this count is the only thread reading messages then this value can be viewed as the minimum number of messages pending. i.e. the client-application should always be able to read the returned number of messages.

A client-application using select() to do a non-busy wait for a message should not normally need to worry about the number of pending messages. This config *key* support is provided to correspond with the functionality described by the CCB protocol documentation.

CYG_IO_GET_CONFIG_CCB_STATISTICS

This option allows, where provided by the underlying hardware interface port driver, sets of statistics to be monitored. The <cyg/io/ccb_port.h> header file defines the cyg_ccb_devio_stats_t structure used to hold RX and TX information for a specific device driver. This config *key* functionality uses the <cyg/io/ccb.h> header file defined cyg_ccb_io_stats_t structure to step through the available interface statistics.

The initial cyg_ccb_io_stats_t.priv_ctx field should be initialised to NULL, and then this *key* config call repeated until the common CCB support returns cyg_ccb_io_stats_t.priv_ctx == NULL (indicating no more data). As per the following pseudocode example:

```
cyg_ccb_io_stats_t stats;
cyg_bool moredata = true;

stats.priv_ctx = NULL; // start

do {
  int res = cyg_fs_fgetinfo(pcapp->fd,CYG_IO_GET_CONFIG_CCB_STATISTICS,&stats,sizeof(stats));
  if (res < 0) {
    diag_printf("FAIL:<Get statistics error %d \"%s\">\n",res,strerror(errno));
    moredata = false;
  }
  if (moredata) {
    moredata = (stats.priv_ctx != NULL);
    if (moredata) {
      diag_printf("Device \"%s\" : RX pkts=%u (bytes=%llu) dropped=%u : TX pkts=%u (bytes=%llu) retrans=%u failed=
                  stats.dname,
                  stats.dstats.rx_pkts,
                  stats.dstats.rx_bytes,
                  stats.dstats.rx_pkts_dropped,
                  stats.dstats.tx_pkts,
                  stats.dstats.tx_bytes,
                  stats.dstats.tx_pkts_retrans,
                  stats.dstats.tx_pkts_failed);
    }
  }
} while (moredata);
```

When using a `cyg_io_handle_t` reference to the common CCB layer then the example above would use the corresponding `cyg_io` interface:

```
  Cyg_ErrNo res = cyg_io_get_config(pcapp->handle,CYG_IO_GET_CONFIG_CCB_STATISTICS,&stats,&slen);
```

CYG_IO_SET_CONFIG_CCB_BUS_RESET

Normally the client-application should not need to force a global bus reset. The common CCB layer performs a bus reset as part of the normal application startup. This config “key” may be useful during testing/development, or if an unrecoverable error is detected.

There is also a minimal function call API providing some “stateless“ message helper routines.

Application support API

These functions are available for the client-application to aid in message processing.

See the Testing section's `ccb_master` test client-application for an example of access to the `/dev/ccb` and use of these functions.

Name

cyg_ccb_build_message — Construct message

Synopsis

#include <cyg/io/ccb.h>

cyg_uint32 **cyg_ccb_build_message**(*msg*, *slave_addr*, *tag*, *cmdreq*);

Description

This function allows a standard client-application message to be constructed. The *msg* parameter is used to reference a message object to be filled. The *slave_addr* and *tag* parameters describe the destination address and client-application “message tracking number” respectively. The final parameter *cmdreq* is the NUL-terminated ASCII command or request. The passed *cmdreq* string should *NOT* contain a terminating CR (Carriage-Return). Any command/request terminators needed are added by this function.

The following pseudocode example shows the use of the function to construct a message and then send this message via the write function to a previously opened CCB handle.

```
cyg_uin32 mlen = cyg_ccb_build_message(msg,slave_addr,tag,"*IDN0?");
if (mlen) {
  write(fd,msg,mlen);
} else {
  raise_error();
}
```

Return value

The function returns the total number of bytes written to the passed *msg* buffer, or zero (`0`) if an error is detected.

Name

cyg_ccb_check_response — Check response

Synopsis

#include <cyg/io/ccb.h>

`cyg_bool` **`cyg_ccb_check_response`**`(`*`response`*`, `*`rlen`*`, `*`ecode`*`);`

Description

This helper function allows standard CCB client-application message responses to be parsed. The *`response`* is a pointer to the response data to be processed, with the *`rlen`* specifying the number of bytes (characters) of data valid in the supplied *`response`* buffer.

Responses are expected to be either the non-error “OK\r” or an error number indicated “ERR#\r” form (where # is either a positive or negative decimal number).

If non-NULL then the *`ecode`* parameter references the location updated with the “ERR” response error number, or the value `0` if an “OK”: response is given.

Return value

The boolean `true` result indicates that a valid response string was supplied. The return value of `false` indicates that the string was malformed (possibly a data reply and not a response string after all).

I/O Device Driver Interface

The header file `<cyg/io/ccb_devio.h>` defines the interface between the common CCB support and the target specific device drivers. The device drivers provide the physical CCB packet communication support.

Physical connections are supplied to the common layer via the relevant target/platform defining a `cyg_ccb_port_instance_t` structure (via the `CCB_PORT()` macro), which provides the mapping to the relevant low-level hardware I/O driver via the supplied named device.

The `cyg_ccb_devio_port_t` structure defines a hardware port instance (i.e. a physical RS-485 hardware interface) driver in conjunction with a standard I/O driver device descriptor `DEVTAB_ENTRY()` definition. A driver normally instantiates itself via the `CCB_DEVIO_PORT()` macro to populate a `cyg_ccb_devio_port_t` structure.

The device drivers interface with the CCB common layer via the `cyg_ccb_devio_funs_t` and `cyg_ccb_callbacks_t` structures implemented by the `src/ccb_devio.c` support.

The device drivers fundamentally provide a per-port blocking transmit function, and asynchronous packet reception. The driver calls back into the common CCB layer via the (DSR context) `cyg_ccb_callbacks_t` functions `tx_done()` and `rx_pkt()`.

Chapter 103. Internals

The main CCB protocol control thread is provided by the package's `src/ccb_protocol.c` source file. The control thread loops waiting for event flags indicating that some CCB processing is required.

The main tasks of the control loop are monitoring slave packet reception timing and polling slaves as configured, to ensure they are still connected, and processing asynchronous RX packets from any of the available hardware ports. The CCB bus management messages are handled by this control loop; and validated client-application messages are forwarded to the client-application via a RX message queue for the client-application to use via the relevant read interface. The bus management code can also inject locally generated slave connect/disconnect messages into this RX queue for processing by the client-application (as per the CCB design).

The `src/ccb_protocol.c` source also implements the I/O driver layer used to present the “/dev/ccb” named device, used by the client-application to allow messages to be sent and received. This works in conjunction with the `src/ccb_devio.c` source that provides the basic message<->packet framing/deframing support.

Chapter 104. Debug and Test

Debugging

Asserts

If the target platform resources allow, then the first step in debugging should be to enable ASSERTs. The inclusion of assert checking will increase the code footprint and lower the performance, but does allow the code to catch internal errors from unexpected data values. e.g. when the application/client is not able to guarantee the validity of data passed into the CCB code.

The CCB asserts are controlled via the standard eCos Infrastructure CYGPKG_INFRA package CYGDBG_USE_ASSERTS option. If enabled then run-time assertion checks are performed by the CCB package.

If assertions are enabled and a debugger is being used, it is normally worthwhile setting a breakpoint at start-up on the cyg_assert_fail symbol. The debugger will then stop prior to entering the default busy-loop assert processing.

Diagnostic Output

In conjuction with the CYGDBG_COHERENT_CCB_DEBUG CDL configuration setting and its sub-options, the header-file src/ccb_diag.h implements the CCB I/O package specific debug control.

When CYGDBG_COHERENT_CCB_DEBUG is enabled a set of individually selectable sub-systems are available to control the diagnostic output generated.

However, when developing or debugging the CCB implementation it may be simpler (with less build side-effects) to control the debugging output via direct uncommenting of the necessary manifests at the head of the src/ccb_diag.h source file, than re-configuring the complete eCos configuration via the CDL. This approach will limit rebuilding to just the CCB package.

Note

When enabled, some diagnostic output may adversely affect the operation of the CCB support as seen by 3rd-party code. For example, “slow” serial diagnostic output of the packet parsing and response generation could mean that a significant amount of time passes, such that the CCB support no longer adheres to the timeout limits imposed by external code.

Testing

The configuration option CYGPKG_IO_CCB_TESTS defines a set of tests that are built.

By default the package will only build the deterministic, automatic, tests. However, the option CYGPKG_IO_CCB_TESTS_MANUAL can be defined to build extra tests that may require manual user-intervention, or are more realistic real-world example applications.

ccb_ut

The ccb_ut test application performs some unit-testing of the CCB implementation. The test assumes specific features of the tests/ccb_master.c example client-application to perform a variety of fixed tests.

The ccb_ut implements a software driver which can be used to simulate a bus, without the requirement for the configuration to have access to a physical RS-485 bus. This is used to test core MASTER CCB client-application functionality.

Note

It is recommended that before executing this test that you disconnect any physical hardware.

Currently not all aspects of the CCB protocol are exercised by the test.

ccb_master

The ccb_master is a simple example client-application that could form the basis of an actual customer implementation. The test does not automatically exit (and hence is unsuitable for the eCosCentric automated test farm).

The application currently just waits for a slave to connect, and then issues a fixed set of queries to the slave.

Part XXIX. STM32 Coherent Connection Bus Driver

Table of Contents

Chapter 105. STM32 Coherent Connection Bus Driver overview

Introduction

The CYGPKG_DEVS_CCB_CORTEXM_STM32 package provides a low-level bus driver implementation for use by the Coherent Connection Bus (CCB) CYGPKG_IO_CCB communication package. It provides the device-level API to implement the actual hardware interface support as required. Familiarity with CCB and the relevant specifications is assumed in the following documentation.

The implementation is based on the relevant sections of the Coherent's “Integrator's Guide Coherent OBIS“ document (Part No. 1215508 Rev. AB - CoherentOBIS_IntegratorsGuide_1215508RevAB.pdf).

This driver package provides the I/O connection via the STM32 U(S)ART interfaces. Normally CCB is routed over a half-duplex RS-485 connection. This driver provides software collision detection, with the corresponding TX auto-retry (up to to an optional configuration limit if required).

Chapter 106. Configuration

This chapter shows how to incorporate the CCB support into an eCos configuration, and how to configure it once included.

Configuration Overview

The common CCB support is contained in the eCos package `CYGPKG_IO_CCB`. However, it depends on the services of a collection of other packages for complete functionality, with this `CYGPKG_DEVS_CCB_CORTEXM_STM32` package providing specific I/O functionality.

Normally this package should not need to be manually added, since it will be automatically provided as part of suitable target configurations.

The functionality of this driver package itself relies on some platform/variant provided configuration. For platforms that require software control of the transceiver Device Enable (DE) signal for any of the CCB ports they will need to implement the feature `CYGINT_DEVS_CCB_CORTEXM_STM32_TXCTRL`.

Configuring the STM32 CCB driver

CCB use of the underlying STM32 U(S)ART interfaces is only enabled if the serial driver support for the specific hardware interface is disabled.

Common configuration options applicable to all configured U(S)ART interfaces:

CYGPKG_DEVS_CCB_CORTEXM_STM32_TIMER

> This option is used to select the STM32 timer block assigned to this CCB I/O driver. It is used to ensure correct bus operation timing. The sub-option `CYGNUM_DEVS_CCB_CORTEXM_STM32_TIMER_INTR_PRI` is used to configure the relative interrupt priority for the timer handler.

CYGNUM_DEVS_CCB_CORTEXM_STM32_RETRIES

> This option enables support for abandoning a transmission after the configured number of retry attempts. The default of 0 disables the retry limit check, with a colliding transmission being retried infinitely. NOTE: The Coherent OBIS Integrators Guide Part# 11215508 Rev. AB (dated 4/2012) has conflicting descriptions re. transmission. The “Random Delay” section is explicit in stating “… there is no provision for discarding a message after many collisions; message transmission will retry until it succeeds”. This however is counter to the Figure 5-6 “Outbound Message Transmission Flow” diagram, which implements a retry counter and terminates the transmission attempt after a number of retries. This configuration option allows the developer to choose the model required by their application. A value of 0 will disable the retry support and a colliding TX will be retried until it is successful (no collision detected). A non-zero value will be treated as a count of the number of attempts to be made before abandoning the transmission and indicating a TX BUSY error.

CYGIMP_DEVS_CCB_CORTEXM_STM32_STATISTICS

> This option is normally disabled by default since it has a (minor) memory footprint and performance hit. If enabled then the driver will track counts of packet transfers and errors. This may be useful to client applications to ascertain bus performance and “quality”.

For the following CDL option names the *#* character in the option names indicates the port number for a specific hardware interface.

If the underlying platform/variant provides access to a STM32 U(S)ART interface, via implementing `CYGINT_DEVS_CCB_CORTEXM_STM32_UART#`, then the following per-interface configuration options are available:

CYGPKG_DEVS_CCB_CORTEXM_STM32_UART#

This is the main option to control use of an interface as a CCB port. Access to the options described below are dependant on this option being enabled.

CYGDAT_DEVS_CCB_CORTEXM_STM32_UART#_NAME

This option specifies the name of the CCB port for the corresponding STM32 U(S)ART. This is the name that an eCos application should use to access this device via cyg_io_lookup(), open(), or similar calls.

Note

Normally for CCB use the client-application should *NOT* need to directly interact with this named device driver, since the common `CYGPKG_IO_CCB` support will automatically access the target platform configured devices declared via `CCB_PORT()` definitions.

CYGNUM_DEVS_CCB_CORTEXM_STM32_UART#_INT_PRI

Interrupt handler priority for U(S)ART events.

CYGNUM_DEVS_CCB_CORTEXM_STM32_UART#_TXINTR_PRI

TX DMA interrupt handler priority.

CYGNUM_DEVS_CCB_CORTEXM_STM32_UART#_RXINTR_PRI

RX DMA interrupt handler priority.

CYGHWR_DEVS_CCB_CORTEXM_STM32_UART#_ONEBIT

This option controls the configuration of the STM32 hardware serial bit sampling. The (default) NOISY selection is suited to off-board interfaces where noise/glitches may occur, but is less tolerant of clock differences. The CLOCK selection is more tolerant of clock deviation between the transmitted and receiver. Use of CLOCK may be more suited to on-board high bitrate connections.

Chapter 107. Debug and Test

Debugging

Asserts

If the target platform resources allow, then the first step in debugging should be to enable ASSERTs. The inclusion of assert checking will increase the code footprint and lower the performance, but does allow the code to catch internal errors from unexpected data values. e.g. when the application/client is not able to guarantee the validity of data passed into the CCB code.

The CCB driver asserts are controlled via the standard eCos Infrastructure CYGPKG_INFRA package CYGDBG_USE_ASSERTS option. If enabled then run-time assertion checks are performed by the CCB driver package.

If assertions are enabled and a debugger is being used, it is normally worthwhile setting a breakpoint at start-up on the cyg_assert_fail symbol. The debugger will then stop prior to entering the default busy-loop assert processing.

Diagnostic Output

The STM32 CCB driver provides the ability for some diagnostic output to be manually enabled by editing the src/stm32_ccb.c directly. However, in normal application development the low-level diagnostics for this driver should not be required.

Note

The diagnostics within this package are to aid driver development and debug, and will adversely affect the operation of the CCB support as seen by 3rd-party code. For example, “slow” serial diagnostic output of the packet parsing and response generation could mean that a significant amount of time passes, such that the CCB support no longer adheres to the timeout limits imposed by external code.

Similar to the diagnostic output, the source can be edited to manually enable support for software driven signals that can be sampled by a suitable Logic State Analyser (LSA) setup. This can be used to track time critical events.

Warning

Any STM32 I/O pins chosen for LSA signalling should be carefully chosen to avoid adverse operation of the target platform in use.

Part XXX. MODBUS

Important

This eCosPro-MODBUS package is STRICTLY LICENSED FOR INTERNAL EVALUATION AND TESTING PURPOSES ONLY for a maximum period of THREE months from the initial delivery of your eCosPro release. It may not be used for production purposes nor redistributed in full or in part in any format, including source code, binary code and object code format. Shipment of prototypes, hardware or products containing the package in any format is STRICTLY PROHIBITED.

A separate COMMERCIAL LICENSE for this package from eCosCentric is required to receive technical support for the package as well as permit distribution of binary forms of this package.

Some releases of eCosPro may not include evaluation copies of this package. In this case, please contact eCosCentric for licensing and availability. You must obtain written permission from eCosCentric to exceed the evaluation period.

Table of Contents

Chapter 108. MODBUS overview

Introduction

eCosPro-MODBUS is eCosCentric's commercial name for the `CYGPKG_MODBUS` package. The `CYGPKG_MODBUS` package implements a MODBUS server and a ModbusTCP transport layer, and provides an API to enable applications to implement the actual hardware interaction as required.

The implementation is based on the following documents available from the MODBUS www.modbus.org website:

- “MODBUS Application Protocol Specification V1.1b3”
- “MODBUS Messaging on TCP/IP Implementation Guide V1.0b”

Familiarity with MODBUS, and ModbusTCP, and the relevant specifications is assumed in the following eCosPro-MODBUS specific documentation.

The MODBUS package features:

- MODBUS server

  Generic MODBUS request processing. This parses MODBUS function code requests, passing validated requests to the relevant backend handler function as appropriate.

- ModbusTCP transport

  TCP/IP (Ethernet) transaction support. This accepts ModbusTCP client requests, passing valid requests to the MODBUS server for processing.

- Example applications

For MODBUS server applications the user-supplied code registers a backend driver, which will implement the actual hardware operations as defined by the supported MODBUS function codes.

The backend interface is transport agnostic. MODBUS over serial or TCP share the same PDU format structure within requests, with the transport layer wrapping requests and responses as appropriate for the medium being used:

```
ModbusTCP       | MBAP Header | FuncCode | Data…. |
MODBUS Serial       | Address | FuncCode | Data…. | Checksum |
                              \                     /
                               \_____identical_____/
```

The `CYGPKG_MODBUS` package currently only implements a ModbusTCP transport layer. There is no MODBUS client API, or serial (MODBUS-RTU, MODBUS-ASCII) transport support.

Chapter 109. Configuration

This chapter shows how to incorporate the MODBUS support into an eCos configuration, and how to configure it once included.

Configuration Overview

The MODBUS support is contained in a single eCos package `CYGPKG_MODBUS`. However, it depends on the services of a collection of other packages for complete functionality. For example, the ModbusTCP server implementation is tightly bound with the eCos networking stack support.

Quick Start

Incorporating the MODBUS support into your application is straightforward. The essential starting point is to incorporate the MODBUS eCos package (`CYGPKG_MODBUS`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Depending on the MODBUS package configuration other packages may be required (e.g. network stack support). The package requires that the `CYGPKG_KERNEL`, `CYGPKG_ERROR` and `CYGPKG_MEMALLOC` packages are included in the eCos application configuration.

Configuring the MODBUS server

The common MODBUS server support is enabled by the `CYGFUN_MODBUS_SERVER` option. When enabled it provides access to the following relevant options.

CYGNUM_MODBUS_SERVER_MAXSERVER

> This option defines the maximum number of client connections supported by the server. This is the number of individual, active, concurrent, socket connections allowed.

CYGNUM_MODBUS_SERVER_TRANSACTIONS

> This option specifies the maximum number of active, simultaneous, MODBUS transactions per client connection.

CYGNUM_MODBUS_SERVER_TRANSPORTS

> This option defines the maximum number of active transports the MODBUS server will support. If the end application configuration provides more than this number then not all transports may be instantiated. For most applications only a single transport will ever be provided and needed. For example, ModbusTCP for Ethernet based systems.

CYGNUM_MODBUS_SERVER_MESSAGES_API

> Depending on the other configuration options the package will define a base number of message descriptors needed in `CYGNUM_MODBUS_SERVER_MESSAGES`. This option extends the size of the message pool over and above the explicit active MODBUS transaction message requirement. This can be tuned to reflect the requirements of the user application implementing the backend.

CYGNUM_MODBUS_SERVER_THREAD_STACK_SIZE

> This option is used to increase the size of the main MODBUS control thread. This value is added to the platform defined `CYGNUM_HAL_STACK_SIZE_TYPICAL`.

CYGNUM_MODBUS_SERVER_THREAD_PRIORITY

This option defines the scheduler priority of the main MODBUS control thread.

Configuring the ModbusTCP Server

The `CYGPKG_MODBUS_TRANSPORT_TCP` provides the transport implementation for ModbusTCP. When enabled the configuration must include a suitable network stack (BSD or lwIP).

CYGNUM_MODBUS_SERVER_PORT

This option defines the port that the ModbusTCP server will listen to for client requests. The default of `502` is the standard ModbusTCP port, and normally would not need to be re-configured.

CYGIMP_MODBUS_TRANSPORT_TCP_ACM

Enabling this option allows a set of client network addresses to be configured at run-time via the ACM API. When addresses have been configured only connections from those registered hosts will be accepted.

- The `Disabled` mode configures the ModbusTCP transport to ignore ACM API operations, and to accept connections from any host.
- The `Insecure` mode will accept any connection UNTIL at least one explicit address has been registered via the ACM API, and then host addresses will be checked for acceptance.
- The `Secure` mode will NOT accept any connections unless the address has been explicitly registered via the ACM API.

The setting of this option will depend on how the server device will be deployed and accessed in the field. For testing it may be acceptable to have any client host interact with the device, in which case `Disabled` or `Insecure` should be selected. Selecting `Insecure` allows for start-of-day acceptance of any client host address, but for some application control, configuration, to subsequently limit the acceptable addresses. The `Secure` mode ensures that only application configured client host addresses are ever supported, which requires suitable run-time application configuration to setup the required ACM pools to allow access.

Warning

Using `Secure` mode means that if the application does NOT call the `cyg_modbus_acm_add()` to register an address then *NO* connections can be established to the MODBUS server.

CYGNUM_MODBUS_TRANSPORT_TCP_IDLE_TIMEOUT

This option specifies the number of seconds before idle connections to the ModbusTCP server are closed. The default setting of 0 disables the feature. Normally connections from clients are held open until the client explicitly closes them. This option allows for an “idle” timeout to be specified that will close the connection at the server end if no MODBUS requests are received from a client connection within this configured timeout.

Note

If ACM support is configured then only non-priority connections will be closed by the ModbusTCP server.

CYGNUM_MODBUS_TRANSPORT_TCP_THREAD_STACK_SIZE

This option is used to increase the size of the ModbusTCP internal thread. This value is added to the platform defined `CYGNUM_HAL_STACK_SIZE_TYPICAL`.

CYGNUM_MODBUS_TRANSPORT_TCP_THREAD_PRIORITY

This option defines the scheduler priority of the ModbusTCP internal thread.

Chapter 110. API Overview

The main MODBUS API provides a serialisation layer between the low-level MODBUS operations and user-application threads.

For MODBUS server configurations the main server control loop thread interacts with a transport layer, for example ModbusTCP, and an application specific backend layer.

The transport layer provides the physical communication support for the selected medium. For ModbusTCP this will normally be Ethernet, and for MODBUS ASCII/RTU a RS232 or RS485 connection. The transport medium layer wraps the common MODBUS PDU request and response messages for transmission.

The server control thread processes the MODBUS PDU encapsulated requests, calling the provided backend routines as appropriate.

The application supplied backend *`descriptor`* provides the support for the specific hardware I/O present on the device being implemented.

Application API

These functions are used by the user application to configure the server operation.

Name

cyg_modbus_server_start — Start MODBUS server

Synopsis

#include <cyg/modbus.h>

```
cyg_handle_t cyg_modbus_server_start(descriptor, backend_private);
```

Description

Initialise the server from the CDL configured state, and start the transport layers listening for client requests. The supplied *descriptor* specifies the backend driver to be used to handle requests. The *backend_private* parameter can be used to reference any context required by the specific backend *descriptor*.

The call will block until all the configured transports are ready to accept connections from remote clients.

Return value

A handle onto the server instance, or 0 on failure.

Name

cyg_modbus_server_stop — Stop MODBUS server

Synopsis

#include <cyg/modbus.h>

```
Cyg_ErrNo cyg_modbus_server_stop(server);
```

Description

Stop the referenced *server* from accepting any new requests. The call may block until any "pending" transactions are completed by the backend-handlers/user-application, or such pending transactions have been timed-out by the main MODBUS server control loop. This means the function may block for a maximum of the active transaction timeout (as specified by the backend supplied `timeout` field).

Return value

The function will return `ENOERR` on success. If the stop event cannot be delivered to the MODBUS control thread due to the communication mailbox being full, then `EAGAIN` is returned. If the *server* parameter is invalid then `EINVAL` will be returned.

Backend API

These functions are provided for the user application attached backend handler routines. They are used to provide responses back to the remote client, with the necessary control thread and transport layer information referenced by the opaque `cyg_handle_t ctx` parameter passed to the backend handler function.

For handlers that can provide immediate responses the functions can be called directly from the handler function (in the main MODBUS control thread context). If the handler cannot provide an immediate response, then the processing should be deferred to another thread which can then subsequently use the same API to deliver a response.

Note

For valid responses it is the responsibility of the handler function to return a correctly formatted PDU object to the client.

Name

cyg_modbus_response — Provide MODBUS response

Synopsis

#include <cyg/modbus.h>

```
Cyg_ErrNo cyg_modbus_response(ctx, len, data);
```

Description

Provide the MODBUS server with a valid PDU response for a request handed to the relevant backend handler. The *data* allows the backend application to reference its own data buffer, which may be in read-only memory.

Return value

Currently only `ENOERR` is returned.

Name

cyg_modbus_raw_pdu — Access raw PDU buffer

Synopsis

#include <cyg/modbus.h>

`void` **`cyg_modbus_raw_pdu`**`(`*`ctx`*`, `*`len`*`, `*`data`*`);`

Description

This function provides low-level access to the request PDU buffer for the backend handler code. Before calling the backend handler function the MODBUS server will have already parsed the request and will pass the relevant request data as parameters to the handler function. However, for some backend implementations it may be useful to re-use the request memory space as the holding location for the response. This can avoid the backend having to manage its own dynamic memory allocations.

The example `packages/services/modbus/current/tests/backend_dummy.c` source file provided with the package provides examples of using this `cyg_modbus_raw_pdu()` function in conjunction with `cyg_modbus_response_nocopy()` to re-use the transaction PDU buffer. For example:

```
{
  cyg_uint8 len;
  cyg_uint8 *pdata;
  cyg_modbus_raw_pdu(ctx,&len,&pdata);
  … code to fill pdata buffer …;
  len = response_length;
  cyg_modbus_response_nocopy(ctx,len);
}
```

Name

cyg_modbus_response_nocopy — Provide MODBUS response (no copy)

Synopsis

#include <cyg/modbus.h>

```
cyg_bool cyg_modbus_response_nocopy(ctx, len);
```

Description

Like the `cyg_modbus_response()` call this function is used to provide the MODBUS server with a valid response to a request handed to the backend for processing. This call assumes that the original PDU buffer (as referenced through the opaque *`ctx`* handle) contains the response data.

This “PDU buffer” re-use can simplify the backend processing, since it no longer needs to dynamically manage buffers that are handed-off to the main MODBUS server control.

Return value

Currently only `ENOERR` is returned.

Name

cyg_modbus_response_exception — Provide MODBUS exception response

Synopsis

#include <cyg/modbus.h>

```
cyg_bool cyg_modbus_response_exception(ctx, ecode);
```

Description

If the backend handler detects an error, or needs to notify the remote client of an exceptional result, this function is used to provide such a MODBUS exception response.

Return value

Currently only `ENOERR` is returned.

Name

cyg_modbus_get_uid — Read “Unit ID” of request

Synopsis

#include <cyg/modbus.h>

Cyg_ErrNo **cyg_modbus_get_uid**(*ctx*, *uid*);

Description

This function provides access to the underlying “Unit ID” value for the passed *ctx* request handle parameter. The passed *uid* parameter references the location to be written with the relevant identifier value.

Return value

On success `ENOERR` is returned, and if non-`NULL` then the referenced *uid* location is updated with the “Unit ID”. If the underlying transport does not provide access to a suitable identifier value then the `ENOENT` error code is returned.

ModbusTCP specific API

These functions are used by the user application to configure features of the ModbusTCP specific transport layer.

Name

cyg_modbus_acm_add — Add client address to Access Control Mechanism pool

Synopsis

#include <cyg/modbus.h>

```
Cyg_ErrNo cyg_modbus_acm_add(server, ptype, ipaddr, addrlen);
```

Description

Depending on the `CYGPKG_MODBUS` and user application configuration, the ModbusTCP transport layer may provide support for an Access Control Mechanism (ACM) based on client (remote host) network addresses. This function allows addresses to be registered, so that subsequent connections from the remote host will be allowed.

The *`ptype`* defines which of the ModbusTCP ACM pools the supplied client address will be registered with:

- MODBUS_CONNPOOL_PRI

  The priority pool is for addresses for which the server should never close the socket connection.

- MODBUS_CONNPOOL_NONPRI

  The non-priority pool is for addresses where the server may close the socket connection.

Currently the *`ipaddr`* can describe either a `AF_INET` (for IPv4) or `AF_INET6` (for IPv6) family address, with *`addrlen`* being the size of the relevant address family.

Return value

A standard `Cyg_ErrNo` error code is returned, with `ENOERR` indicating success. If the ModbusTCP ACM is not provided by the attached transport layer then `ENOENT` is returned. The error `EIO` indicates a failure to communicate with the server control thread. The transport specific implementation may return further error indications as appropriate.

Name

cyg_modbus_acm_remove — Remove ACM registered client address

Synopsis

#include <cyg/modbus.h>

`Cyg_ErrNo` **`cyg_modbus_acm_remove`**`(`*`server`*`, `*`ipaddr`*`, `*`addrlen`*`);`

Description

This function will remove the supplied remote host address from all ACM pools that have a matching entry. If ACM is being used then this may stop future requests from the remote host being processed.

Currently the *`ipaddr`* can describe either a `AF_INET` (for IPv4) or `AF_INET6` (for IPv6) family address, with *`addrlen`* being the size of the relevant address family.

Return value

A standard `Cyg_ErrNo` error code is returned, with `ENOERR` indicating success. If the ModbusTCP ACM is not provided by the attached transport layer then `ENOENT` is returned. The error `EIO` indicates a failure to communicate with the server control thread. The transport specific implementation may return further error indications as appropriate.

MODBUS Exceptions

The MODBUS standard defines a fixed set of exception codes, with implicit interpretations. These should be used in conjunction with the `cyg_modbus_exception()` function by backend handlers to notify the requesting client of an error.

MODBUS_EXCEPTION_ILLEGAL_FUNCTION

> The function code received in the request is not an allowable action for the server. This may be because the function code is only applicable to newer devices, and was not implemented in the unit selected. It could also indicate that the server is in the wrong state to process a request of this type, for example because it is unconfigured and is being asked to return register values.

MODBUS_EXCEPTION_ILLEGAL_ADDRESS

> The data address supplied in the request is not an allowable starting address for the server when taken into account with the number of items to be accessed. For example, for a device with 100 registers (accessed as addresses 0 thru 99) then the PDU supplied address 96 is valid when a request for 4 or fewer items is made, but invalid if 5 or more items are requested.

MODBUS_EXCEPTION_ILLEGAL_VALUE

> A value suppled in the request is not valid for the server. This normally indicates a fault in the structure of a request PDU (e.g. unexpected length). It should be noted that it does *NOT* indicate that a supplied data item is outside of the set acceptable for a specific register. The MODBUS protocol does not interpret or apply any significance of any particular data values for any particular registers.

MODBUS_EXCEPTION_DEVICE_FAIL

> Indicates an unrecoverable error occurred whilst the server was performing the requestion MODBUS function.

MODBUS_EXCEPTION_ACKNOWLEDGE

> This is a specialized response used with specific programming commands. This is where the server has accepted a request, and is processing it, but where the action will take a long time to complete. This response is returned to the client to prevent a

client timeout error waiting for a standard response. It is expected that the client will periodically issue the specific “Poll Program Complete” request to check if the processing has completed.

Note

The eCosPro-MODBUS server does not explcitly support this functionality, since it would be a feature of the user-application supplied backend driver.

MODBUS_EXCEPTION_DEVICE_BUSY

This is a specialized response used with specific programming commands. This is used to indicate to the client that the server is busy processing a long-duration command. The client should re-attempt the request in the future.

MODBUS_EXCEPTION_MEMORY_PARITY_ERROR

This exception is specific to the `MODBUS_FUNC_READ_FILE_RECORD` (20) and `MODBUS_FUNC_WRITE_FILE_RECORD` (21) functions, when using with reference type 6. It is used to indicate that the extended file area failed to pass a consistency check. i.e. the server attempted to read the record file, but detected a parity error in the memory. The client may retry the request, but maintenance of the server device may be required.

MODBUS_EXCEPTION_GW_PATH_UNAVAILABLE

This is a specialized exception returned in conjunction with gateway support. It indicates that the gateway was unable to allocate an internal communication path to the requested UID. This exception usually indicates the gateway device is misconfigured or overloaded.

MODBUS_EXCEPTION_GW_TARGET_FAILED

This is a specialized exception returned in conjuction with gateway support. It indicates that no response was obtained from the target device. This usually indicates that the target device is not present on the MODBUS network.

Backend Interface

The `cyg_modbus_backend_t` structure defines the set of handler functions used to implement the support for the relevant MODBUS operation. A simple NUL terminated ASCII `name` can be provided as a human-readable description of the backend. The application attaches the backend descriptor structure via the `cyg_modbus_server_start()` function.

Note

To avoid blocking the main MODBUS server processing loop the attached handler functions should *NEVER* block. The handlers should be written to return control as quickly as possible. If a hardware operation required by the specific MODBUS function then the handler should schedule suitable code, which will asynchronously respond to the request when the required data is available or action has been performed. The provided `tests/modbus_ut.c` example application provides one possible implementation of such “deferred” support.

If a particular MODBUS function is not supported (or required) by the backend implementation then a `NULL` pointer can be used, with the server support returning a `CYG_MB_EXCEPTION_ILLEGAL_FUNCTION` equivalent error to the calling client.

The backend structure is defined in the `<cyg/modbus.h>` header, which also provides the function prototypes for the individual handlers as detailed over the following pages. The `cyg_mbop_` prefix is used for the prototypes to indicate a MODBUS Backend OPeration.

Each handler is passed the parameters `ctx` and `private`. The `ctx` value is an opaque context descriptor for the main server loop, and is used to identify individual transactions via the API. The `private` parameter is the `private` context value specified when the backend is registered, and can be the hook for the user application hardware support.

The backend descriptor also provides the BASIC (mandatory) and REGULAR (optional) NUL terminated ASCII identification strings accessed via the MEI Type 14 function code.

The `timeout` descriptor field is used to force a timely “exception” response back to a client when the backend does not provide a response within the configured number of seconds. This MODBUS control generated timeout exception replaces any subsequent response made by the user-application for the relevant `ctx` handle.

Other than the device `idread` function the handlers do not return any error state. The handlers are passed validated requests, and are expected to return a valid response or exception via the provided MODBUS API.

Name

cyg_mbop_read_discrete_inputs — Read discrete inputs

Synopsis

```
#include <cyg/modbus.h>
```

```
void cyg_mbop_read_discrete_inputs(ctx, private, addr, numinputs);
```

Description

Discrete inputs are read-only status bits.

Name

cyg_mbop_read_coils — Read coils

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_read_coils(ctx, private, addr, numcoils);
```

Description

Coils are read/write single-bits.

Name

cyg_mbop_write_single_coil — Write single coil

Synopsis

#include <cyg/modbus.h>

void **cyg_mbop_write_single_coil**(*ctx*, *private*, *addr*, *outval*);

Description

Coils are read/write single-bits.

Name

cyg_mbop_write_multiple_coils — Write multiple coils

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_write_multiple_coils(ctx, private, addr, numout, outputs);
```

Description

Coils are read/write single-bits.

Name

cyg_mbop_read_input_regs — Read input registers

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_read_input_regs(ctx, private, addr, numin);
```

Description

Input registers are 16-bit read-only registers.

Name

cyg_mbop_read_holding_regs — Read holding registers

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_read_holding_regs(ctx, private, addr, numregs);
```

Description

Holding registers are 16-bit read/write registers.

Name

cyg_mbop_write_single_reg — Write single holding register

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_write_single_reg(ctx, private, addr, value);
```

Description

Holding registers are 16-bit read/write registers.

Name

cyg_mbop_write_multiple_regs — Write multiple holding registers

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_write_multiple_regs(ctx, private, addr, numregs, outputs);
```

Description

Holding registers are 16-bit read/write registers.

Name

cyg_mbop_rw_multiple_regs — Read and/or write multiple holding registers

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_rw_multiple_regs(ctx, private, raddr, rnum, waddr, wnum, outputs);
```

Description

Holding registers are read/write 16-bit registers.

Note

The MODBUS standard dictates that the write is performed *BEFORE* the read.

Name

cyg_mbop_mask_reg — Mask holding register

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_mask_reg(ctx, private, addr, and, or);
```

Description

Holding registers are read/write 16-bit registers.

Name

cyg_mbop_read_fifo_queue — Read FIFO contents

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_read_fifo_queue(ctx, private, addr);
```

Description

FIFO queues are sets of 16-bit registers. This operation should not empty the queue.

Name

cyg_mbop_read_file_record — Read file records

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_read_file_record(ctx, private, numrec, records);
```

Description

Read one or more file records.

Name

cyg_mbop_write_file_record — Write file records

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_write_file_record(ctx, private, numrec, records);
```

Description

Write one or more file records.

Name

cyg_mbop_read_id — Return specific extended device ID

Synopsis

#include <cyg/modbus.h>

Cyg_ErrNo **cyg_mbop_read_id**(*private*, *objectid*, *nextid*, *len*, *buffer*);

Description

This function does not provide a response, but purely supplies “Extended” `ObjectID` data to the common MEI Type 14 request handler.

The *objectid* parameter specifies the object to be returned. The caller supplies an optional data buffer pointer in the *buffer* parameter, with the value referenced by the *len* pointer being the space available in the buffer. If the *objectid* is supported then the buffer is filled, and *len* is updated with the actual length of the object. The use of a `NULL` *buffer* allows a caller to ascertain the length of an object prior to calling again with a supplied buffer of the required size.

If the *nextid* pointer is supplied then the next available object ID after *objectid* is written, or `0` if no more objects are available.

Return value

On success `ENOERR` is returned and the *len* and *nextid* values updated accordingly. If the handler does not recognise the passed *objectid* then `ENOENT` is returned and **len* is *NOT* updated. If the passed **len* is not large enough for the object then `EAGAIN` is returned and **len* is update with the required length.

Name

cyg_mbop_canopen — Perform CANOPEN operation

Synopsis

#include <cyg/modbus.h>

```
void cyg_mbop_canopen(ctx, private, len, data);
```

Description

The CYGPKG_MODBUS does not implement any specific CANOPEN support, but does pass through the raw request to the backend driver which may implement support as required.

Note

Please refer to the MODBUS website or the CiA (CAN in Automation) website for a copy and terms of use that cover Function Code 32 MEI Type 13.

Example backend

The `packages/services/modbus/current/tests/backend_dummy.c` source file provides an example of the backend support required for a MODBUS server implementation. It can form the starting point for a customer hardware solution.

The source as provided implements a very basic system to allow verification of the MODBUS server support. The backend does not provide real hardware I/O interaction, but “simulates” responses.

Chapter 111. Internals

The main MODBUS control thread serialises MODBUS backend processing by accepting requests from a mailbox. It parses the request data, and where valid (and supported by the user-application supplied backend) will pass the data to the relevant handler function for processing.

Note

Since the backend handler functions are called from the main MODBUS control thread context they should *NEVER* block. This limits the operations that can be performed within the specific handler functions. If scheduling is required to complete an operation then control should be passed to a suitable user-application thread.

The MODBUS requests are posted to the main MODBUS control thread from the transport listener code. The transports are responsible for the specific communication layer wrapping of the MODBUS PDU packets.

Multiple transport layers can be configured and the main control loop will handle requests from all, directing responses back to the original requesting transport layer. This allows a single application (for example) to provide ModbusTCP support as well as serial line server support. Normally transport implementations would be limited to ModbusTCP, MODBUS-RTU or MODBUS-ASCII however the user could provide support for arbitrary transport mechanisms, e.g. a MODBUS-LOCALTEST special transport for doing internal memory-based loopback messaging for unit-testing.

Chapter 112. Debug and Test

Debugging

Asserts

If the target platform resources allow then the first step in debugging should be to enable ASSERTs. The inclusion of assert checking will increase the code footprint and lower the performance, but does allow the code to catch internal errors from unexpected data values. e.g. when the application/client is not able to guarantee the validity of data passed into the MODBUS code.

The MODBUS asserts are controlled via the standard eCos Infrastructure CYGPKG_INFRA package CYGDBG_USE_ASSERTS option. If enabled then run-time assertion checks are performed by the MODBUS package.

If assertions are enabled, and a debugger is being used it is normally worthwhile setting a breakpoint at start-up on the cyg_assert_fail symbol, so that the debugger will stop prior to entering the default busy-loop assert processing.

Diagnostic Output

In conjuction with the CYGDBG_MODBUS_DEBUG CDL configuration setting and sub-options, the header-file src/modbus_diag.h implements the MODBUS specific debug control.

When CYGDBG_MODBUS_DEBUG is enabled a set of individually selectable sub-systems are available to control the diagnostic output generated.

However, when developing or debugging the MODBUS implementation it may be simpler (with less build side-effects) to control the debugging output via direct uncommenting of the necessary manifests at the head of the src/modbus_diag.h source file, than re-configuring the complete eCos configuration via the CDL. That way only the MODBUS package will be re-built.

Note

Some diagnostic output if enabled may adversely affect the operation of the MODBUS support as seen by 3rd-party code. For example, “slow” serial diagnostic output of the packet parsing and response generation could mean that a significant amount of time passes, such that the MODBUS support no longer adheres to the timeout limits imposed by external code.

Testing

The configuration option CYGPKG_MODBUS_TESTS defines a set of tests that are built.

By default the package will only build the deterministic, automatic, tests. However, the option CYGPKG_MODBUS_TESTS_MANUAL can be defined to build extra tests that may required manual user-intervention, or are more realistic real-world example applications.

modbus_ut

The modbus_ut test application performs some unit-testing of the ModbusTCP server implementation. The test assumes specific features of the tests/backend_dummy.c backend implementation to perform a variety of fixed tests.

Since the backend handler funtions can *NEVER* block the test code will explicitly test pending responses to simulate application situations where hardware responses may take arbitrary periods of time, and hence are passed to other user-application threads for processing.

Note

When configured against the lwIP network stack the unit-testing relies on lwIP being configured with CYGFUN_LWIP_NETIF_LOOPBACK. This is required to allow the test code to connect to the ModbusTCP server running on the same network interface.

modbus_server

The modbus_server is only built when CYGPKG_MODBUS_TESTS_MANUAL is configured. It uses the tests/backend_dummy.c as the backend for a simple example server.

The application just runs for a fixed period of time before terminating, and can be used with external ModbusTCP clients.

Part XXXI. Direct Memory Access Controller (DMAC) Device Drivers

Documentation for drivers of this type may also be integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 113. Atmel DMA Controller (DMAC)

Name

DMAC — eCos Support for the Atmel DMA Controller

Synopsis

#include CYGBLD_DEV_DMA_H

ch = **atmel_dmac_chan_alloc**(*cyg_uint32 descriptor*, *atmel_dmac_callback *cb*, *CYG_ADDRWORD priv*);

void **atmel_dmac_chan_config**(*atmel_dmac_channel *ch*, *cyg_uint32 extended*);

void **atmel_dmac_chan_free**(*atmel_dmac_channel *ch*);

void **atmel_dmac_start**(*atmel_dmac_channel *ch*, *CYG_ADDRWORD src*, *CYG_ADDRWORD dst*, *cyg_uint32 size*);

void **atmel_dmac_stop**(*atmel_dmac_channel *ch*);

void **atmel_dmac_dma_poll**(*atmel_dmac_channel *ch*);

Description

This package provides access to the Atmel DMAC (DMA Controller) devices. This support is not intended to expose the full functionality of these devices. It is mainly limited to supporting peripheral DMA (e.g. USART, SPI, etc.). It is currently limited to single DMA transfers.

There is currently no cross-platform/variant standardised eCos DMA I/O interface package, since DMA features and functionality vary greatly between architectures, and event within variants of an architecture. This stand-alone device package allows common DMA support to be shared between devices that implement Atmel DMA Controllers.

The user is directed towards the relevant Atmel documentation for a full description of the DMAC devices, and to the variant device drivers for examples of the use of this API. This documentation only gives a brief description of the functions available.

A DMAC instance is defined by a controller number (0 or 1), and each controller has support for a number of (variant defined) channels. The API uses a simple 32-bit encoding to describe how a specific DMA channel should be used, with this package providing helper macros to combine the necessary information into a unique descriptor. These descriptors may be stored with a device driver as required.

The following are examples of how definitions can be made:

```
// USART0 TX on controller 0, 8-bit mem-to-peripheral transfers using AHB_IF2
#define AT91_SERIAL0_DMA_TX      CYGHWR_ATMEL_DMA_M2P(0,USART0_TX,8,IF2)

// USART0 RX on controller 0, 8-bit peripheral-to-mem transfers using AHB_IF2
#define AT91_SERIAL0_DMA_RX      CYGHWR_ATMEL_DMA_P2M(0,USART0_RX,8,IF2)
```

Before DMA transfers can be performed, a DMA channel must be claimed. This is done by calling `atmel_dmac_chan_alloc()`. The *`descriptor`* argument describes the majority of the DMA transfer configuration that will be used. As shown in the examples above the passed descriptor not only encodes the source and destination interfaces, but also the transfer sizes. Also, depending on the descriptor construction macros used, it is possible to control the direction and modification of addresses during transfers. The *`cb`* argument is used to register a client function that will be called when a requested transfer completes. The *`priv`* argument is a client specified value that will be passed to the callback function, and can be used to reference client driver specific data.

If DMA chunk transfers of more than one item per transaction are required then an “extension” 32-bit configuration descriptor can be specifed using the `atmel_dmac_chan_config()` function. The extended descriptor allows for non-default FIFO configurations and transfer chunk sizes to be specified. The `<cyg/hal/sama5d3.h>` header file contains examples of defining extended descriptors. For example, see the `ATMEL_AES_DMA_TX_EXT` manifest.

Most drivers will allocate a DMA channel object and keep it active throughout the system lifetime. However, if it is necessary to share a channel, or otherwise disable the use of a stream, the driver may call `atmel_dmac_chan_free()` to return a channel to an unused state. It will be necessary to call `atmel_dmac_chan_alloc()` before specific DMA descriptor operations can be performed again.

The register callback function has the following prototype:

```
typedef void atmel_dmac_callback( atmel_dmac_channel  *ch,
                                  cyg_uint32          cbid,
                                  cyg_uint32          count,
                                  CYG_ADDRWORD        data );
```

The *`ch`* is the channel structure describing the transfer. The *`cbid`* argument is a completion identifier:

Table 113.1. Completion Codes

`CYGHWR_ATMEL_DMA_COMPLETE`	A valid transfer completion. The *`count`* argument should match the *`size`* passed to the `atmel_dmac_start()` call.
`CYGHWR_ATMEL_DMA_AHBERR`	This code indicates that the DMA Controller has detected an AHB read or write access error. This may indicate invalid memory addresses have been passed, or invalid AHB_IF mappings have been used.
`CYGHWR_ATMEL_DMA_DICERR`	For configurations where Descriptor Integrity Check support is available, and enabled, then if an error is detected in a referenced memory-based transfer structure this result will be raised.

The *`count`* argument is the number of data items successfully transferred. The *`data`* argument is the client private data registered for the callback.

A transfer is configured and started by calling `atmel_dmac_start()`. The *`ch`* argument describes the DMA channel, with the descriptor used when allocating the channel defining how the other arguments are used. The *`src`* argument defines the peripheral or memory address from which the transfer will be made. The *`dst`* argument supplies the peripheral or memory address to which the transfer will write. The *`size`* argument defines the number of data items to be transferred. Once this function call completes the channel is operational and will transfer data once the relevant peripheral starts triggering transfers.

When the transfer completes the registered callback is called from DSR mode.

Notes:

1. Since the callback function is executed as a DSR, only a subset of eCos operations are valid.
2. It is expected that the client driver will perform any necessary CACHE operations within either its supplied callback handler functions, or *before* calling `atmel_dmac_start()` as required.

Chapter 114. Atmel DMA Controller (XDMAC)

Name

XDMAC — eCos Support for the Atmel XDMAC Controller

Synopsis

#include CYGBLD_DEV_DMA_H

`ch = `**`atmel_dmac_chan_alloc`**`(`*`cyg_uint32 descriptor`*`, `*`atmel_dmac_callback *cb`*`, `*`CYG_ADDRWORD priv`*`);`

`void `**`atmel_dmac_chan_config`**`(`*`atmel_dmac_channel *ch`*`, `*`cyg_uint32 extended`*`);`

`void `**`atmel_dmac_chan_free`**`(`*`atmel_dmac_channel *ch`*`);`

`void `**`atmel_dmac_start`**`(`*`atmel_dmac_channel *ch`*`, `*`CYG_ADDRWORD src`*`, `*`CYG_ADDRWORD dst`*`, `*`cyg_uint32 size`*`);`

`void `**`atmel_dmac_stop`**`(`*`atmel_dmac_channel *ch`*`);`

`void `**`atmel_dmac_dma_poll`**`(`*`atmel_dmac_channel *ch`*`);`

Description

This package provides access to the Atmel XDMAC (Extended DMA Controller) devices. This support is not intended to expose the full functionality of these devices. It is mainly limited to supporting peripheral DMA (e.g. USART, SPI, etc.). It is currently limited to single DMA transfers.

There is currently no cross-platform/variant standardised eCos DMA I/O interface package, since DMA features and functionality vary greatly between architectures, and event within variants of an architecture. This stand-alone device package allows common DMA support to be shared between devices that implement Atmel DMA Controllers.

The user is directed towards the relevant Atmel documentation for a full description of the XDMAC devices, and to the variant device drivers for examples of the use of this API. This documentation only gives a brief description of the functions available.

The API of this controller is designed to be compatible with that for the Atmel DMAC controller and is a drop-in replacement for it. Thus the API refers to the DMAC in its naming, not the XDMAC.

A XDMAC instance is defined by a controller number (0 or 1), and each controller has support for a number of (variant defined) channels. The API uses a simple 32-bit encoding to describe how a specific DMA channel should be used, with this package providing helper macros to combine the necessary information into a unique descriptor. These descriptors may be stored with a device driver as required.

The following are examples of how definitions can be made:

```
// USART0 TX on controller 0, 8-bit mem-to-peripheral transfers using default memory interfaces
#define AT91_SERIAL0_DMA_TX      CYGHWR_ATMEL_DMA_M2P(0,USART0_TX,8)

// USART0 RX on controller 0, 8-bit peripheral-to-mem transfers using default memory interfaces
#define AT91_SERIAL0_DMA_RX      CYGHWR_ATMEL_DMA_P2M(0,USART0_RX,8)
```

Before DMA transfers can be performed, a DMA channel must be claimed. This is done by calling `atmel_dmac_chan_alloc()`. The *`descriptor`* argument describes the majority of the DMA transfer configuration that will be used. As shown in the examples above the passed descriptor not only encodes the source and destination interfaces, but also the transfer sizes. Also, depending on the descriptor construction macros used, it is possible to control the direction and modification of addresses during transfers. The *`cb`* argument is used to register a client function that will be called when a requested transfer completes. The *`priv`* argument is a client specified value that will be passed to the callback function, and can be used to reference client driver specific data.

The `atmel_dmac_chan_config()` function is present for compatibility with the DMAC driver. It is not currently needed, but device drivers that may use both drivers may call this with not effect.

Most drivers will allocate a DMA channel object and keep it active throughout the system lifetime. However, if it is necessary to share a channel, or otherwise disable the use of a stream, the driver may call `atmel_dmac_chan_free()` to return a channel to an unused state. It will be necessary to call `atmel_dmac_chan_alloc()` before specific DMA descriptor operations can be performed again.

The register callback function has the following prototype:

```
typedef void atmel_dmac_callback( atmel_dmac_channel  *ch,
                                  cyg_uint32          cbid,
                                  cyg_uint32          count,
                                  CYG_ADDRWORD        data );
```

The *`ch`* is the channel structure describing the transfer. The *`cbid`* argument is a completion identifier:

Table 114.1. Completion Codes

`CYGHWR_ATMEL_DMA_COMPLETE`	A valid transfer completion. The *`count`* argument should match the *`size`* passed to the `atmel_dmac_start()` call.
`CYGHWR_ATMEL_DMA_AHBERR`	This code indicates that the DMA Controller has detected an AHB read or write access error. This may indicate invalid memory addresses have been passed, or invalid AHB_IF mappings have been used.
`CYGHWR_ATMEL_DMA_DICERR`	For configurations where Descriptor Integrity Check support is available, and enabled, then if an error is detected in a referenced memory-based transfer structure this result will be raised.

The *`count`* argument is the number of data items successfully transferred. The *`data`* argument is the client private data registered for the callback.

A transfer is configured and started by calling `atmel_dmac_start()`. The *`ch`* argument describes the DMA channel, with the descriptor used when allocating the channel defining how the other arguments are used. The *`src`* argument defines the peripheral or memory address from which the transfer will be made. The *`dst`* argument supplies the peripheral or memory address to which the transfer will write. The *`size`* argument defines the number of data items to be transferred. Once this function call completes the channel is operational and will transfer data once the relevant peripheral starts triggering transfers.

When the transfer completes the registered callback is called from DSR mode.

Notes:

1. Since the callback function is executed as a DSR, only a subset of eCos operations are valid.
2. It is expected that the client driver will perform any necessary CACHE operations within either its supplied callback handler functions, or *before* calling `atmel_dmac_start()` as required.

Part XXXII. RPMSG Support

Name

Overview — eCosPro Support for RPMSG

Description

This package provides support for RPMSG communications between separate CPU, microcontrollers or virtual machines. It provides an implementation of the OpenAMP RPMSG API for application use as well as an interface for hardware drivers of communication devices.

At present this package is mainly oriented to using RPMSG under the Xvisor hypervisor. As such it takes certain short cuts and does not support all RPMSG features.

Name

API — Functions

Synopsis

#include <cyg/io/rpmsg.h>

```
struct rpmsg_device *cyg_rpmsg_open(char *devname);

int cyg_rpmsg_close(struct rpmsg_device *dev);

void cyg_rpmsg_poll(void);

typedef int (*rpmsg_ept_cb)(struct rpmsg_endpoint *ept, const void *data, int len,
uint32_t src, void *priv);

typedef int (*rpmsg_ns_unbind_cb)(struct rpmsg_endpoint *ept);

int rpmsg_create_ept(struct rpmsg_endpoint *ept, struct rpmsg_device *dev, const char
*name, uint32_t src, uint32_t dst, rpmsg_ept_cb cb, rpmsg_ns_unbind_cb ns_unbind_cb);

void rpmsg_destroy_ept(struct rpmsg_endpoint *ept);

unsigned int is_rpmsg_ept_ready(struct rpmsg_endpoint *ept);

int rpmsg_send(struct rpmsg_endpoint *ept, const void *data, int len);

int rpmsg_sendto(struct rpmsg_endpoint *ept, const void *data, int len, uint32_t dst);

int rpmsg_send_offchannel(struct rpmsg_endpoint *ept, uint32_t src, uint32_t dst, const
void *data, int len);

int rpmsg_trysend(struct rpmsg_endpoint *ept, const void *data, int len);

int rpmsg_trysendto(struct rpmsg_endpoint *ept, const void *data, int len, uint32_t dst);

int rpmsg_trysend_offchannel(struct rpmsg_endpoint *ept, uint32_t src, uint32_t dst,
const void *data, int len);

int rpmsg_send_offchannel_raw(struct rpmsg_endpoint *ept, uint32_t src, uint32_t dst,
const void *data, int len, int wait);
```

Description

The RPMSG API follows the standard API in most details. The main difference is that currently it is oriented towards supporting the Xvisor VMSG infrastructure, which differs from the standard in some ways. As a result the name service functionality is not supported, and there are some eCos specific extensions.

The eCos extensions provide a mechanism for managing RPMSG devices. The function `cyg_rpmsg_open()` looks for an RPMSG device with the given name and returns a pointer to it. The function `cyg_rpmsg_close()` closes a device down when it is no longer needed. The function `cyg_rpmsg_poll()` is used in systems where interrupts are disabled to process RPMSG transfers; where interrupts are enabled the RPMSG package calls this function internally and the application does not need to do it itself.

The remaining API functions follow the OpenAMP API with the exception of the name server functionality.

The function `rpmsg_create_ept()` initializes an application-supplied endpoint object with a name, addresses and callbacks; any messages directed to the given destination address will cause the callback on this endpoint to be called. An RPMSG client should create an endpoint to communicate with a remote node. The client should provide at least a channel name and a callback for message notification. By default the endpoint source address should be set to RPMSG_ADDR_ANY.

The function `rpmsg_destroy_ept()` unregisters the endpoint from the device.

The function `is_rpmsg_ept_ready()` returns 1 if the endpoint has both local and destination addresses set, 0 otherwise.

The function `rpmsg_send()` sends *`data`* of length *`len`* based on the endpoint *`ept`*. The message will be sent to the remote node which the channel belongs to, using the endpoint's source and destination addresses. If there are no TX buffers available, the function will block until one becomes available, or a timeout of 15 seconds elapses. When the latter happens, `RPMSG_ERR_NO_BUFF` is returned. The function returns the number of bytes sent if successful, or a negative error code on failure.

The function `rpmsg_sendto()` functions in the same way as `rpmsg_send()` except that the destination address is taken from the *`dst`* argument and not the endpoint.

The function `rpmsg_send_offchannel()` functions in the same way as `rpmsg_send()` except that both the source and destination addresses are taken from the *`src`* and *`dst`* argument and not the endpoint.

The functions `rpmsg_trysend()`, `rpmsg_trysendto()` and `rpmsg_trysend_offchannel()` function in the same way as their non-try equivalents except that when no buffers are available they return immediately with `RPMSG_ERR_NO_BUFF`.

The function `rpmsg_send_offchannel_raw()` allows all options supported by the previous functions to be specified as arguments.

When a message is received for an endpoint it is passed to the application by calling the callback function registered when the endpoint was created. The endpoint, data pointer and length and the source endpoint address are passed in. The callback is made from a thread that is part of the RPMSG subsystem. The callback is permitted to call any functions that are allowed from a thread but should avoid doing anything that might take a long time since it would block processing of new messages for other endpoints.

The following code shows an example of the use of this API. For clarity, error checking code is omitted.

```
void rpmsg_test( void )
{
    struct rpmsg_device *rdev = NULL;
    struct rpmsg_endpoint ept;
    int err;
    int i;
    uint32_t src = 0x501;
    uint32_t dst = 0x502;

    // Locate device "rpmsg0"
    rdev = cyg_rpmsg_open( "rpmsg0" );

    // Create an endpoint for the given src and dst pair
    err = rpmsg_create_ept( &ept, rdev,
                            "ecos-ept0", src, dst,
                            rpmsg_ept_cb, NULL );

    // Send some messages, we assume the peer will
    // reply in some way.
    for( i = 0; i < 100; i++ )
    {
        char msg[40];

        int len = diag_sprintf( msg, "%3d 1234567", i );

        err = rpmsg_send( &ept, msg, len );

        diag_printf("SENT: %4d %04lx %s\n", len, dst, (char *)msg);
    }

    // Close the device when we are finished
    cyg_rpmsg_close(rdev);
}

// Receive callback
int rpmsg_ept_cb(struct rpmsg_endpoint *ept, void *data,
                 size_t len, uint32_t src, void *priv)
{
    // Handle received message

    diag_printf("GOT : %4d %04lx %s\n", len, src, data);

    return RPMSG_SUCCESS;
}
```

Part XXXIII. Serial Device Drivers

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 115. Freescale MCFxxxx Serial Driver

Name

CYGPKG_DEVS_SERIAL_MCFxxxx — eCos Support for the MCFxxxx On-chip Serial Devices

Description

All members of the Freescale MCFxxxx ColdFire family of processors contain a number of on-chip UARTs for serial communication. They all use very similar hardware. There are some variations such as different fifo sizes, and some processors contain extra functionality such as autobaud detection, but a single eCos device driver can cope with most of these differences. The CYGPKG_DEVS_SERIAL_MCFxxxx package provides this driver. It will use definitions provided by the variant HAL CYGPKG_HAL_M68K_MCFxxxx, the processor HAL and the platform HAL.

The driver provides partial support for hardware flow control and for serial line status. Only CTS/RTS hardware flow control is supported since the UART does not provide DTR/DSR lines. Similarly only line breaks, and certain communication errors are supported for line status since the UART does not provide other lines such as DCD or RI. On some platforms it should be possible to emulate these lines using GPIO pins, but currently there is no support for this.

Once application code accesses a UART through the serial driver, for example by opening a device /dev/ser0, the driver assumes that it has sole access to the hardware. This means that the UART should not be used for any other purpose, for example HAL diagnostics or gdb debug traffic. Instead such traffic has to go via another communication channel such as ethernet.

Configuration Options

The MCFxxxx serial driver should be loaded automatically when selecting a platform containing a suitable processor, and it should never be necessary to load it explicitly. The driver as a whole is inactive unless the generic serial support, CYGPKG_IO_SERIAL_DEVICES, is enabled. Exactly which UART or UARTs are accessible on a given platform is determined by the platform because even if the processor contains a UART the platform may not provide a connector. Support for a given UART, say uart0, is controlled by a configuration option CYGPKG_DEVS_SERIAL_MCFxxxx_SERIAL0. The device driver configuration option in turn depends on a HAL configuration option CYGHWR_HAL_M68K_MCFxxxx_UART0 to indicate that the UART is actually present and connected on the target hardware. If a given UART is of no interest to an application developer then it is possible to save some memory by disabling this option.

For every enabled UART there are a set of configuration options. The following use SERIAL0 as an example, though each UART device available will have its own unique SERIAL*n* naming:

CYGDAT_DEVS_SERIAL_MCFxxxx_SERIAL0_NAME

> Each serial device should have a unique name so that application code can open it. The default device names are /dev/ser0, /dev/ser1, and so on. It is only necessary to change these if the platform contains additional off-chip UARTs with clashing names.

CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_ISR_PRIORITY

> By default the driver arranges for the UARTs to interrupt at a low interrupt priority. Usually there will be no need to change this because the driver does not actually do very much processing at ISR level, and anyway UARTs are not especially fast devices so do not require immediate attention. On some Coldfires with MCF5282-compatible interrupt controllers care has to be taken that all interrupt priorities are unique.

CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_BAUD

> Each UART will be initialized to a given baud rate. The default baud rate is 38400 because in most scenarios this is fast enough yet does not suffer from excess data corruption. Lower baud rates can be used if the application will operate in an electrically noisy environment, or higher baud rates up to 230400 can be used if 38400 does not provide sufficient throughput.

CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_BUFSIZE

The serial driver will maintain software buffers for incoming and outgoing data. The former allows data to continue to arrive even if the application is still busy processing the previous transfer, and thus potentially improves throughput. The latter allows the application to transmit data without immediately blocking until the transfer is complete, often eliminating the need for a separate thread. The size of these buffers can be controlled via this configuration option, or alternatively these buffers can be disabled completely to save memory.

CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_ISR_BUFSIZE

If the serial driver has been configured with buffering (non-zero CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL*n*_BUFSIZE option) then this RX ISR specific option allows extra ISR buffering to be used to minimise the chances of dropped characters at high baud rates. The use of this extra ISR->DSR buffer reduces the number of DSR calls needed to pass data to the higher I/O layer whilst also minimising the latency in processing individual received characters.

Note

If debugging using RedBoot “GDB over Ethernet”, due to the increased ISR and DSR latency from the debugging support, the I/O and ISR buffers may need to be very large to minimise the chance of dropped characters at high baud rates (e.g. 230400). For example the CYGPKG_IO_SERIAL test serial3 (against the hosted ser_filter) can, when debugging via BDM (i.e. no RedBoot) and configured with diagnostics at 115200 using UART0, run the test at 230400 using UART1 successfully with CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL1_BUFSIZE of 128-bytes and a CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL1_ISR_BUFSIZE of 32-bytes. However, if RedBoot “GDB over Ethernet” debugging is used, with diagnostics over the Ethernet/RedBoot channel, then the test running at 230400 over UART1 will complete without dropped characters with CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL1_BUFSIZE of 8192-bytes and a CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL1_ISR_BUFSIZE of 4096-bytes. If even larger (e.g. 64K) continuous 230400 transfers are required then those buffers need to be further increased. This is an unfortunate side-effect of the ISR/DSR latencies introduced by RedBoot Ethernet based debugging.

Careful application specific tuning of the buffer sizes, and potentially the CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL*n*_ISR_PRIORITY, may be needed to ensure the desired baud rate and bandwidth requirements are met. If the ISR latency is too high, or the application thread reading data from the serial I/O layer cannot empty the CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL*n*_BUFSIZE quickly enough, then characters can still be dropped even with large buffers.

It is important that any thread priorities and/or scheduling requirements match the desired UART device use, and that the higher-level buffering and DMA receive buffers are tuned to match the worse-case load.

If the processor HAL is capable of supporting eDMA and the specific UART device is configured to use buffering, by setting a suitable CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL*n*_BUFSIZE value, then DMA specific options are made available:

CYGPKG_DEVS_SERIAL_MCFxxxx_SERIAL0_EDMA

This option, when enabled, allows eDMA support for the UART device to be configured via the following configuration options:

CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_EDMA_TX

If I/O buffering is configured then this option allows eDMA to be used for transmissions. This can greatly reduce the number of ISR and DSR operations needed to support transmission, reducing the CPU load needed.

CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_EDMA_PRIORITY

By default the driver arranges for the UART DMA to interrupt at the highest priority. For lower baud rates this is less critical, but when configured for high baud rates (e.g. 115200 or higher, and especially for ColdFire processors with UARTs with a shallow hardware FIFO) the aim is to minimise the interrupt latency for DMA buffer switch events.

Note

eDMA use for RX is not yet implemented.

There are additional options in the generic serial I/O package `CYGPKG_IO_SERIAL` which will affect this driver. For example `CYGPKG_IO_SERIAL_FLOW_CONTROL` and its sub-options determine what flow control mechanism (if any) should be used.

This package also defines some configuration options related to testing. Usually these options are of no interest to application developers and can be ignored.

Porting

The generic driver needs some information from other packages about the exact hardware, for example how many UARTs are available and where in memory they can be accessed.

1. Another package, usually the processor HAL, should provide one or more options `CYGHWR_HAL_M68K_MCFxxxx_UART0`, `CYGHWR_HAL_M68K_MCFxxxx_UART1` or `CYGHWR_HAL_M68K_MCFxxxx_UART2`. These may be calculated or user-configurable depending on the processor.
2. The device driver will also look for symbol definitions `CYGHWR_HAL_M68K_MCFxxxx_UART0_RTS` and `CYGHWR_HAL_M68K_MCFxxxx_UART0_CTS`, and the equivalents for the other UARTs, to determine whether or not these handshake lines are connected. These may be configuration options or they may be statically defined in a HAL I/O header file. The platform HAL should also implement the generic serial package's interface `CYGINT_IO_SERIAL_FLOW_CONTROL_HW` if appropriate.
3. If RTS is connected then the driver will also look for a symbol `CYGHWR_HAL_M68K_MCFxxxx_UART0_RS485_RTS`. This enables partial support for RS485 communication in that the device driver will arrange for the RTS line to be asserted during a transmit. The driver has no support for more advanced RS485 functionality such as multidrop.

In addition the driver assumes the standard MCFxxxx HAL macros are defined for the UART base addresses and the registers. The driver primarily targets MCF5282-compatible UARTs but there is also some support for functionality available on other members of the Coldfire range, for example the MCF5272's fractional baud rate support.

The HAL can optionally define the `HAL_PLF_DEVS_SERIAL_MCFxxx_XMIT_HOOK`. macro to provide code called to indicate when the driver transmissions are started and stopped. The macro is passed the base H/W address for the device in use (to identify the port when multiple serial interfaces are active) as well as a boolean indicating the start (`true`) and stop (`false`) status for TX.

Chapter 116. NXP PNX8310 Serial Driver

Name

`CYGPKG_DEVS_SERIAL_MIPS_PNX8310` — eCos Support for the PNX8310 On-chip UARTs

Description

The PNX8310 comes with two on-chip UARTs for serial communication. Other PNX83xx processors come with compatible devices. The `CYGPKG_DEVS_SERIAL_MIPS_PNX8310` package provides an eCos serial device driver. It can support up to three UARTs, depending on the processor and on which of the UARTs are connected on any given platform. If the CTS and RTS lines are connected then hardware flow control is supported. Line status is supported for line breaks and for certain communication errors. The UARTs do not have any support for DTR, DSR, DCD or RI lines. On some platforms these lines may be emulated using GPIO pins, but the driver does not currently have any support for this.

Once application code accesses a UART through the serial driver, for example by opening a device `/dev/ser0`, the driver assumes that it has sole access to the hardware. This means that the UART should not be used for any other purpose, for example HAL diagnostics or gdb debug traffic. Instead such traffic has to go via another communication channel such as ethernet.

Configuration Options

The PNX8310 serial driver should be loaded automatically when selecting a platform containing a suitable processor, and it should never be necessary to load it explicitly. The driver as a whole is inactive unless the generic serial support, `CYGPKG_IO_SERIAL_DEVICES`, is enabled. Exactly which UART or UARTs are accessible on a given platform is determined by the platform because even if the processor contains a UART the platform may not provide a connector. Support for a given UART, say uart0, is controlled by a configuration option `CYGPKG_DEVS_SERIAL_PNX8310_SERIAL0`, which will be active only if the platform enables the device. If a given UART is of no interest to an application developer then it is possible to save some memory by disabling this option.

For every enabled UART there are a further four configuration options:

`CYGDAT_DEVS_SERIAL_PNX8310_SERIAL0_NAME`

> Each serial device should have a unique name so that application code can open it. The default device names are `/dev/ser0`, `/dev/ser1`, and so on. It is only necessary to change these if the platform contains additional off-chip UARTs with clashing names.

`CYGNUM_DEVS_SERIAL_PNX8310_SERIAL0_ISR_PRIORITY`

> By default the driver arranges for the UARTs to interrupt at a low interrupt priority. Usually there will be no need to change this because the driver does not actually do very much processing at ISR level, and anyway UARTs are not especially fast devices so do not require immediate attention.

`CYGNUM_DEVS_SERIAL_PNX8310_SERIAL0_BAUD`

> Each UART will be initialized to a given baud rate. The default baud rate is 38400 because in most scenarios this is fast enough yet does not suffer from excess data corruption. Lower baud rates can be used if the application will operate in an electrically noisy environment, or higher baud rates up to 230400 can be used if 38400 does not provide sufficient throughput.

`CYGNUM_DEVS_SERIAL_PNX8310_SERIAL0_BUFSIZE`

> The serial driver will maintain software buffers for incoming and outgoing data. The former allows data to continue to arrive even if the application is still busy processing the previous transfer, and thus potentially improves throughput. The latter allows the application to transmit data without immediately blocking until the transfer is complete, often eliminating the need for a separate thread. The size of these buffers can be controlled via this configuration option, or alternatively these buffers can be disabled completely to save memory.

There are additional options in the generic serial I/O package CYGPKG_IO_SERIAL which will affect this driver. For example CYGPKG_IO_SERIAL_FLOW_CONTROL and its sub-options determine what flow control mechanism (if any) should be used.

This package also defines some configuration options related to testing. Usually these options are of no interest to application developers and can be ignored.

Porting

The generic driver needs some information from other packages about the exact hardware, for example how many UARTs are available and whether or not they are connected.

1. Another package, usually the platform HAL, should implement one or more of the interfaces CYGINT_DEVS_SERIAL_PNX8310_UART0, CYGINT_DEVS_SERIAL_PNX8310_UART1, or CYGINT_DEVS_SERIAL_PNX8310_UART2. Typically this is left to the platform HAL because even if the processor contains the UART device it may not be accessible on a given platform because there is no suitable connector.

2. If the RTS and CTS are connected for a given UART then the platform HAL should also implement the appropriate interface, for example CYGINT_DEVS_SERIAL_PNX8310_UART0_RS232_RTSCTS. This will enable driver support for hardware handshaking.

3. If a given UART is supported then the generic driver will need to know where it is mapped in the address space. Typically this is handled by the processor or variant HAL package via a definition HAL_PNX8310_UART0_BASE in cyg/hal/proc_io.h or cyg/hal/var_io.h.

4. On some platforms or processors additional initialization may be needed, for example to connect certain pins to the internal UART rather than to other on-chip devices. The processor or platform HAL can define a macro HAL_PNX8310_UART0_PROC_INIT for this purpose.

Chapter 117. Nios II Avalon UART Serial Driver

Name

CYGPKG_DEVS_SERIAL_NIOS2_AVALON_UART — eCos Serial Driver for Nios II Avalon UARTs

Description

A Nios II hardware design can include one or more Avalon uart devices for serial communication. On typical hardware each uart requires an external transceiver chip on the board to convert between FGPA and RS232 voltage levels, so the actual number of uarts is more a property of the board than of the FPGA hardware design. CYGPKG_DEVS_SERIAL_NIOS2_AVALON_UART provides an RS232 serial device driver for up to eight Avalon uarts in the design. It should be noted that in typical eCos configurations the first uart will be used for the HAL diagnostics and debug channel, either directly or via virtual vector calls to the RedBoot ROM monitor, so that uart should not be accessed via the serial driver.

Configuration Options

The Nios II Avalon uart serial driver should be loaded automatically when creating an eCos configuration for a hardware design which includes a suitable device, and it should never be necessary to load the package explicitly. The driver as a whole is inactive unless the generic serial support CYGPKG_IO_SERIAL_DEVICES is enabled.

For each uart in the h/w design the driver package provides a component, for example, CYGPKG_DEVS_SERIAL_NIOS2_AVALON_UART0, allowing driver support for that uart to be enabled or disabled. When enabled this component contains a number of options related to that uart:

CYGDAT_DEVS_SERIAL_NIOS2_AVALON_UART0_NAME

> Each serial device should have a unique name so that application code can open it. The default names may be provided by the h/w design HAL, otherwise they are strings such as /dev/ser0 and /dev/ser1. Usually it is only necessary to change these names if the h/w design involves different types of uarts and hence multiple serial device drivers.

CYGDAT_DEVS_SERIAL_NIOS2_AVALON_UART0_BAUD

> If the h/w design supports variable baud rates then this option can be used to set the default baud rate. This may be different from the default set in the h/w design. It will be installed when the device is opened by application code. If the h/w design does not support variable baud rates then this option will be inactive.

CYGDAT_DEVS_SERIAL_NIOS2_AVALON_UART0_BUFSIZE

> The serial driver will maintain software buffers for incoming and outgoing data. The former allows data to continue to arrive even if the application is still busy processing the previous transfer, and thus potentially improves throughput. Also since Avalon uarts do not have fifos a software buffer reduces the risk of lost data. The latter allows the application to transmit data without immediately blocking until the transfer is complete, often eliminating the need for a separate thread. The size of these buffers can be controlled via this configuration option, or alternatively these buffers can be disabled completely to save memory.

In addition the package provides control over the compiler flags used to build the driver code and some support for serial testing. There are further options in the generic serial I/O package CYGPKG_IO_SERIAL which will affect this driver. For example CYGPKG_IO_SERIAL_FLOW_CONTROL and its sub-options determine what flow control mechanism (if any) should be used. Hardware flow control will only be available if the h/w design includes support for the RTS/CTS lines.

Porting

This serial driver package needs information from the h/w design HAL about the number of Avalon uarts and how they have been configured. Note that this information can also affect the implementation of the HAL diagnostics and debug channel in the Nios II architectural HAL package so the relevant CDL interfaces are provided there. Also note that in accordance with eCos conventions uart numbering starts with 0.

1. The CDL interface `CYGHWR_HAL_NIOS2_AVALON_UARTS` should be implemented once for every Avalon uart in the h/w design.

2. Avalon uarts can be designed with RTS/CTS support if desired. If a given uart has this support enabled then the h/w design HAL should implement the appropriate CDL interface, for example `CYGHWR_HAL_NIOS2_AVALON_UART0_RTSCTS`. In the absence of RTS/CTS support the serial driver will not attempt hardware flow control on that uart.

3. Avalon uarts can be designed with either a fixed or a variable baud rate. If the latter then the h/w design HAL should implement the appropriate CDL interface, for example `CYGHWR_HAL_NIOS2_AVALON_UART0_VARIABLE_BAUD`.

4. For each uart the h/w design HAL should define the base address, the interrupt vector, the uart's input clock, the default baud rate, the number of stop bits, the parity, and the word length. This information should come from the `cyg/hal/nios2_hwconfig.h` header.

5. Default device names and baud rates can be provided using configuration options such as `CYGDAT_DEVS_SERIAL_NIOS2_AVALON_UART0_DEFAULT_NAME` and `CYGNUM_DEVS_SERIAL_NIOS2_AVALON_UART0_DEFAULT_BAUD`.

Unlike more conventional uarts, with an Avalon uart the number of bits per word, the number of stop bits, and the parity support are all fixed when the hardware is designed. Any attempt to change these settings at run-time will fail. The baud rate may also be fixed in the h/w design, or run-time changes may be supported. If the latter then the baud rate will be constrained by the input clock and a 16-bit divisor register, so for example with a 100MHz input clock the lowest standard baud rate that can be supported is 1800.

The serial driver does not provide any support for DMA transfers so it ignores any end-of-packet register that may have been included in the h/w design. Only RS232 is supported, not RS485 networking. There is no support for the DTR, DSR, DCD or RI lines. If these are needed then the lines would have to be wired up to an Avalon GPIO unit and handled by application code.

Part XXXIV. USB Support

Name

Overview — eCosPro Support for USB

Description

Important

This eCosPro-USB Middleware package is STRICTLY LICENSED FOR NON-COMMERCIAL PURPOSES ONLY. It may not be used for Commercial purposes in full or in part in any format, including source code, binary code and object code format.

A Commercial eCosPro License version 3 (or above) which explicity includes this Middleware Package is required for Commercial use.

The eCosPro-USB package only provides USB functionality for embedded systems. Where USB connectivity between eCos-based USB devices and host systems is required, it is your responsibility to ensure that a suitable host operating system class driver is available. Common host operating systems such as Windows, Linux and OS X include support for several standard USB classes. Unfortunately the specific classes supported varies considerably between them. If a host operating system you wish to support does not provide the necessary class support, then a suitable driver will need to be sourced from a third party USB class provider.

All USB Vendor and Product IDs used within this stack are for testing purposes only. It is your responsibility to obtain and deploy valid identifiers for your product; information about this can be found at the following link: www.usb.org/developers/vendor . It is also your responsibility to undertake any compliance testing needed to use the USB logo. Information regarding the USB-IF compliance program can be found here: http://www.usb.org/developers/compliance/.

Class Support

The individual USB classes are documented in the sections of the eCosPro documentation most relevant to that functionality. For example, information regarding the configuration and use of the Host Mass Storage Class is organized together with other file system related documentation.

Table 5. USB class support

USB Class	eCos Package Name and Documentation Link	Description
Host Mass Storage Class (MSC)	Host mass storage driver package `(CYGPKG_DEVS_DISK_USBMS)`	Supports use of USB memory sticks, hard disk drives and similar storage devices. USB mass storage devices essentially provide a block level interface, which by convention, a FAT format file system is layered over.
Host Communication Device Class (CDC), Abstract Control Model (ACM) subclass	Host CDC ACM protocol driver package `(CYGPKG_IO_USB_CDC_ACM_HOST)`	This class enables USB to serial converters conforming to the USB-IF defined CDC ACM class to be connected to embedded hardware. This can be used to expand the number of serial port connections available and can also be used for straightforward interconnection of embedded hardware; where one side implements the USB host class, and the other the device (target) side support. Read the USB Serial Support section for an overview of general USB serial functionality.
Host FTDI serial adapter class	Host FTDI protocol driver package `(CYGPKG_IO_USB_FTDI)`	This class enables FTDI USB to serial adapters to be connected to the embedded hardware, expanding the number of serial port connections available. This is a proprietary standard defined and supported by FTDI.

USB Class	eCos Package Name and Documentation Link	Description
		Read the USB Serial Support section for an overview of general USB serial functionality.
Target Communication Device Class (CDC), Abstract Control Model (ACM) subclass	Target CDC ACM protocol driver package (`CYGPKG_IO_USB_CDC_ACM`)	This class enables simple, straightforward connectivity and communication between embedded hardware and host PC's, or other embedded hardware. It is a USB-IF defined class that is supported by all major host operating systems. Read the USB Serial Support section for an overview of general USB serial functionality.
Target Remote Network Driver Interface Specification (RNDIS) Class	Target RNDIS driver package (`CYGPKG_DEVS_ETH_USB_RNDIS`)	The RNDIS support provides network level connectivity to host PCs. Note that this does not provide physical network access, but rather enables generic networking level communications between the USB attached Host and Target devices. RNDIS is a proprietary Microsoft defined class and is particularly suited for use with Windows-based systems. Compatible drivers are also available for other major operating systems.
Target Communication Device Class (CDC), Ethernet Emulation Model (EEM) subclass	Target CDC EEM driver package (`CYGPKG_DEVS_ETH_USB_CDCEEM`)	CDC-EEM provides direct network level connectivity between embedded targets and host PCs. Note that this does not provide physical network access, but rather enables generic networking level communications between the USB attached Host and Target devices. It is a USB-IF defined USB standard and is supported natively by both Linux and Mac OS.

Stack Limitations

The eCosPro USB stack stack currently implements a subset of the complete USB functionality. It is intended that it will eventually fully support not just host and target sides of the USB protocol, but also On-The-Go functionality. The current state of the stack is as follows:

- OTG support is not implemented.
- The host stack implements only control and bulk transfers. Interrupt and Isochronous transfers are not currently implemented. Additionally, only fixed size transfers are supported, short transfers are not, and scatter/gather support is not implemented.
- Hub and root hub support is limited to those control requests directly needed by the stack. Hub connect state is polled, hub interrupt status transfers are not supported.
- There is a limited set of host controllers supported. Currently only OHCI and the Synopsys DWC_usb controller are supported.
- The target stack implements control, bulk and interrupt transfers. Isochronous transfers are not implemented. Limited support for short OUT transfers is implemented.
- A relatively limited set of peripheral controllers is currently supported. For example, the Synopsys DWC_usb controller, as used on the STM32 Cortex-M family and the Atmel UDPHS controller driver.
- There is no intrinsic support for composite devices. In target mode applications can define and service composite devices directly. In host mode class drivers should be able to extract the specific interfaces they need from a composite device, although this has never been tested.
- The stack can currently only function within eCos with the kernel present. Support for unthreaded, non-interrupting environments such as RedBoot has not been implemented.

Terminology

USB has its own terminology, some of which conflicts with similar terms used in eCos. Some terms are used several times for slightly different but related concepts. The following lists some of the terms used and how they relate to the eCosPro USB stack.

Device

A device is something that is plugged into a USB bus, for example a flash drive, a serial adaptor or an ethernet adaptor. When its attachment is detected it is given an address and descriptors are fetched. These will generally be referred to by the term *physical device*.

In the eCosPro USB host stack the term *device* is also used to refer to the data structure allocated in the host stack to represent and manage the physical device while it is attached.

Target

A target is the name used in the eCosPro USB stack for a peripheral device implemented by eCosPro.

Host Controller (HC)

A host controller is the hardware device that provides access to a USB bus. It typically controls the transfer of packets between the USB stack and devices. It usually also provides support for one or more external ports into which devices and hubs are plugged.

Host Controller Driver (HCD)

A host controller driver is the software component that controls the host controller hardware and provides a standard interface by which the rest of the USB stack accesses the bus.

Peripheral Controller (PC)

A peripheral controller is the hardware device that provides access to a USB bus in peripheral mode. It typically controls the transfer of packets between the USB stack and the USB host.

Peripheral Controller Driver (PCD)

A peripheral controller driver is the software component that controls the peripheral controller hardware and provides a standard interface by which the rest of the USB stack accesses the bus.

Hub

A hub is a USB bus component that splits the USB bus into a number of additional ports. A typical external hub has four downstream ports for connecting new devices and a single upstream port that connects to a downstream port of another hub or host controller.

A host controller also acts as a hub, known as a *root hub*. It typically contains one, two or more ports which form the external interface to the USB bus. These are usually controlled by a handful of registers in the controller and accessed by the HCD. The USB host stack usually virtualizes the root hub so that it can be controlled in exactly the same way as an external hub through the exchange of control messages.

Endpoint

In the USB specification an endpoint is the terminus of communication between the host and a device. All USB transfers are directed to a combination of device address and endpoint number. Endpoints are uni-directional, and each device can have up to 16 endpoints in each direction, except endpoint 0 which is bidirectional.

In the eCosPro USB stack, the term *endpoint* is often used to refer to data structures that represent and manage transfers between the host and the target. Endpoint data structures can exist in both the USB stack itself and in the HCD/PCD.

Transfer

All communication is handled through a `usb_tfr` object. Internally to an HCD/PCD, the term transfer may also refer to an internal data structure. There may be a many-to-one relationship between HCD/PCD transfers and `usb_tfr` objects.

Port

A port is the connection point for attached devices. Both external hubs and host controllers have downstream ports. A hub's port is the target of various control operations to enable/disable and reset the connected device.

Class Driver	A class driver is a software component that converts a USB device into a particular eCos device type. Typically it operates between two interfaces, acting as a client to the USB stack and providing an eCos device interface to higher level components.

To configure and use the USB stack support, you should mainly refer to the class specific documentation linked to above. The following sections of this document are intended for developers who wish to build a deeper understanding of how the USB stack functions, for example to add their own class support.

Host Support Overview

Host support comprises the USB stack itself, one or more Host Controller Drivers and one or more Class Drivers.

During initialization the USB stack calls the init routine of each HCD. Platform-specific code called by the HCD locates all the instances of that host controller and configures it for host usage. This usually involves supplying power and clocks to the HC, configuring external pin multiplexing and enabling any external PHY, charge pump or power switches. Each HC is then registered with the USB stack as a separate USB bus. The first thing that happens for each bus is that a new device object is created to represent the root hub for that bus. The root hub is a virtual USB hub implemented by the USB stack to control the downstream ports of the HC. The USB stack controls the downstream ports by calling functions in the HCD.

All hubs, including the root hubs, are polled on a regular basis by the USB stack to detect any new device connections. If a new connection is detected then a device object is allocated and initialized. This object is then driven through a state machine that resets the device, assigns an address to it and fetches its device and configuration descriptors. Once this is done the device type is inspected. If it is a hub then the device object is passed over to the hub state machine which fetches further descriptors and starts polling the downstream ports for new connections. If it is not a hub, then the list of registered class drivers is searched for a class driver that recognizes the device type.

Class drivers interact with the device by allocating and initializing USB transfer objects and passing them to the USB stack for execution. Each transfer object identifies the device it applies to together with the endpoint and transfer type. It also points to a data buffer to/from which the data will be transferred and for control messages also contains the SETUP packet. Transfers are passed into the USB stack and are processed asynchronously to the client; completion of a transfer is signalled by calling a callback function in the transfer. The transfer's status indicates whether this was a successful exchange of data, some error has occurred, or the device has been disconnected. At this point the class driver is free to release the transfer, or resubmit it.

Device disconnection usually results in any active transfers receiving an error. It is also noticed by the hub polling machine and results in the device being detached from its parent hub. A call is also made to the class driver, which should then cancel any active transfers, dismantle any device specific data structures and optionally signal the event to its clients in turn.

The existence of transfers and device objects is controlled by reference counts. For each device the presence of the physical device counts as a reference, as should its use by a class driver; each active transfer also counts as a reference. So, when a device is detached, the physical device reference will be removed, but it will only be returned to the free pool once all transfers have completed and the class driver has finished with it. Similarly, transfers are created with a single reference, but the HCD will take one or more references while the transfer is active in the controller. To release a transfer, the class driver simply needs to decrement the reference counter in the completion callback, which will return it to the pool immediately, or maybe a little later when the HCD has finished with it.

Target Support Overview

Target, or peripheral, support comprises the USB stack itself plus one or more Peripheral Controller Drivers. There is currently no equivalent of the host class driver mechanism for targets and instead peripheral functionality is provided by application code. See the `acm_example.c` source for an example; this can be found in the `packages/io/usb/<version>/tests` directory.

Initialization of the target USB stack is similar to that for the host stack as far as Peripheral Controller Drivers are concerned. The USB stack calls the init routine of each PCD. Platform-specific code called by the PCD locates all the instances of that peripheral controller and configures them for peripheral usage. This usually involves supplying power and clocks to the Peripheral Controller, configuring external pin multiplexing and enabling any external PHY, charge pump or power switches. For dual mode

OTG controllers, much of this can be shared with the host controller mode. Finally, the peripheral controller is registered with the USB stack under a unique name.

Application code instantiates a target by creating a target object and populating it with pointers to device, string and configuration descriptors. Most of this can be done statically, and apart from the target object, can be constant data stored in ROM or flash memory. The target object also contains pointers to a number of callback routines that the USB stack uses to signal events to the application. The target is activated by attaching it to the specific peripheral controller that controls the external USB socket on which the peripheral is to be presented.

The USB stack remains quiescent until the PCD detects that the peripheral port has been attached to a host controller. From this point the USB stack handles most of the initial interaction with the host as it resets the peripheral port, assigns an address and fetches descriptors. Most descriptors will be fetched from those statically defined in the target object, but if any are not found then a callback to the application is made which allows it to manufacture any special descriptors dynamically. Also during this process, callbacks will be made to indicate the progress of the peripheral through the USB peripheral state machine.

Once the target reaches `CONFIGURED` state it is ready for operation and application code can start exchanging messages with the host. This is done using exactly the same transfer objects as are used in host mode. Each transfer object identifies the endpoint, transfer type and data to be exchanged, and its completion is signalled by calling a callback function. Transfers are controlled by reference counts in the same way as for host support; since the target is statically allocated by the application it is not subject to reference count control in the same way as host device objects.

If the peripheral is detached then any active transfers will be cancelled and the target is returned to an earlier state. Reconnection will restart the configuration process and eventually return the target to `CONFIGURED` state. Application code should avoid submitting transfers unless the target is in `CONFIGURED` state.

Structure of this Document

This document is divided into a number of sections. Some of these are of interest to all users, others will only be useful to writers of class or host controller drivers. Other parts are only useful to those who are working on the USB stack itself:

- The Configuration section describes the CDL configuration options that can be applied to the USB stack.
- The Transfer Objects section describes the message-like transfer objects that are used for all data transfers in the USB stack, together with various API functions that apply to them.
- The Host Device Object section describes the data structure used to represent a device connected to the stack in host mode. This section also describes the lifecycle of a device and a hub.
- The Class Drivers section describes the interface to host device class drivers.
- The Host Controller Drivers section describes the interface to Host Controller Drivers.
- The Target Objects section describes the data structure used to represent a target device connected to the stack in peripheral mode. This section also describes the support for string descriptor encoding and the target object API together with a description of what an application should do to create a target peripheral device.
- The Peripheral Controller Drivers section describes the interface to Peripheral Controller Drivers.

Name

Configuration — USB System Configuration

Description

USB support consists of several packages: the main USB subsystem `CYGPKG_IO_USB`; at least one HCD or PCD package, for example `CYGPKG_DEVS_USB_OHCI` or `CYGPKG_DEVS_USB_PCD_DWC`; and a target specific configuration package, for example `CYGPKG_DEVS_USB_STM32`. The driver and configuration packages are usually part of the target specification in `ecos.db`. Once these packages are installed, there are a number of configuration options that may be set. Those for the controllers and configuration packages are described in their own documentation, those for the USB subsystem are described here.

To enable USB support in any configuration it should simply be necessary to add the `CYGPKG_IO_USB` package and then enable `CYGPKG_IO_USB_HOST` and/or `CYGPKG_IO_USB_TARGET` to provide the appropriate stack modes.

Options

The following configuration options control the behaviour of the USB subsystem.

cdl_component CYGPKG_IO_USB_HOST

> This component enables USB host support in the USB stack.

cdl_option CYGNUM_IO_USB_HOST_BUFFER_SIZE

> The USB subsystem uses a shared buffer for some purposes. This option defines the size of that buffer. Class drivers may require that this buffer be increased in size. The default size is 64 bytes, which is sufficient for the configurations of most devices.

cdl_component CYGSEM_IO_USB_HUB

> This option controls the level of HUB support. When enabled, full HUB support is provided, for both root and external HUBs. When disabled, only rudimentary root hub support is provided, external hubs are not supported, and all devices must be plugged in to the USB host device. This option is enabled by default.

cdl_option CYGNUM_IO_USB_HUB_POLL_INTERVAL

> This option defines the interval in milliseconds between polls of a hub's ports for device attach and detach events. This value effectively defines how responsive the system is to device attach/detach. The default value is 1000, causing the hubs to be polled once a second.

cdl_option CYGNUM_IO_USB_HUB_PORT_MAX

> This option defines the maximum number of ports allowed per hub. The default value is four since most external hubs have just four downstream ports; virtual root hubs seldom have more and usually have fewer.

cdl_component CYGPKG_IO_USB_TARGET

> This component enables USB target support in the USB stack.

cdl_option CYGNUM_IO_USB_MEMORY_TABLE_TARGET_ENDPOINT_SIZE

> Number of endpoints allocated for target use.

cdl_option CYGNUM_IO_USB_OS_THREAD_STACK_SIZE

> The USB subsystem uses an internal thread to handle asynchronous actions. This option defines the size of this stack in addition to CYGNUM_HAL_STACK_SIZE_TYPICAL. The default value is 4KiB.

cdl_option CYGNUM_IO_USB_OS_THREAD_PRIORITY

The USB subsystem uses an internal thread to handle asynchronous actions. This option defines the priority at which this thread is scheduled. The default value is set to 10, which makes the USB thread run at a medium high priority.

cdl_component CYGSEM_IO_USB_MEMORY_SYSTEM_HEAP

This option enables use of the system heap for all USB memory allocations. It is orthogonal to the `PRIVATE_HEAP` and `TABLES` options. This is the default memory allocation option.

cdl_option CYGNUM_IO_USB_MEMORY_SYSTEM_HEAP_LIMIT

This option sets a limit on the amount of memory allocated from the system heap. Once the USB stack has allocated this much, it will refuse further allocations until memory is freed. If this value is set to 0 (the default) the limit is not enforced.

cdl_component CYGSEM_IO_USB_MEMORY_PRIVATE_HEAP

This option enables use of a fixed size private heap for all USB memory allocations. It is orthogonal to the `SYSTEM_HEAP` and `TABLES` options.

cdl_option CYGNUM_IO_USB_MEMORY_PRIVATE_HEAP_SIZE

This option defines the size of the private heap. Once this heap is exhausted, no more memory will be allocated.

cdl_component CYGSEM_IO_USB_MEMORY_TABLES

This option enables use of fixed sized static tables for all USB memory allocations. It is orthogonal to the `SYSTEM_HEAP` and `PRIVATE_HEAP` options.

cdl_option CYGNUM_IO_USB_MEMORY_TABLE_TFR_SIZE

Number of transfer objects in table. This option defaults to 4.

cdl_option CYGNUM_IO_USB_MEMORY_TABLE_DEVICE_SIZE

Number of device objects in table. This option defaults to 4.

cdl_option CYGNUM_IO_USB_MEMORY_TABLE_ENDPOINT_SIZE

Number of endpoints allocated. The endpoint object table will be the device table size multiplied by this value plus the value of `CYGNUM_IO_USB_MEMORY_TABLE_TARGET_ENDPOINT_SIZE`. The default value is 3. Typically devices need an entry for endpoint zero plus input and output endpoints. If any class driver needs more it should require a larger value for this option.

cdl_option CYGNUM_IO_USB_MEMORY_TABLE_DESC_SIZE

Number of descriptor objects in table. This option defaults to five times the number of entries in the device table. Typically each device needs an entry each for one configuration, one interface and three endpoints. Class drivers can increase this value if necessary.

cdl_option CYGNUM_IO_USB_TRANSFER_POOL_SIZE

This option defines the number of transfer objects maintained in the free pool for fast allocation. When the memory allocation strategy is to use tables, this option is ignored and the pool is set to the same size as the transfer table, and all transfers are kept in the pool. The default value is 4.

cdl_option CYGDBG_IO_USB_DIAG

This option controls the inclusion of diagnostics in the USB stack. The exact set of diagnostic messages can be further controlled at runtime on a per-subsystem basis.

cdl_option CYGDBG_IO_USB_LOG

This option controls the inclusion of logging in the USB stack. This differs from diagnostics in that only major events like device attach/detach are logged.

cdl_option CYGDBG_IO_USB_STATISTICS

This option controls the inclusion of statistics gathering in the USB stack.

cdl_option CYGNUM_IO_USB_STATISTICS_INTERVAL

This option defines the interval between reporting USB stack statistics. The time is given in seconds. A value of 0 disables the regular reports and statistics will only be reported if the application calls `usb_statistics_log()`.

Description

Most interaction between clients of the USB stack and the stack itself happens through the use of transfer objects (or just transfers). These data structures are allocated and initialized by the client and passed to the USB stack. When the transfer completes, the client is notified via a callback, following which it may release or reuse the object for another transfer.

Transfer Class Object

A transfer has the following structure:

```
struct usb_tfr
{
    usb_node                    node;           // List/queue node

    union
    {
        usb_device              *dev;           // Host device
        usb_target              *tgt;           // Target device
    };

    usb_uint16                  refcount;       // Reference count
    usb_uint16                  endpoint;       // Endpoint address
    usb_uint8                   attr;           // Transfer type
    usb_uint8                   flags;          // Additional flags
    int                         status;         // Current/returned status

    void                        *tfr_buffer;    // Data buffer
    usb_uint16                  tfr_size;       // Size of transfer/buffer
    usb_uint16                  tfr_actual;     // Actual size transferred

    usb_tfr_callback            *callback[2];   // Completion callback stack
    void                        *callback_data; // Callback data

    // The following fields are used by the HCD or PCD
    void                        *hcd_endpoint;  // HCD endpoint private data
    usb_list                    hcd_list;       // HCD transfer list

    // Per-transfer-type fields.
    union
    {
        struct
        {
            usb_uint8           setup[8];       // Setup packet
        } control;
        struct
        {
        } bulk;
#ifdef USB_CONFIG_INTERRUPT
        struct
        {
        } interrupt;
#endif
#ifdef USB_CONFIG_ISOCHRONOUS
        struct
        {
            int                 start_frame;    // Start frame
            int                 interval;       // transfer interval
            int                 pkt_count;      // Number of packets
            usb_iso_packet_desc *iso_packet;    // packet descriptors
        } isochronous;
#endif
    };
};
```

The fields of the transfer are as follows:

node
: A list node, which is used to link this transfer into internal lists in the USB stack. It may also be used by the client when the object is in its possession, but should be unlinked whenever passed to `usb_tfr_submit()`.

dev
: A pointer to the host device object on which this transfer will operate. This is filled in when the transfer is allocated by `usb_device_tfr_alloc()`. This value should not be changed directly by the client since other fields in this object may depend on this field. The transfer also holds a reference to the device which may not be decremented properly if this field is changed. If the client needs to communicate with a different device, it should allocate a new transfer object.

dev
: A pointer to the target object on which this transfer will operate. This is filled in when the transfer is allocated by `usb_target_tfr_alloc()`. This value should not be changed directly by the client since other fields in this object may depend on this field. The transfer also holds a reference to the target which may not be decremented properly if this field is changed.

refcount
: Transfer reference count. This controls the existence of this transfer. It can be incremented with a call to `usb_tfr_ref()` and decremented with a call `usb_tfr_unref()`. This field is set to 1 when the transfer is allocated, and the reference count on the associated device or target is also incremented. If the refcount is decremented to zero then the device or target reference is decremented, and the transfer returned to the free pool.

endpoint
: This is the endpoint number and direction. This field has the same format as the *`bEndpointAddress`* field of an endpoint descriptor and is initialized from the descriptor.

attr

This is the endpoint attributes; it mainly defines the type of transfer: control, bulk, interrupt or isochronous. It may contain other information for some transfer types. This field is initialized from the *`bmAttributes`* field of an endpoint descriptor and has the same format.

flags

This field contains a number of flag bits that control the nature of the transfer. If `USB_TFR_FLAGS_TARGET` is set then this is a target mode transfer and the *`tgt`* field is is valid, otherwise it is a host mode transfer and the *`dev`* field is valid. The flags `USB_TFR_FLAGS_START` and `USB_TFR_FLAGS_END` allow transfers to be chained together to provide a scatter/gather facility; this is currently not implemented. The `USB_TFR_FLAGS_CALLBACK` flag indicates that this transfer's callback should be called when it is complete. The `USB_TFR_FLAGS_SHORT_OK` flag indicates that a short transfer should be treated as a success and not a failure; this is currently not implemented for host transfers, but is for target OUT transfers.

By default, a transfer is initialized with the `START`, `END` and `CALLBACK` flags set. Additionally a target mode transfer is initialized with the `TARGET` flag set.

status

This field contains the transfer status. While it is in the possession of the USB stack, this field may be used to record internal state transitions. When it is returned to the client via a callback, it will contain either `USB_OK` to indicate the transfer was successful, an error code, or a status code (e.g. `USB_TFR_CANCELLED`).

tfr_buffer

A pointer to a buffer containing the data to be transmitted, or where the received data should be places. There are no explicit alignment requirements on this buffer, but on some platforms this buffer may need to be synchronized to external memory or flushed from the data cache, so if it is not cache line aligned these operations may have a side-effect on other data.

tfr_size

The size of the data buffer, in bytes, and hence the size of the transfer. The transfer size is not limited by the maximum packet size of the addressed endpoint, the driver may split the transfer into a sequence of packets if necessary.

tfr_actual

When the transfer is complete, this will contain the number of bytes actually transferred. This should only differ from *`tfr_size`* if the `SHORT_OK` flag is set.

callback

When a transfer has completed, this is signalled to the client by calling a callback routine. Callbacks are managed as a stack, with the client callback as the lowest, last, callback. This mechanism allow the USB stack to interpose its own finalization processing for a transfer if required. This callback stacking is opaque to the client.

callback_data

This is a client-supplied data value that the client can supply to ensure continuity between the submitter and the callback; it is usually a pointer to some controlling data structure. The client's callback can retrieve this value from the transfer by accessing this field. While callbacks are stacked, the callback_data is not, internal callbacks only make use of the standard transfer fields.

hcd_endpoint

This field is for use by the HCD or PCD, and typically contains a pointer to the data structure in the driver that controls the endpoint to which this transfer is directed.

hcd_list

This field is for use by the HCD or PCD, and typically is the root of a chain of internal data structures that define the data transfer.

control

This sub-structure is part of an anonymous union that defines per-transfer-type fields consisting of this field and the following *`bulk`*, *`interrupt`* and *`isochronous`* fields. This structure contains the contents of the setup packet. In host mode normally the setup packet is not assigned directly, but is copied here by `usb_tfr_control()` after being initialized elsewhere with `usb_request_init()`.

bulk

This field contains bulk transfer control fields. It is currently empty.

interrupt

This field contains interrupt transfer control fields. It is currently empty and is only defined if interrupt transfer support is configured. It's contents may change significantly when interrupt transfer support is implemented.

isochronous This field contains isochronous transfer control fields. It is currently empty and is only defined if isochronous transfer support is configured. At present isochronous transfers are not supported. It's contents may change significantly when isochronous transfer support is implemented.

API

There are a number of API functions associated with the management of transfer objects.

Host mode clients should allocate a transfer by calling `usb_device_tfr_alloc()`. The result will be a pointer to a transfer which has been zeroed except that the *`node`* field will be initialized, the *`dev`* field will be set to the supplied device pointer and the *`refcount`* will be set to 1. Additionally, `usb_device_ref()` will have been called on the device. This function will return a NULL pointer if there are no transfers available for allocation.

Target mode clients should allocate a transfer by calling `usb_target_tfr_alloc()`. The result will be a pointer to a transfer which has been zeroed except that the *`node`* field will be initialized, the *`tgt`* field will be set to the supplied target pointer, the *`refcount`* will be set to 1 and `usb_target_ref()` will have been called on the target. The *`flags`* field will be initialized with the `USB_TFR_FLAGS_TARGET` flag. This function will return a NULL pointer if there are no transfers available for allocation.

If a client needs to take further reference to the transfer it can call `usb_tfr_ref()`. References are released by calling `usb_tfr_unref()`. When a client is finished with a transfer it should call `usb_tfr_unref()` a last time to release the initial reference. This may have the side-effect of calling `usb_device_unref()` or `usb_target_unref()` which may result in the device object being freed.

In general, a transfer is initialized by one of several routines to create a specific type of transfer. The most general initialization routine is `usb_tfr_init()` which sets up the transfer with the endpoint address and attributes, a data buffer, and a callback. This is the only initialization function that should be applied to target mode transfers, the remaining initialization functions only apply to host mode transfers.

Control transfer initialization is supported by a number of functions. The function `usb_tfr_control()` initializes a general control transfer. The *`endpoint`* argument is used to look up the endpoint in the device and initialize the *`endpoint`* and *`attr`* fields in the transfer. The *`req`* argument points to a completed USB request that will be copied into the *`setup`* buffer. The data buffer and callback are initialized too. The USB request can be initialized using the `usb_request_init()` macro. The first argument to this is the name of the request to initialize, not a pointer. The remaining arguments give values for the various fields; the 16 bit fields will potentially be byte swapped into little endian order.

The function `usb_control_tfr()` provided a higher level interface to create control transfers that do not transfer additional data. This is given the destination device plus values for the request type, request code, value and index field (but not the length), and the callback. Using these parameters, a transfer is allocated, a request buffer created and the transfer initialized with an endpoint address of zero. If a transfer cannot be allocated, a NULL pointer is returned.

A bulk transfer can be initialized using `usb_tfr_bulk()`. The *`endpoint`* argument is used to look up the endpoint in the device and initialize the *`endpoint`* and *`attr`* fields in the transfer. The buffer and callback are also initialized.

Interrupt and Isochronous transfers are not currently supported, but when they are similar functions to initialize those will be available.

A transfer is submitted to the USB stack by calling `usb_submit()`. This function performs some simple checks before passing the transfer on to the appropriate driver. If this function is passed a NULL transfer, it will return `USB_ERR_TFR_ALLOC`. The transfer initialization routines also return if a NULL transfer is passed to them. This allows detection and handling of transfer allocation failures in most cases to be deferred until this call, keeping error handling simpler.

A transfer can be cancelled by calling `usb_cancel()`. This may simply mark the transfer for cancellation, the transfer may not actually be cancelled until some time after this function returns. When the transfer is actually cancelled, its callback will be called with a status of `USB_TFR_CANCELLED`. However, if the transfer was already finished, or caused an error, the callback status may be `USB_OK` or an error code. Thus client code cannot rely on the transfer completing with a CANCELLED status; this call just ensures that the transfer will be returned to the client in some way. Note that it is not very useful to cancel host mode control or bulk transfers since they will usually be processed as soon as submitted and will be returned quickly; the client is unlikely to catch them in time.

Name

Host Device Object — Structure and Interface

Synopsis

#include <cyg/io/usb.h>

void **usb_device_ref**(*dev*);

void **usb_device_unref**(*dev*);

Description

Whenever a new device or hub is attached to a USB, a device object is created to represent it in the USB stack. Most users of the USB stack do not need to concern themselves with the contents of a device object, so most of the information here is for the use of USB stack developers.

Host Device Object

This structure does double duty for both standard devices and for hubs. The internal union separates out the role specific fields. This structure also has two typedef names, usb_device and usb_hub, which can be used interchangeably, but help keep track of which role the structure is currently being used in. A device object has the following structure:

```
struct usb_device
{
    usb_node                    node;           // Node in per-hub list
    usb_bus                     *bus;           // Controlling bus
    usb_hub                     *parent;        // Parent hub

    usb_uint32                  flags;          // Flags
    usb_uint8                   refcount;       // Reference counter
    usb_uint8                   id;             // Device ID
    usb_uint8                   port;           // Port on parent hub
    usb_uint8                   state;          // Current device state
    usb_uint8                   state_data;     // Associated data

    usb_device_descriptor       desc;           // Device descriptor
    usb_descriptor              *config;        // Current configuration
    usb_descriptor              *interface;     // Current interface
    usb_descriptor              *desc_chain;    // Chain of all descriptors

    usb_resource_client         res_client;     // Resource client

    void                        *hcd_priv;      // HCD private data

    usb_device_endpoint         *endpoints;     // List of active endpoints

    union
    {
        struct
        {
            union
            {
                // Used only during initialization
                usb_uint8               *buf;          // Descriptor read buffer
                usb_config_descriptor   *config;       // Config descriptor view of buf

                // Used only when state >= RUNNING
                usb_class_driver        *class_driver; // Attached class driver

            };
        } device;
        struct
        {
            int                 port_count;     // Number of downstream ports
            usb_hub_port_status port_status[USB_HUB_PORT_MAX+1];

            usb_uint8           *buf;           // Descriptor read buffer

            usb_list            devices;        // List of attached devices

            // Status tfr state
            usb_tfr             *status_tfr;    // Current status change tfr
            usb_uint8           status_buf[4];  // Status change buffer
            usb_descriptor      *intr_desc;     // Interrupt endpoint descriptor

            // TODO: Power allocation stuff

            // TODO: Transaction translator stuff
        } hub;
    };
};
```

The fields of the device are as follows:

node
A list node that is used to link this device into a list in the hub object to which this device is attached.

bus
A pointer to the object representing the bus to which this device is attached. This pointer provides access to the HCD that communicates with this device. The bus object also controls the allocation of device IDs.

parent
A pointer to the parent hub, the same hub in whose device list this device must be linked via the *node* field.

flags
Flag bits controlling aspects of this device. The `USB_DEVICE_FLAGS_HUB` indicates that this device is a hub, and `USB_DEVICE_FLAGS_HUB_ROOT` indicates that this is a root hub.

refcount
Device reference count. This is initialized to 1 when the device is first attached, representing a reference held by the physical device, and incremented for each active transfer for this device. Class drivers may also take their own references. When the physical device is detached the refcount is decremented, which should result in the device object being freed.

id
Device ID. Each device starts with an ID of zero while it is being configured. This field will be set to the allocated ID once the physical device has had its address set successfully.

port
This is the port number within the parent hub to which this device is attached.

state
Device state. During their lifetime devices pass through a set of different states. This field described what state the device is currently in.

state_data
Some device states need some additional data in addition to the state. That data is stored here.

desc
During initialization the USB stack will read the device device descriptor and store it here.

config
When the device has been configured, this will point to the descriptor for the configuration that has been set in the physical device.

interface
When the device has been configured, this will point to the descriptor for the interface that has been set in the physical device.

desc_chain
This points to a chain of usb_descriptor objects which contain all the configuration, interface and endpoint descriptors that have been read from the physical device. They are stored in a single linear chain with the descriptors for each configuration chained on to the end of the previous descriptor chain.

res_client
: This structure is used internally by the USB stack to enable devices to wait for resources such as memory, or to implement delays.

hcd_priv
: This is a pointer to private data defined by the HCD that controls the physical device. It is copied from the *hcd_priv* field of the usb_bus object from which the device attachment was detected.

endpoints
: This points to a chain of usb_device_endpoint objects which associate an endpoint descriptor with an HCD supplied pointer that implements that endpoint. Only the endpoints for the interface currently selected appear in this list, together with endpoint 0 for control packets.

device
: This sub-structure is part of an anonymous union that provides fields for either devices or hubs, depending on the *flags* field. At present this contains an anonymous union that contains either a pointer to a buffer used to read configurations, or during normal running a pointer to the class driver that is using this device.

hub
: This is the second element of the anonymous union and contains field used if this device is a hub. This contains a number of fields that are mainly used internally by the USB stack. Included are a count of the number of downstream ports the hub contains together with the most recent reported state of each and a list of the devices attached to this hub. As hub support evolves, this sub-structure will acquire further fields.

Device Lifecycle

From initial attachment through configuration, data transfer and final detachment, a device goes through a lifecycle in the USB stack. This section looks at this lifecycle.

When a physical device is attached to a port on a hub the state change is detected by the hub state machine (see Hub Lifecycle). This results in a device object being created and initialized. The *refcount* is set to 1, representing a reference held by the physical device.

A device runs through a state machine that is generally run in the callbacks of transfers, delays and resource allocations. Each state assesses the result of the previous operation, issues new transfers/delays/allocations, sets the next state and waits for completion. States are generally named for the operation for which they waiting to complete. The device moves through the following states:

NEW

> This is the initial state, the device is further initialized to have an endpoint for device 0 endpoint 0. A request is set up to wait for allocation of the shared configuration buffer.

BUFFER

> This state is entered when the shared configuration buffer has been allocated. This buffer allocation has two purposes. First, it provides us with a buffer large enough to read entire configurations into. Second, and more importantly, it serializes all device initializations, which is necessary before setting the device address. The device sends a control packet to the hub to clear the connect change bit. The *state_data* field is initialized to contain a pair of 4 bit counters which count the number of reset and port status retries that have been tried.

CLEAR_CONNECT

> Once the connect change bit has been cleared, the device sends a control command to the hub to reset the physical device. This puts the device into a state where it responds to commands sent to device ID 0.

RESETTING

> After the reset command has been sent, the device waits 200ms for the reset to complete.

RESET_DELAY

> After the delay, a control request is sent to the hub to get the status of the port.

PORT_STATUS

The result of the port status request is analyzed. If the device appears to have disconnected, then the state machine is terminated, and the detach event will be detected by the hub state machine. If the port status indicates that the device has not been reset, then the port status retry counter is decremented, and after a delay the state machine goes back to the RESETTING state, to re-submit the port status request. If the port status counter is zero, then a clear port enable command is sent, the reset retry counter is decremented, the port status counter reset to its original value and the next state set to CLEAR_CONNECT. This will cause the port to be reset again. If both retry counters are zero, then the device is considered unusable and the device state set to UNDEFINED. If the device has been rest and enabled then the reset is successful. A control command is sent to the hub to clear the reset change bit in the port and the next state set to CLEAR_RESET.

CLEAR_RESET

In this state we are reasonably sure that the device has been reset correctly, it should respond to control commands sent to device ID 0. A new device ID is allocated from the usb_bus object and stored in the state_data field. A control command is now sent to device ID 0 to set the address of the device to the allocated value. The next state is set to ADDRESS.

ADDRESS

If the attempt to set the address failed then the device is disabled, the ID freed and the state set to CLEAR_CONNECT to go through the rest and port status cycle again. If it was successful then the device ID is set to the allocated value and a new control endpoint is attached in the HCD. A control request is sent to the device to read the device descriptor into the buffer and the next state set to DEV_DESC.

DEV_DESC

Once the device descriptor has been successfully read, it is copied into the *desc* field of the device object. A request is now sent to read the first 9 bytes of the first configuration descriptor into the buffer. The next state is set to CFG_DESC and the state_data set to zero.

CFG_DESC

From the first 9 bytes of the configuration descriptor it is possible to get the whole size of the configuration. This is used to send a request to read the entire configuration into the buffer. The next state is set to CFG_ALL.

CFG_ALL

The read configuration is parsed and converted into a chain of usb_descriptor objects, which are then appended to the *desc_chain* in the device. If there are more configurations to read, then a new request to read the first 9 bytes of the next descriptor is sent and the state set to CFG_DESC; the state_data field is used to keep track of which descriptor is currently being read.

If all the descriptors have been read then the device configuration is inspected. If the device is a hub, then the hub state machine is started. Otherwise, the shared buffer is released and a class driver is sought to support this device. If no class driver is found, the device state is set to UNSUPPORTED, otherwise it is set to RUNNING.

RUNNING

This is the eventual state for a device supported by a class driver. The device will stay in this state until the physical device detaches.

A device can end up in two other states instead of this one. UNSUPPORTED state is similar to RUNNING except that there is no class driver. UNDEFINED state is reached if the device appears to be attached to the hub port, but does not communicate with the USB stack.

When a device detach is detected by the hub state machine, `usb_device_detach()` is called. This function puts the device into DETACH state, deallocates the device ID and unlinks the device from the parent hub. If the device is a hub, then it also recursively detaches any devices attached to the ports of this hub. If the device has a class driver attached to it, then the driver's detach routine is called. Finally, `usb_device_unref()` is called to remove the physical device's reference. This should result in the device being deallocated once any pending transfers have terminated.

Hub Lifecycle

Initially a hub passes through the same state machine as any other device to reset it, allocate an ID and read the descriptors. Once this is done and the device is identified as a hub, control moves to the hub state machine, which is an additional set of states to the device state machine.

RUNNING

> The hub starts out in device RUNNING state. The shared buffer is still allocated and a control command is sent to the hub to read its hub descriptor. The next state is set to DESC.

DESC

> When the hub descriptor has been read, the number of downstream ports is extracted and saved. A control command is sent to power up port 1 and the state_data is set to 1. The next state is set to PORT_POWER.

PORT_POWER

> The state machine loops in this state sending a command to power up each hub port in turn, using state_data to keep track of the current port. Once all ports have been powered up, a command to fetch the port status of port 1 is sent and status_data set to 1. The next state is set to PORT_STATUS.

PORT_STATUS

> The port status result is analyzed and if it shows a connection status change then `usb_device_attach()` or `usb_device_detach()` are called as appropriate. If there are more ports to poll, then a port status command is sent for the next port, and state_data incremented to track which port is being polled. If all the ports have been polled, then the state is set to READY and a delay set up for some number of milliseconds in the future.

READY

> This is the default state of a hub when it is not polling the ports. When the delay set up in PORT_STATUS expires, this state is processed. A new port status request is sent for port 1, state_data set to 1, and the next state set to PORT_STATUS. This re-executes the loop in PORT_STATUS state to poll all the ports and act on any attach/detach events.

Name

Class Drivers — Structure and Interface

Synopsis

#include <cyg/io/usb.h>

int **usb_class_driver_register**(*class_driver*);

int **usb_class_driver_deregister**(*class_driver*);

usb_descriptor ***usb_descriptor_find**(*desc*, *type*);

usb_descriptor ***usb_device_class_find**(*dev*, *class*, *subclass*, *protocol*, *configuration*, *interface*);

int **usb_device_configure**(*dev*, *config*, *callback*, *callback_data*);

Description

A class driver translates between operations on a standard eCos device interface and operations on a USB device. For example the USB mass storage class driver translates between disk driver operations and USB mass storage operations.

USB Class Object

A class driver interfaces initially to the USB stack through a usb_class_driver object:

```
struct usb_class_driver
{
    usb_node            node;           // Link in class driver list
    int                 priority;       // Priority in list

    int                 (*attach)( usb_class_driver *class_driver,
                                   usb_device *device );

    int                 (*detach)( usb_class_driver *class_driver,
                                   usb_device *device );

    void                (*poll)( usb_class_driver *class_driver,
                                 usb_uint32 interval );
};
```

The fields in this structure are as follows:

node

A list node, which is used to link this object into a prioritized list of class drivers. This is initialized by `usb_class_driver_register()` so does not need to be initialized by the class driver.

priority

The priority of this class driver. This should be a positive integer. When looking for a class driver to handle a newly attached device, the list is scanned in increasing priority order. So lower values are handled first.

attach

Whenever a new device is attached to a hub, the USB stack assigns it an address, fetches any descriptors, and then tried to find a class driver for it. It does this by calling the `attach()` functions of all registered class drivers until one indicates that it is willing to handle this device. The `attach()` function indicates acceptance by returning `USB_OK`, it indicates non-acceptance by returning an error code, preferably `USB_ERR_NO_SUPPORT`.

If the `attach()` function returns `USB_OK` then it should also set the device's *`device.class_driver`* field to point to the usb_class_driver object. It should call `usb_device_ref()` on the USB device to ensure that it remains valid. It must also call `usb_device_select_interface`.

detach — This function is called when the USB device detaches. In addition to cleaning up its own data structures, the main thing this function should do it arrange for the reference to the USB device taken in the attach function to be released by calling `usb_device_unref()`, directly or otherwise.

poll — This function is called periodically from the USB subsystem. The *`interval`* parameter indicates the number of milliseconds since the last call to this function. It can be used by the class driver to operate timeouts and retries. The exact interval between calls will depend on the level of activity of the USB stack and the resolution of the main system timer. Class drivers should therefore not depend on this for accurate timing operation and may need to make their own arrangements for such things.

USB Class API

The USB stack exports a number of functions that are intended for use by class drivers.

The function `usb_class_driver_register()` is used by a class driver to register itself with the USB stack. Typically a class driver is initialized as an instance of the driver type that it is intending to serve (e.g. disk, network, serial etc.) and during the initialization function for that driver will call `usb_class_driver_register()`. If the driver ever needs to detach itself from the USB stack then it can call `usb_class_driver_deregister()`.

Within the `attach()` function, the class driver can call some USB stack functions to help it decide whether a device is one that it can support. The most important of these is `usb_device_class_find()` which scans the descriptors attached to a a device for an interface that implements the given *`class`*, *`subclass`* and *`protocol`* types. A value of -1 for *`subclass`* and *`protocol`* acts as a wildcard. If successful it returns pointers to the configuration and interface found. The function `usb_descriptor_find()` can be used on *`dev->desc_chain`*, or any other descriptor pointer, to find the next descriptor of a given type. The class driver can also just inspect the device and parse the descriptor chain itself if necessary.

Before returning, the `attach()` function should call `usb_device_configure()`. Which will configure the device to use the configuration descriptor is supplied. The class driver must also supply a callback which will be called when the configuration has been done, or has failed. Further device setup can then be done in the callback.

Putting all that together, the functions of a class driver should have the following approximate form:

```
//--------------------------------------------------------------------------
// Attach device call

static int mydev_attach( usb_class_driver *class_driver, usb_device *dev )
{
    int result = USB_OK;
    mydev_data *mydev;

    // Look for configuration and interface. Here we assume that the
    // first configuration is the one we want to use and that we are
    // not worried about the function type, hence the wildcard.
    usb_descriptor *cdesc, *idesc;

    usb_device_class_find( dev, USB_CLASS_MYCLASS, USB_SUBCLASS_MYSUBCLASS, -1, &cdesc, &idesc );

    if( cdesc == NULL || idesc == NULL )
        return USB_ERR_NO_SUPPORT;

    // Set up device data structures here...
    mydev = mydev_alloc();
    mydev->dev = dev;

    // Extract any useful information from the interface descriptor
    // chain, such as endpoint addresses...

    // Reference the device
    usb_device_ref( dev );
    // Send off a command to select the configuration
    // we have found.
    result = usb_device_configure( dev, cdesc, mydev_attach_tfr_done, mydev );

    // If it all worked, set the device's class driver to point to us.
    if( result == USB_OK )
        dev->device.class_driver = class_driver;

    return result;
}

//-----------------------------------------------------------------------------
// Configuration callback

static int mydev_attach_tfr_done( usb_tfr *tfr )
{
    int result = tfr->status;
    mydev_data *mydev = tfr->callback_data;
    usb_device *dev = tfr->dev;

    // Release tfr object
    usb_tfr_unref( tfr );

    if( result != USB_OK )
    {
        // Handle configuration error by detaching from USB device and
        // freeing local resources.
        mydev_free( mydev );
        usb_device_unref( dev );
        return result;
    }

    // Continue device initialization...

    return result;
}

//-----------------------------------------------------------------------------
// Device detach call

static int mydev_detach( usb_class_driver *class_driver, usb_device *dev )
{
    int result = USB_OK;

    // Find my device data from device pointer.
    mydev_data *mydev = mydev_find( dev );

    // Shut down device...

    // Free device data structure
    mydev_free( mydev );

    // Release reference to device
    usb_device_unref( dev );

    return result;
}

//-----------------------------------------------------------------------------
// Device poll call

static void mydev_poll( usb_class_driver *class_driver, usb_uint32 interval )
{
    // Handle timeouts and delays in active devices...
}
```

Name

Host Controller Drivers — Structure and Interface

Description

This section is mainly of interest to developers who want to write a new host controller driver. It describes the interface used by the USB stack to initiate HCD operations and the API that an HCD can use to interact with the USB stack.

HCD Object

The main interface between the USB stack and each type of HCD is the usb_hcd object:

```
struct usb_hcd
{
    const char                  *name;          // Driver name

    // Initialization etc.
    void (*init)( void );                       // Initialize controller(s)
    int  (*attach)( usb_bus *bus );             // Attach to hardware
    int  (*detach)( usb_bus *bus );             // Detach from hardware

    // Endpoint handling
    int (*endpoint_attach)( usb_device *dev, usb_device_endpoint *dep );
    int (*endpoint_detach)( usb_device *dev, void *hcd_endpoint );

    // Transfer handling
    int  (*submit)( usb_device *dev, usb_tfr *tfr ); // Submit transfer (chain)
    int  (*cancel)( usb_device *dev, usb_tfr *tfr ); // Cancel transfer

    // Controller operation
    void (*poll)( usb_bus *bus );               // Poll controller for events

    int  (*frame_number)( usb_bus *bus );       // Get current frame number

    // Root hub support

    int (*port_status)( usb_bus *bus, int port, usb_hub_port_status *status);
    int (*set_port_feature)(usb_bus *bus, int port, usb_uint16 feature );
    int (*clear_port_feature)(usb_bus *bus, int port, usb_uint16 feature );

    // TODO: Bandwidth support

} CYG_HAL_TABLE_TYPE;
```

The fields are as follows:

name

This is a pointer to a string that names this device. It is mainly used for debugging.

init

This is called once by the USB stack to initialize all HCDs of this type. In combination with platform code this function should enumerate all the HCDs of the supported type and eventually call `usb_hcd_register()` to make the controller available to the USB stack.

The call to `usb_hcd_register()` is passed a hcd_bus object that the HCD should allocate in its private data structures. Within this object the *`hcd`* field should be set to this HCDs usb_hcd object. The *`hcd_priv`* field should be set to point to the HCDs per-controller private data structure; this value will be copied to the *`hcd_priv`* field of any device attached to this bus. The *`hcd_ep0`* field should be set to point to an HCD control endpoint for device 0; this will be used to communicate with a newly attached device before its ID has been set. The second argument to `usb_hcd_register()` is a count of the number of downstream, ports the root hub contains.

While this function should locate the devices and initialize the HCD data structures it should not access the Host Controller hardware at this point.

attach
: This is called to attach the HCD to the hardware. This is when the hardware should be initialized, interrupt handlers registered and everything made ready for transfers to occur.

detach
: This is called to detach the HCD from the hardware. It should undo the initialization done by the attach function, leaving the device free for other software to take control.

The main reason for this attach/detach mechanism is to allow OTG devices to be shared between host and peripheral drivers.

endpoint_attach
: This is called to create an endpoint in the host controller. The HCD should use the id of the device plus the endpoint descriptor in the usb_device_endpoint object to create an endpoint of the correct type and direction for the device.

The HCD will typically allocate controller and driver data structures to represent this endpoint. If the underlying controller only supports a limited number of endpoints, then the driver should either fail excess endpoint attachments, or arrange to share the physical endpoints between a larger number of virtual endpoints. If the HCD endpoint is created successfully the it should assign a pointer to it to the hcd field in the usb_device_endpoint object.

endpoint_detach
: This is called when the device is detached, or changes its active interface. It undoes the resource allocation made in `endpoint_attach`. Additionally, this function must cancel any transfers that are pending on the endpoint. Depending on the nature of the controller, these transfer cancellations and the eventual deallocation of the endpoint may happen after this function returns.

submit
: This is called to submit a transfer to a device. Internally, this function should extract the HCD private data from the device *`hcd_priv`* and the endpoint from the device's usb_device_endpoint object for the transfer's endpoint address. The HCD is free to use the *`hcd_endpoint`* and *`hcd_list`* fields in the usb_tfr object; the latter should be initialized before use.

cancel
: This is called to cancel a pending transfer. In general this is only necessary for interrupt or isochronous transfers, control and bulk transfers will always terminate within a finite time. The transfer will not necessarily be available for reuse once this function returns. This is only guaranteed once the transfer's callback is invoked, either with a `USB_TFR_CANCELLED` status, some other error, or even `USB_OK`.

poll
: This is called from the main USB handling loop to give the HCD the chance to service the hardware. In general all controller operations should be handled in this function rather than the ISR or DSR. The HCD should test the hardware for transfer completion, device attach/detach and errors and handle them here.

If a transfer completes in this polling routine its callback may either be invoked directly by calling `usb_tfr_callback_pop()` or may be deferred for later processing by calling `usb_tfr_complete_async()`. The latter is preferable since it avoids any problems of recursion if the callback submits another transfer.

The simplest way to write an HCD is to do all device event handling in the `poll()` routine. If the controller supports interrupts then the HCD can call `usb_signal_poll()` to cause the poll routine to be called. If it makes sense to handle device events in the ISR or DSR, callbacks, such as returning transfers, should still happen in the poll routine.

frame_number
: This simply returns the current USB frame number.

port_status

This call fills in the *status* buffer with information on the state of the given port. This routine should query the port in the host controller's root hub registers and translate the results into the standard format expected in the status result, which should be returned in little endian order.

set_port_feature

This is called to set a port feature. The *feature* argument is a standard hub port feature code as defined in the USB standard. Only the subset of features relevant to a root hub are supported.

clear_port_feature

This is called to clear a port feature. The *feature* argument is a standard hub port feature code as defined in the USB standard. Only the subset of features relevant to a root hub are supported.

Name

Target Object — Structure and Interface

Synopsis

#include <cyg/io/usb.h>

void **usb_target_ref**(*tgt*);

void **usb_target_unref**(*tgt*);

int **usb_target_attach**(*tgt*, *pcdi*);

int **usb_target_detach**(*tgt*);

int **usb_target_stall**(*tgt*, *ep*, *stall*);

usb_pcdi ***usb_pcdi_find_by_name**(*name*);

int **usb_string_descriptor_utf8**(*buf*, *len*, *u8*);

int **usb_string_descriptor_create**(*buf*, *len*, *index*, *strings[]*, *strings_num*);

Description

In order to support a target device, application code must create and initialize a usb_target object, which is then passed to the USB stack.

Throughout this section the code that instantiates and uses the target object is referred to an an "application". Normally this will be a device driver or other middleware that translates USB operations into some other interface that eCosPro understands. Examples would be the CDC ACM driver that translates USB traffic into a serial device, or the RNDIS driver that translates into a Ethernet driver interface.

The target mode stack retains the USB terminology for data transfer direction, which can be a little confusing. So a transfer which involves data being passed from the host to be received by the target, is referred to as an OUT transfer. Similarly, transmission from the target to the host is referred to an an IN transfer.

Target Object

A target object has the following structure:

```
struct usb_target
{
    usb_pcdi                    *pcdi;          // PCD device instance

    usb_uint32                  flags;          // Flags
    usb_uint8                   refcount;       // Reference counter
    usb_uint8                   id;             // Device ID
    usb_uint8                   state;          // Current target state

    const usb_device_descriptor *desc;          // Device descriptor
    const usb_device_qual_descriptor *qdesc;    // Device qualifier descriptor

    const usb_config_descriptor **configs;      // Array of configurations
    int                         config_count;   // Size of array
    const usb_config_descriptor *config_current;// Currently selected config
    const usb_string_descriptor **strings;      // Array of string descriptors
    int                         string_count;   // Size of array

    usb_target_endpoint         ep0;            // Control endpoint

    usb_target_interface        *interfaces;    // List of active interfaces

    void                        *data;          // Client private data pointer

    // Optional callbacks to user code

    // Control message escape
    int (*control)(usb_target *tgt, usb_request *req, void **buf, usb_uint16 *len );

    int (*new_state)(usb_target *tgt);          // Signals state change

    // Dynamic descriptor callback, called if the addressed static
    // descriptor pointer is NULL.
    int (*get_descriptor)(usb_target *tgt, usb_uint8 type, usb_uint8 index,
                          usb_uint8 **buf, usb_uint16 *len );

#if CYGINT_IO_USB_TARGET_INTERFACE_CALLBACK>0
    // Interface change callback
    int (*set_interface)(usb_target *tgt, usb_uint8 intf, usb_uint8 alt);
#endif
};
```

The fields of the target object are as follows:

pcdi

This is a pointer to the PCD instance to which this target object is attached. This is initialized during the call to `usb_target_attach()` and cleared by `usb_target_detach()`. This field should not be initialized or changed by the application.

flags

Various flag bits. At present only two flags are defined, `USB_TGT_FLAG_CALLBACK_CTRL` and `USB_TGT_FLAG_CALLBACK_DESC` which control the invocation of the `control()` and `get_descriptor()` callbacks.

refcount

Target reference count. Since target objects are allocated by the application, zeroing this count does not cause the target to be zeroed. This count is used to keep track of the number of transfers associated with the target and for consistency checking.

id

The device ID. This is the ID that the host has set via a SET ADDRESS command. Before that happens, and when the target is reset, this will be set to zero.

state

Target state. This moves through states as defined by the USB specification and controls how the target reacts to bus events such as suspend, resume and reset.

desc

A pointer to the device descriptor for this target. If this pointer is NULL, then the `get_descriptor()` callback is called to supply the descriptor.

qdesc

A pointer to the device qualifier descriptor for this target. If this pointer is NULL, then the `get_descriptor()` callback is called to supply the descriptor.

configs

A pointer to an array of pointers to configuration descriptors. If this pointer is NULL, or a pointer in the array is NULL, then the `get_descriptor()` callback is called to supply the descriptor.

config_count

The size of the *`configs`* array. If a descriptor index greater than this value is requested, then the `get_descriptor()` callback is called to supply the descriptor.

config_current

When a target passes into the CONFIGURED state, this field will be set to point to the configuration selected. When the target is reset, this will be set back to NULL.

strings

A pointer to an array of pointers to string descriptors. If this pointer is NULL, or a pointer in the array is NULL, then the `get_descriptor()` callback is called to supply the descriptor.

There are a number of issues with string descriptors and their encoding which are covered in the section titled String Descriptor Encoding.

string_count

The size of the *`strings`* array. If a descriptor index greater than this value is requested, then the `get_descriptor()` callback is called to supply the descriptor.

ep0

A target endpoint structure. This is initialized and attached to the PCDI when the target is initially connected to the bus. It is used for all control endpoint transfers.

The *`desc`* sub-field of this object may be initialized to point to a descriptor for endpoint 0. If this is left NULL, it will be initialized to point to a default descriptor that allows a maximum packet size of 64 bytes. If the client needs to use a different maximum packet size on endpoint zero, it should set this sub-field.

interfaces

A chain of dynamically allocated target interface objects. When the target is configured by the host the selected configuration is scanned and for each endpoint in each active interface an endpoint is created and attached to the PCDI. A usb_target_endpoint object is allocated and attached to this list for each interface, and itself contains a list of usb_target_endpoint objects for each attached endpoint. When the target is reset, this list is scanned, the endpoints detached from the PCDI, and all the objects freed. A switch to a different alternate setting for an interface will result in the interface object in this list being detached, its endpoints detached from the PCDI, and a new interface and endpoints for the selected alternate created.

data

A data pointer that the application may use for its own purposes. Normally this will point to some data structure associated with the application.

`control()`

Normally, the USB target mode stack will handle all control SETUP messages to read descriptors, set the address, set the configuration and other commands. If a SETUP packet arrives that has a request type or code that is not recognized, then this function will be called. The return code defines what will happen next:

`USB_OK`

> This indicates that the command was recognized and processed and there is no further action required. The USB stack will return a status packet to the host and then return to looking for the next SETUP packet.

`USB_TARGET_CONTROL_DATAIN`

> This indicates that the USB stack should return data to the host. The data to be returned should be described by setting `*buf` and `*len` to the address and size of a buffer.
>
> When the data has been successfully sent, this function will be called again, with the same request structure, the buffer pointer as passed, and `*len` set to the actual quantity of data sent. This is done so that the application can release or reuse the buffer; it can distinguish this call from the first by looking at `*buf` which will be NULL in the first call and non-NULL in the second. On return from this second call a status packet will be received from the host and the USB stack will return to looking for the next SETUP packet.

`USB_TARGET_CONTROL_DATAOUT`

This indicates that the USB stack should receive data from the host. A buffer into which the data should be received is described by setting `*buf` and `*len` to the address and size of the buffer.

When the data has been successfully received, this function will be called again, with the same request structure, the buffer pointer as passed, and `*len` set to the actual quantity of data received. The application can distinguish this call from the first by looking at `*buf` which will be NULL in the first call and non-NULL in the second. On return from this second call a status packet will be return to the host and the USB stack will return to looking for the next SETUP packet.

`USB_ERR_COMMAND_INVALID`

If the callback returns this error code, then the USB stack will generate a STALL condition on the bus, which will act to abort the control transfer. The stack will then return to looking for the next SETUP packet.

If this callback is NULL, then any unrecognized SETUP packets will cause a STALL. So, unless the target device protocol contains extra control operations, it is not necessary for the application to supply this callback.

`new_state()`

This callback is called each time the target moves into a new state. The application can perform any processing of its own in response to this call. If the application does no need to process these events, it can set this pointer to NULL.

`get_descriptor()`

If any of the descriptor pointers in the target object is NULL, or a descriptor outside the supplied set is fetched, this callback will be called. The *`type`* and *`index`* values identify the descriptor being read. If the application can generate the descriptor itself, it should set `*buf` and `*len` to point to the descriptor and return.

When the descriptor has been returned to the host, this callback will be called again with the same type and index values. This is done so that the application can release or reuse the buffer; it can distinguish this call from the first by looking at `*buf` which will be NULL in the first call and non-NULL in the second.

`get_interface()`

If a target implements interfaces with alternate settings, the CDL interface CYGINT_IO_USB_TARGET_INTERFACE_CALLBACK should be implemented to cause this callback to be present. Subsequently, whenever the host sends a `SET_INTERFACE` operation to select an alternate setting, this function will be called. This allows the client code to adapt to the potential change in endpoint configuration.

Since relatively few targets implement alternate interface settings, this callback is only present if the CDL interface is implemented.

String Descriptor Encoding

USB string descriptors are in Unicode, encoded in UTF-16LE. Unfortunately, this is not a character encoding that is directly supported by the GCC toolchain. There are a number of ways to work around this. The first, and simplest is to use the `-fshort-char` compiler option to force `wchar_t` to be 16 bits rather than the default 32 bits. Strings can then be prefixed by `L` to ensure 16 bit Unicode encoding. A typical static descriptor can then be defined as follows:

```
static const usb_string_descriptor mytgt_string_manufacturer =
{
    .bLength                            = 2+2*11,
    .bDescriptorType                    = USB_DESC_STRING,
    .bString                            = L"eCosCentric"
};
```

However, there are a number of problems with this. The encoding is strictly 16 bits, and any code points that require a surrogate pair cannot be defined. Compiling files with the `-fshort-char` option will throw up compiler warnings since it differs from the defaults with which the libraries will have been built. But, most importantly, it only works for little endian targets; big endian targets will generate the 16 bit values in big endian byte order.

A more portable approach would be to encode the UTF-16LE directly using optional byte swaps where necessary, as in the following example:

```
static const usb_string_descriptor mytgt_string_manufacturer =
{
    .bLength                            = 2+2*11,
    .bDescriptorType                    = USB_DESC_STRING,
    .bString                            = { USB_CPU_TO_LE16('e'),
                                            USB_CPU_TO_LE16('C'),
                                            USB_CPU_TO_LE16('o'),
                                            USB_CPU_TO_LE16('s'),
                                            …
                                          }
};
```

However, this approach is clumsy and does not allow the size or contents of the string to be made a configuration option, or even easy to change in the code.

The preferred approach in the USB stack is to generate and store string descriptors in UTF-8 and to convert them to UTF-16LE at run time, when the descriptor is requested. A UTF-8 string is just a sequence of bytes and can be defined and manipulated like any other byte array. Most text editors will allow a UTF-8 string to be created or pasted in from some other source without any problems. Most UTF-8 strings occupy less space than their UTF-16LE equivalents. A standard ASCII string is just a UTF-8 string that contains no code points beyond the basic ASCII set.

To simplify use of UTF-8 strings, the USB stack exports a couple of helper functions. The function `usb_string_descriptor_utf8()` takes a pointer and length of a buffer in which a string descriptor is created, and a pointer to a UTF-8 string. It recodes the UTF-8 string into UTF-16LE in the buffer together with setting the descriptor size and type. If successful, the buffer will contain a string descriptor ready to be transmitted. If the buffer is not large enough for the descriptor, an error code will be returned.

The function `usb_string_descriptor_create()` is passed a buffer pointer and length, the index of the descriptor to be returned and a pointer to an array of UTF-8 strings. It checks that the index is correct and then creates a new string descriptor in the buffer using the indexed string from the array; it calls `usb_string_descriptor_utf8()` to do this.

To put all this together, the strings for a device can be defined statically as follows:

```
static const usb_string_descriptor mytgt_string_langid =
{
    .bLength                            = 2+2*1,
    .bDescriptorType                    = USB_DESC_STRING,
    .bString                            = { USB_CPU_TO_LE16(0x0809) },
};

static const usb_string_descriptor *mytgt_string_descriptors[1] =
{
    [0]                 = &mytgt_string_langid,
};

static const char *mytgt_descriptor_strings[] =
{
    [1]                 = "eCosCentric",
    [2]                 = "My Device",
    [3]                 = "01234567890",
};
```

In the target object, the *strings* field is set to point to `mytgt_string_descriptors` and string_count set to 1. This will cause the USB target stack to call the target's get_descriptor function for the remaining string descriptors. This function should look like the following example:

```
static usb_uint8 mytgt_dynamic_desc[64];       // Dynamic descriptor buffer

static int mytgt_get_descriptor(usb_target *tgt, usb_uint8 type, usb_uint8 index,
                                usb_uint8 **buf, usb_uint16 *len )
{
    int result = USB_OK;

    // A non-NULL buffer pointer is the USB stack returning the buffer
    // to us for reuse.
    if( *buf != NULL )
        return USB_OK;

    if( type == USB_DESC_STRING )
    {
        result = usb_string_descriptor_create( mytgt_dynamic_desc, sizeof(mytgt_dynamic_desc),
                                               index,
                                               mytgt_descriptor_strings,
                                               sizeof(mytgt_descriptor_strings)/sizeof(char *) );
        if( result == USB_OK )
        {
            *buf = mytgt_dynamic_desc;
            *len = mytgt_dynamic_desc[0];
        }
    }
    else
    {
        // Handle any other descriptor types
    }

    return result;
}
```

Note that in this example the serial number string is a constant. For devices where a unique serial number is required for each unit, a different approach may be needed. First the unit must have a unique identifier that can be used for this purpose. Depending on the platform this could be fetched from EPROM, FLASH, a serial number chip or a built-in chip ID. The simplest approach is to convert this value into an ASCII string. Then in the `get_descriptor()` function this string can be converted to a string descriptor when the serial number is requested. For an example take a look at the `hid_test.c` test program where a serial number is manufactured from a checksum of the executable.

Target Object API

The USB stack exports a number of functions that are intended for use by applications using targets.

The function `usb_target_attach()` must be called to attach a target to a specific peripheral interface. Peripheral interfaces are named and a pointer to a particular interface can be obtained by calling `usb_pcdi_find_by_name()`. Following this, most target events will be handled by the USB stack with calls to the callbacks as necessary. If the application wants to stop the target, it should call `usb_target_detach()`.

Some USB protocols require an endpoint stall to signal various conditions. The function `usb_target_endpoint_stall()` allows this to be done. The *ep* argument contains the endpoint address, and should have `USB_ENDPOINT_ADDR_IN` set for IN endpoints. The *stall* argument is 1 to stall the endpoints and zero to clear the stall condition.

An application must instantiate a usb_target object and initialize it before calling `usb_target_attach()`. Typically this object can be defined statically as in the following example:

```
static usb_target mytgt_target =
{
    .desc               = &mytgt_device_descriptor,
    .qdesc              = &mytgt_device_qual_descriptor,

    .configs            = mytgt_config_descriptors,
    .config_count       = 1,

    .strings            = mytgt_string_descriptors,
    .string_count       = 1,

    .control            = mytgt_control,
    .new_state          = mytgt_new_state,
    .get_descriptor     = mytgt_get_descriptor,

    .data               = &mytgt_data,
};
```

This defines the target object, initializes the static descriptors and callbacks. No fields beyond those shown above need to be initialized. While none of the fields is mandatory, if a static descriptor is not present, the `get_descriptor()` callback will be called, so it is not sensible to have both NULL descriptors and no `get_descriptor()`.

Once the application has started, it should locate the PCDI it wants to attach the target to and call `usb_target_attach()`, as in the following example:

```
void mytgt_init( void )
{
    usb_pcdi *pcdi;

    // Find PCDI by name
    pcdi = usb_pcdi_find_by_name( "usb_fs" );

    if( pcdi == NULL )
    {
        // Handle error
    }

    // Attach our target to the PCDI
    result = usb_target_attach( &mytgt_target, pcdi );

    if( result != USB_OK )
    {
        // Handle error
    }
}
```

Once the target has been attached, all further interaction with the application will be via the callbacks. Most `new_state()` callbacks can be ignored while the target is going through the initial connect/reset/address sequence. The transition to CONFIGURED state is the most important since this is when the target should become ready to interact with the host. Normally this will be the point at which it submits transfers to the OUT endpoints to receive packets from the host and maybe starts sending data via the IN endpoints.

For a complete example take a look at the `acm_example.c` test program. This source is annotated with extra comments. The `usbms_tgt.c` and `hid_test.c` test programs in `packages/io/usb/<version>/tests` directory. The CDC/ACM protocol driver can also examined for example code.

Name

Peripheral Controller Drivers — Structure and Interface

Description

This section is mainly of interest to developers who want to write a new peripheral controller driver. It describes the interface used by the USB stack to initiate PCD operations and the API that a PCD can use to interact with the USB stack.

PCD Objects

The main interface between the USB stack and each type of PCD is the usb_pcd object:

```
struct usb_pcd
{
    const char                  *name;                          // Driver name

    int pad;

    // Initialization etc.
    void (*init)( void );                                       // Initialize controller(s)
    int  (*attach)( usb_pcdi *pcdi, usb_target *tgt );          // Attach to hardware
    int  (*detach)( usb_pcdi *pcdi, usb_target *tgt );          // Detach from hardware

    // Endpoint attach/detach
    int (*endpoint_attach)( usb_pcdi *pcdi, usb_target_endpoint *tep );
    int (*endpoint_detach)( usb_pcdi *pcdi, usb_target_endpoint *tep );

    // Set/clear endpoint stall
    int (*endpoint_stall)( usb_pcdi *pcdi, usb_target_endpoint *tep, int stall );

    // Transfer handling
    int  (*submit)( usb_target *tgt, usb_tfr *tfr );            // Submit transfer (chain)
    int  (*cancel)( usb_target *tgt, usb_tfr *tfr );            // Cancel transfer

    // Controller operation
    void (*poll)( usb_pcdi *pcdi );                             // Poll controller for events

    int (*set_address)( usb_pcdi *pcdi, usb_uint8 addr );       // Set new target address

};
```

The fields are as follows:

name

This is a pointer to a string that names this device. It is mainly used for debugging.

init

This is called once by the USB stack to initialize all PCDs of this type. In combination with platform code this function should enumerate all the PCDs of the supported type and eventually call `usb_pcdi_register()` to make the controller available to the USB stack.

The call to `usb_pcdi_register()` is passed a usb_pcdi object that the PCD should allocate in its private data structures.

While this function should locate the devices and initialize the PCD data structures it should not access the Peripheral Controller hardware at this point.

attach

This is called to attach the PCD to the hardware. This is when the hardware should be initialized, interrupt handlers registered and everything made ready for transfers to occur.

detach

This is called to detach the PCD from the hardware. It should undo the initialization done by the attach function, leaving the device free for other software to take control.

The main reason for this attach/detach mechanism is to allow OTG devices to be shared between host and peripheral drivers.

endpoint_attach

This is called to create an endpoint in the peripheral controller. The PCD should use the endpoint descriptor in the usb_target_endpoint object to create an endpoint of the correct type and direction for the device.

The PCD will typically allocate controller and driver data structures to represent this endpoint. If the underlying controller only supports a limited number of endpoints, then the driver should either fail excess endpoint attachments, or arrange to share the physical endpoints between a larger number of virtual endpoints. If the PCD endpoint is created successfully the it should assign a pointer to it to the *`pcd`* field in the usb_target_endpoint object.

endpoint_detach

This is called when the target is detached, or changes its active interface. It undoes the resource allocation made in `endpoint_attach`. Additionally, this function must cancel any transfers that are pending on the endpoint. Depending on the nature of the controller, these transfer cancellations and the eventual deallocation of the endpoint may happen after this function returns.

submit

This is called to submit a transfer to the controller. Internally, this function should extract the PCD private data from the target *`pcdi`* field and the endpoint from the target's usb_target_endpoint object for the transfer's endpoint address. The PCD is free to use the *`hcd_endpoint`* and *`hcd_list`* fields in the usb_tfr object; the latter should be initialized before use.

cancel

This is called to cancel a pending transfer. The transfer will not necessarily be available for reuse once this function returns. This is only guaranteed once the transfer's callback is invoked, either with a `USB_TFR_CANCELLED` status, some other error, or even `USB_OK`.

poll

This is called from the main USB handling loop to give the PCD the chance to service the hardware. Controller operations may be handled either in this function or in the ISR or DSR; however, callbacks must be made from this function. The PCD should test the hardware for transfer completion, device attach/detach and errors and handle them here.

If a transfer completes in this polling routine its callback may either be invoked directly by calling `usb_tfr_callback_pop()` or may be deferred for later processing by calling `usb_tfr_complete_async()`. The latter is preferable since it avoids any problems of recursion if the callback submits another transfer.

The simplest way to write an PCD is to do all device event handling in the `poll()` routine. If the controller supports interrupts then the PCD can call `usb_signal_poll()` to cause the poll routine to be called. If it makes sense to handle device events in the ISR or DSR, callbacks, such as returning transfers, should still happen in the poll routine.

set_address

This is called to set the address of the target in the peripheral controller. This is called after the host has sent a SET_ADDRESS command.

There is just one instance of the usb_pcd object for each type of peripheral controller. However, there may be more than one physical device of each type on the board. Each of these is represented by a usb_pcdi object:

```
struct usb_pcdi
{
    usb_node                    node;                   // Link in PDCI list

    char                        *name;                  // Instance name

    usb_uint8                   state;                  // Controller state

    usb_pcd                     *pcd;                   // Pointer to PCD
    usb_target                  *tgt;                   // Current attached target
    void                        *pcdi;                  // Driver private data
};
```

node Node in list of active PCD instances. This need not be initialized by the PCD, it is initialize by `usb_pcdi_register()`.

name Name of this interface. This should distinguish it from all other PCDIs, and is used by `usb_pcdi_find_by_name()` to locate this PCDI. This field must be initialized by the PCD before calling `usb_pcdi_register()`.

pcd A pointer to the usb_pcd object for the controlling driver. This field must be initialized by the PCD before calling `usb_pcdi_register()`.

tgt When a target is attached to a PCDI by calling `usb_target_attach()`, a pointer to the target is placed here. This field should be initialized to NULL by the PCD before calling `usb_pcdi_register()`.

pcdi A pointer to a per-instance data structure in the PCD. This field must be initialized by the PCD before calling `usb_pcdi_register()`.

Part XXXV. USB Serial Support

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 118. USB Serial Support

Name

Overview — eCosPro Support for USB Serial devices

Description

eCosPro USB serial support is divided into a number of packages. The USB serial driver package (`CYGPKG_IO_SERIAL_USB`) provides the common part of the USB serial device support. It communicates with one or more packages that implement a specific USB serial protocol. Serial support is implemented in both peripheral and host modes. The currently supported USB serial protocol packages include the Target CDC ACM protocol driver, Host CDC ACM protocol driver and Host FTDI protocol driver.

Applications access USB serial devices just as they would a physical UART, using the standard eCos I/O package API to send and receive data, and to set and get configuration and status information.

Example USB serial test applications can be found in the `packages/devs/serial/usb/<VER>/tests` directory. In particular the `usb_echo.c` test demonstrates access to all potentially attached USB serial protocol device types. It also includes code that shows the use of callbacks to determine when a host adapter has been attached or detached.

The following sections describe the configuration, internal data structures and workings of the USB serial package. They will generally only be of interest to someone with specific configuration requirements, or to gain a deeper understanding of the interface between the USB serial and protocol packages.

Data Structures

For various practical reasons, the interface between this package and the protocol drivers is defined in the `usb_serial.h` file in the main USB package.

The interface between the eCos serial driver and the USB protocol driver is defined by a data structure, usb_serial_if. This contains a number of fields that control the transfer of data between the drivers. Many of these are for internal use of the drivers, however, a number must be initialized by the user:

`dev`

In host mode this should be set to point to the usb_device object for the device being used when it has attached to the bus. The protocol driver must take a reference to this device in order to prevent it from being deallocated.

`tgt`

In target mode this points to the usb_target object that represents this peripheral. This target should be populated with suitable descriptors for the protocol being implemented.

`call`

This points to a table of functions that are used to communicate between the two drivers. This is described later.

`chan`

A pointer to the eCos serial device channel.

`rx_buf`

A pointer to a buffer used to receive data from the protocol package.

`rx_maxpkt`

The size of the *`rx_buf`* buffer.

`target.pcdi_name`

In target mode, this points to a string that names the peripheral controller to which the target will be attached.

`host.id`

In host mode, this should be the channel index number. This effectively defines the order in which host channels are searched for a VID/PID match. See the CDC/ACM host driver for details.

`host.vid`

In host mode, this controls whether this serial channel matches a particular USB Vendor ID. If zero it will match any ID, otherwise this channel will only match a device with the given Vendor ID. See the CDC/ACM host driver for details.

`host.pid`

In host mode, this controls whether this serial channel matches a particular USB Product ID. If zero it will match any ID, otherwise this channel will only match a device with the given Product ID. See the CDC/ACM host driver for details.

The *`call`* field points to a table of function calls. The functions in this table provide communication between the serial driver and the protocol driver.

`int (*init)(usb_serial_if *usb_if);`

This is the initialization routine for the protocol driver, it is called from the serial driver during it's initialization. This function should perform any USB stack initialization, such as attaching the target object to the PCDI in target mode, or register the class driver in host mode.

`int (*attach)(usb_serial_if *usb_if);`

This is called from the protocol driver whenever an attach event is detected in both host and target modes. The main side effect of this will be to invoke any registered serial callback.

`int (*detach)(usb_serial_if *usb_if);`

This is called from the protocol driver whenever an attach event is detected in both host and target modes. As with the attach call, this will cause the serial callback to be invoked.

`int (*send_data_start)(usb_serial_if *usb_if);`

This is called from the protocol driver to kick the serial driver transmitter into activity. It should be called when the USB device, host or target, moves into a state where data transfers can be started.

`int (*send_data)(usb_serial_if *usb_if, usb_uint8 *buf, usb_int16 len);`

This is called by the serial driver to transmit data on the USB device. The *`buf`* and *`len`* arguments describe the raw data to be sent. The protocol driver may need to wrap this data in any protocol headers or trailers and send it via the USB stack.

`int (*send_data_done)(usb_serial_if *usb_if, usb_uint8 *buf, usb_int16 len);`

This is called by the protocol driver when the transfer requested by `send_data` has completed. The *`buf`* will match the buffer pointer in the `send_data` call, and *`len`* will give the amount of data transmitted. It is likely that this function will call `send_data` to start another transmission; so the protocol driver must be ready for this.

`int (*recv_data)(usb_serial_if *usb_if, usb_uint8 *buf, usb_int32 len);`

This is called by the serial driver to supply a buffer for asynchronous data reception. It will use the *`rx_buf`* and *`rx_maxpkt`* fields from the common data structure. The protocol driver should use this to submit the necessary USB reception transfers to the USB device.

int (*recv_data_done)(usb_serial_if *usb_if, usb_uint8 *buf, usb_int16 len);

The protocol driver calls this when some data has been received. The *buf* and *len* describe the data received; while these will describe a portion of the *rx_buf* buffer, they may not describe all of it since protocol headers and trailers may be skipped. As with `send_data_done`, the serial driver may call back into the protocol driver during this call.

int (*dev_line_coding)(usb_serial_if *usb_if, usb_line_coding *line_coding);

This is called from the protocol driver when it receives a command from the USB peer to set the line parameters. The parameters passed are encoded in the usb_line_coding as described in the `usb_serial.h` header.

int (*dev_control_line_state)(usb_serial_if *usb_if, usb_uint16 line_state);

This is called from the protocol driver when it receives a command from the USB peer to set the RTS and DTR control line states. The state is encoded in the *line_state* argument as described in the `usb_serial.h` header.

int (*usb_line_coding)(usb_serial_if *usb_if, usb_line_coding *line_coding);

This is called from the serial driver when the eCos client sets any of the serial line parameters. The parameters passed are encoded in the usb_line_coding as described in the `usb_serial.h` header.

int (*usb_control_line_state)(usb_serial_if *usb_if, usb_uint16 line_state);

This is called from the serial driver when the eCos client sets the state of either the RTS or DTR lines. The state is encoded in the *line_state* argument as described in the `usb_serial.h` header.

int (*usb_set_config)(usb_serial_if *usb_if, cyg_uint32 key, const void *xbuf, cyg_uint32 *len);

This may be called from the serial driver if it is passed any `set_config()` keys that it does not recognize. It allows the protocol driver to handle any config options itself. This entry may be set to NULL, in which case no call will be made.

int (*usb_get_descriptor)(usb_serial_if *usb_if, usb_uint8 type, usb_uint8 index, usb_uint8 **buf, usb_uint16 *len);

This is used only for target mode drivers. The target `get_descriptor()` callback will be called if a given descriptor is not statically defined in the target object. If that routine cannot supply the descriptor then this callback should be invoked. The arguments follow the pattern of the target `get_descriptor()` function, except for the first argument, which is a pointer to the serial interface object and not the target object. This entry may be set to NULL if there are no descriptors to be fetched.

The line coding and control line entries in this list provide functionality that in the context of a pseudo-USB-serial connection between two machines have no real purpose. They only make sense if there is a genuine UART being controlled at one end.

Example Target Setup

A USB serial device needs some data structures to be defined and initialized. For a target mode device the following example for a notional target shows what needs to be done. This is usually done in a platform specific USB configuration package to associate a hardware peripheral with the serial protocol driver. This example shows a CDC ACM device, although the same approach should serve for any target protocol.

```
//=============================================================================
// USB serial device ACM0

#define USB_SUBSYSTEM USB_SUBSYSTEM_PCD

#include <cyg/usb/usb.h>
#include <pkgconf/io_usb_cdc_acm.h>
#include <cyg/usb/usb_serial.h>
#include <cyg/usb/cdc_acm.h>

#include CYGDAT_IO_USB_SERIAL_DEVICE_HEADER
```

```
//-----------------------------------------------------------------------------
// Connection calls
//
// Functions that start with usb_serial are supplied by the serial driver.
// Functions that start with cdc_acm are supplied by the CDC ACM protocol
// driver and would be substituted with functions for another protocol
// driver.

static const usb_serial_calls example_serial_calls =
{
    .init                        = cdc_acm_init,
    .attach                      = usb_serial_attach,
    .detach                      = usb_serial_detach,
    .send_data_start             = usb_serial_send_data_start,
    .send_data                   = cdc_acm_send_data,
    .send_data_done              = usb_serial_send_data_done,

        *len = usb_string_serial->bLength;
    }
    else
    {
        usb_serial_if *usb_if = tgt->data;
        if( usb_if->call->usb_get_descriptor )
            result = usb_if->call->usb_get_descriptor( usb_if, type, index, buf, len );
    }

    return result;
}
```

Example Host Setup

Host mode devices need largely the same set of data structures as for target mode, but initialized in a slightly different way. This is usually done in the USB serial protocol driver where a number of channels will be instantiated. The following shows the data structures for CDC ACM channel 0.

```
//------------------------------------------------------------------------------
// Connection calls
//
// Functions that start with usb_serial are supplied by the serial driver.
// Functions that start with cdc_acm_host are supplied by the CDC ACM host protocol
// driver and would be substituted with functions for another protocol
// driver.

static const usb_serial_calls cdc_acm_host_serial_calls =
{
    .init                        = cdc_acm_host_init,

    );
```

Chapter 119. USB Target CDC ACM Protocol Driver

Name

Overview — eCosPro Support for CDC ACM Protocol in Peripheral Mode

Description

This package provides support for a peripheral mode serial connection using the CDC ACM protocol. It needs to be used in conjunction with the USB serial driver package and the reader is referred to that document for additional details.

Configuration

To use this package, various other packages need to be included and configuration options need to be set. The packages that need including are CYGPKG_IO_USB, CYGPKG_IO_SERIAL_USB, CYGPKG_IO_SERIAL and this package CYGPKG_IO_USB_CDC_ACM. To get USB target and serial support running, the options CYGPKG_IO_USB_TARGET and CYGPKG_IO_SERIAL_DEVICES need to be enabled. So long as the hardware USB configuration package defines the target data structures described in the USB serial driver package, a CDC/ACM peripheral will be presented on the selected device port.

The configuration options CYGNUM_IO_USB_CDC_ACM_VID and CYGNUM_IO_USB_CDC_ACM_PID *must* be configured, respectively, with suitable VendorID and ProductID values. These values are used by hosts to identify a specific USB device. The www.usb.org site provides more information, specifically the Getting a Vendor ID page.

The configuration options CYGPKG_IO_USB_CDC_ACM_MANUFACTURER and CYGPKG_IO_USB_CDC_ACM_PRODUCT allow for human-readable identification strings to be supplied by the device. These strings are returned as part of the device USB description, and may be used by the host O/S in its description of the product as presented to end-users.

The configuration option CYGNUM_IO_USB_CDC_ACM_MAXPKT defines the maximum packet size used for USB transfers. It is used to define fields in the CDC ACM descriptors and must be used to define the size of the the *rx_buf* in the usb_serial_if structure.

Configuration Packages

The USB driver configuration packages for some target families (e.g. AT91 and STM32) contain configuration for a CDC ACM device instance. These have some common configuration options. In the following descriptions, XXXX should be replaced by the target family name.

The option CYGNUM_DEVS_USB_XXXX_ACM0_BUFSIZE defines the size of the circular buffer for ACM0. This must be sized such that there is always enough space in the buffer for a maximum sized USB packet after the high water mark is reached.

The option CYGPKG_DEVS_USB_XXXX_ACM0_SERIALNO defines the source of the serial number reported in USB string descriptor 3. The CSUM option generates an executable-unique checksum, which is necessary for the eCosCentric test system. The HAL option calls a function supplied by the platform HAL to supply the serial number. The CONST option uses the value of CYGINT_DEVS_USB_XXXX_ACM0_SERIALNO, which is useful for testing. In all cases the serial number is a 32 bit unsigned value which is encoded into the string descriptor in hexadecimal combined with the test crash ID.

The option CYGINT_DEVS_USB_XXXX_ACM0_SERIALNO supplies the constant value for the serial number if the CONST option is selected. This is useful for testing, but is not a viable solution for production devices.

Protocol Support

This driver only supports a minimal subset of the CDC ACM protocol, sufficient to provide a serial-like interface between a host and the target board. Any unrecognized messages will generate an error response; normally a STALL on the control endpoint.

CDC ACM uses two bulk endpoints to transfer raw data bytes between the host and the target board. Additionally, control messages are sent to the control endpoint to adjust the configuration of the channel. The following commands are supported:

`SET LINE CODING`
: This sets the baud rate, stop bits, parity and character size for the channel. These parameters are simply passed on to the USB serial driver by calling the `dev_line_coding` callback.

`GET LINE CODING`
: This returns the baud rate, stop bits, parity and character size for the channel. Usually this just returns the value set by the last `SET LINE CODING` command. The data structure is initialized to a default set of values in case it is queried before being set.

`SET CONTROL LINE STATE`
: This sets the state of the RTS and DTR lines. These are passed on to the USB serial driver by calling the `dev_control_line_state` callback.

`SEND BREAK`
: This sends a BREAK condition on the line. At present this command is accepted and acknowledged but nothing is done to act on it.

Since the protocol driver is not controlling a real UART, these commands have no real effect and are supported mainly to keep host OS drivers happy.

Host Driver Advice

The Linux operating system includes generic support for CDC ACM class devices and automatically supports standards conforming CDC ACM based devices.

Whilst Windows also includes built-in generic CDC ACM support, it has to be enabled with a specially crafted .inf file. You may alternatively elect to use a third party CDC ACM class driver as this can provide better functionality, reliability and install support compared to the Windows built-in driver.

In-depth information concerning Windows USB class support along with the use, configuration and installation of associated .inf files, are beyond the scope of this documentation. The Microsoft Developer Network documentation should be consulted for specific details. Relevant sections include Windows USB support and USB class drivers included in Windows.

As an aid in the use of Windows built-in CDC ACM class support an example .inf file has been provided here: `packages/devs/usb/pcd/class/cdc_acm/<version>/host/cdcacm-generic.inf`

The .inf file will need to be tailored to match your specific manufacturer VID and PID numbers, as well as manufacturer and device description strings. You will need to modify all the VID and PID references in the [DeviceList] sections, as well as the MFGNAME and DESCRIPTION strings at the end of the file. To enable CDC ACM on a specific Windows system the user should right-click on the .inf file and select the "Install" option from the pop-up menu. A Windows driver validation dialog box will appear, from which the "Install this driver software anyway" option should be selected.

Depending on the Windows version you are using, the CDC ACM driver installation may not be automatic on the first connection of your CDC ACM class device. An error may be reported in finding a suitable device driver during device insertion, or the Device Manager may show your device, but with an associated warning triangle. In these cases you will need to manually select the correct class driver. To accomplish this, right-click on the new entry in the "Ports" section of the Device Manager and select "Update Driver Software" from the pop-up menu. In the following dialog select "Browse my computer for driver software". You should then select the "Let me pick from a list of device drivers on my computer" from the available options that are then displayed. At this point you will then be presented with a list of device types - select "Ports (COM & LPT)" and then the "Next" button. You should then be able to find your company name in the Manufacturer list, and the Model associated with your driver entry - select this and hit the "Next" button. A Warning dialog concerning device verification will appear, select "Yes" to continue and install the driver. A confirmation message indicating the driver has installed should then appear.

Each time an eCos CDC ACM device is plugged in an entry should become visible within the "Ports" section of the Device Manager. The entry's device name should include an associated automatically assigned COM port number in brackets. You should be able to connect to this assigned COM port to communicate with your device.

Chapter 120. USB Host CDC ACM Protocol Driver

Name

Overview — eCosPro Support for CDC ACM Protocol in Host Mode

Description

This package provides protocol driver support for host mode serial adapter connections that use the CDC ACM protocol. It needs to be used in conjunction with the USB serial driver package and the reader is referred to that document for additional details.

Usage Model

The eCos serial driver subsystem does not support the dynamic creation and deletion of serial devices. Instead the CDC/ACM driver allocates a number of permanently available serial channels which are allocated to USB devices as they are attached. In order to retain some continuity, it is possible to assign specific Vendor and Product ID values to individual channels so that the USB device will be allocated the same channel each time it is attached.

Writing data to a detached channel will result in that data being lost, just as if it were being written to a disconnected serial line. A detached channel will not produce any data. Changes to the line configuration (baud rate, parity, stop bits, data size) will be stored and applied to the device once it is attached.

Applications may install a serial line callback function which will be called with the *which* field set to CYGNUM_SERIAL_STATUS_ATTACH and the *value* field set to zero for a detach and one for an attach.

Configuration

To use this package, various other packages need to be included and configuration options need to be set. The packages that need to be included are: USB Support (CYGPKG_IO_USB), USB serial driver (CYGPKG_IO_SERIAL_USB), Serial device drivers (CYGPKG_IO_SERIAL) and this package USB host cdc acm protocol driver (CYGPKG_IO_USB_CDC_ACM_HOST). Packages can be added directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool. Depending on your platform some of these may already be present in the default eCos configuration. To activate the requisite USB host and serial support, the options CYGPKG_IO_USB_HOST and CYGPKG_IO_SERIAL_DEVICES need to be enabled. Following this at least one CDC/ACM channel needs to be configured using the options below.

The configuration option CYGNUM_IO_USB_CDC_ACM_MAXPKT defines the maximum packet size used for USB transfers. It is used define the size of the the *rx_buf* in the usb_serial_if structure. The actual packet size used by any device is specified in its descriptors. Most CDC/ACM devices will use a maximum packet size of 64 bytes, and many will be smaller. So this value should not be reduced unless it is known that only devices with smaller packet sizes will be used.

Each serial channel has a number of configuration options associated with it. The following descriptions show the options for serial channel 0, for other channels the zero should be replaced with the number of the channel, currently up to 4.

CYGINT_IO_USB_CDC_ACM_HOST_SERIAL0

> This interface may be implemented by the platform HAL to instantiate this serial channel.

CYGPKG_IO_USB_CDC_ACM_HOST_SERIAL0

> This is the main component that defines this serial channel, unless this component is enabled, the remaining options will remain undefined. Its default value is derived from CYGINT_IO_USB_CDC_ACM_HOST_SERIAL0, but it may also be enabled with a requires statement or from the configtool.

CYGNUM_IO_USB_CDC_ACM_HOST_SERIAL0_NAME

> This option controls the name that an eCos application should use to access this device via cyg_io_lookup(), open(), or similar calls. The default is "/dev/acm0" and so on.

`CYGNUM_IO_USB_CDC_ACM_HOST_SERIAL0_BAUD`

This option specifies the default baud rate for this channel. Its default value is set to `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD`.

`CYGNUM_IO_USB_CDC_ACM_HOST_SERIAL0_BUFSIZE`

This option specifies the size of both the input and output buffer for the common serial I/O driver layer. This should be at least equal to `CYGNUM_IO_USB_CDC_ACM_HOST_MAXPKT` and preferably somewhat larger. The default value makes it twice the maximum packet size.

`CYGNUM_IO_USB_CDC_ACM_HOST_SERIAL0_VID`

This option controls whether this serial channel matches a particular USB Vendor ID. If zero it will match any ID, otherwise this channel will only match a device with the given vendor ID.

`CYGNUM_IO_USB_CDC_ACM_HOST_SERIAL0_PID`

This option controls whether this serial channel matches a particular USB Product ID. If zero it will match any ID, otherwise this channel will only match a device with the given product ID.

Channels are searched for a VID and PID match in numerical order, skipping any that are already in use. Therefore lower numbered channels should have more specific VID and PID values and generic channels should be at the end of the list.

Protocol Support

This driver only supports a subset of the CDC ACM protocol, sufficient to provide a serial-like interface between the host and the device.

CDC ACM uses two bulk endpoints to transfer raw data bytes between the host and the target board. Additionally, control messages are sent to the control endpoint to adjust the configuration of the channel. Only the following commands are currently sent:

`SET LINE CODING` This sets the baud rate, stop bits, parity and character size for the channel. This is generated in response to a `CYG_IO_SET_CONFIG_SERIAL_INFO` set_config key from the application.

Supported Devices

Any USB serial adapter that implements the standard USB-IF defined CDC ACM protocol should be compatible with the eCosPro host CDC ACM protocol driver. The driver has been tested successfully with the Microchip MCP2200 chip based Microchip MCP2200EV-VCP evaluation board.

Chapter 121. USB Host FTDI Protocol Driver

Name

Overview — eCosPro Support for FTDI Protocol in Host Mode

Description

This package provides protocol support for a host mode connection to FTDI USB to serial adaptors. It needs to be used in conjunction with the USB serial driver package and the reader is referred to that document for additional details.

Usage Model

The eCos serial driver subsystem does not support the dynamic creation and deletion of serial devices. Instead the FTDI driver allocates a number of permanently available serial channels which are allocated to USB devices as they are attached. In order to retain some continuity, it is possible to assign specific Vendor and Product ID values to individual channels so that the USB device will be allocated the same channel each time it is attached.

Writing data to a detached channel will result in that data being lost, just as if it were being written to a disconnected serial line. A detached channel will not produce any data. Changes to the line configuration (baud rate, parity, stop bits, data size, flow control) will be stored and applied to the device once it is attached.

Applications may install a serial line callback function which will be called with the *which* field set to `CYGNUM_SERIAL_STATUS_ATTACH` and the *value* field set to zero for a detach and one for an attach.

Configuration

To use this package, various other packages need to be included and configuration options need to be set. The packages that need to be included are: USB Support (`CYGPKG_IO_USB`), USB serial driver (`CYGPKG_IO_SERIAL_USB`), Serial device drivers (`CYGPKG_IO_SERIAL`) and this package USB host ftdi protocol driver (`CYGPKG_IO_USB_FTDI`). Packages can be added directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool. Depending on your platform some of these may already be present in the default eCos configuration. To activate the requisite USB host and serial support, the options `CYGPKG_IO_USB_HOST` and `CYGPKG_IO_SERIAL_DEVICES` need to be enabled. Following this at least one FTDI channel needs to be configured using the options below.

The configuration option `CYGNUM_IO_USB_FTDI_MAXPKT` defines the maximum packet size used for USB transfers. It is used to define the size of the the *rx_buf* in the usb_serial_if structure. The actual packet size used by any device is specified in its descriptors. Most FTDI devices will use a maximum packet size of 64 bytes, and many will be smaller. So this value should not be reduced unless it is known that only devices with smaller packet sizes will be used.

The option `CYGPKG_IO_USB_FTDI_SUPPORTED_EXTRA` defines an additional set of VID/PID pairs that the driver can support. A user or HAL package can define this to add entries to the table of VID/PID pairs that the driver recognizes as valid devices. This option consists of a comma separated list of initializers for for a VID/PID structure. For example "{ 0x0403, 0x6001 }, …".

Each serial channel has a number of configuration options associated with it. The following descriptions show the options for serial channel 0, for other channels the zero should be replaced with the number of the channel, currently up to 4.

`CYGINT_IO_USB_FTDI_SERIAL0`

This interface may be implemented by the platform HAL to instantiate this serial channel.

`CYGPKG_IO_USB_FTDI_SERIAL0`

This is the main component that defines this serial channel, unless this component is enabled, the remaining options will remain undefined. Its default value is derived from `CYGINT_IO_USB_FTDI_SERIAL0`, but it may also be enabled with a requires statement or from the configtool.

`CYGNUM_IO_USB_FTDI_SERIAL0_NAME`

This option defines the name of this channel, which eCos applications should use to access the device via cyg_io_lookup(), open() or similar calls. The default is to set it to "/dev/ftdi0" and so on.

`CYGNUM_IO_USB_FTDI_SERIAL0_BAUD`

This option specifies the default baud rate for this channel. Its default value is set to `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD`.

`CYGNUM_IO_USB_FTDI_SERIAL0_BUFSIZE`

This option specifies the size of both the input and output buffer for the common serial I/O driver layer. This should be at least equal to `CYGNUM_IO_USB_FTDI_MAXPKT` and preferably somewhat larger. The default value makes it twice the maximum packet size.

`CYGNUM_IO_USB_FTDI_SERIAL0_VID`

This option controls whether this serial channel matches a particular USB Vendor ID. If zero it will match any ID, otherwise this channel will only match a device with the given vendor ID.

`CYGNUM_IO_USB_FTDI_SERIAL0_PID`

This option controls whether this serial channel matches a particular USB Product ID. If zero it will match any ID, otherwise this channel will only match a device with the given product ID.

Channels are searched for a VID and PID match in numerical order, skipping any that are already in use. Therefore lower numbered channels should have more specific VID and PID values and generic channels should be at the end of the list.

`CYGNUM_IO_USB_FTDI_SERIAL0_LATENCY`

This option defines the latency in milliseconds between packets containing data from the FTDI device. If the device has 62 or more bytes available, it will send a packet immediately. Otherwise it will wait this number of milliseconds after the last packet before sending what it has. Decreasing this value will improve responsiveness for low data rate applications at the cost of more activity from the host driver as it processes more packets.

Supported Devices

There is a large family of FTDI devices, some of which support slightly different variants of the communication protocol. It is therefore important to detect what kind of device has been attached. FTDI devices do not have standard class. subclass or protocol codes defined by the USB-IF. Device descriptors have these fields set to zero, to redirect them to the interfaces. The interface fields are set to `0xFF`, which is a reserved vendor specific code. Additionally, FTDI devices can have internal or external PROMs from which `idVendor`, `idProduct` and string descriptors may be fetched. The result of all this is that the exact identity of an FTDI device can be difficult to determine.

The eCosPro FTDI driver employs a number of strategies to determine whether a device is one that can be supported. The first part of this is a table of VID/PID pairs. Only if a device can be found in this table will it be accepted. By default the table contains the standard FTDI VID/PID values and will be extended to contain the values for any other devices that have been tested. There is also a mechanism that allows users or other packages to add entries to this table using the `CYGPKG_IO_USB_FTDI_SUPPORTED_EXTRA` option.

If a device passes the VID/PID test, then other descriptor values such as `bcdDevice` `bNumInterface` are used to determine which FTDI device model this is likely to be and adjust the protocol used to talk to it accordingly.

The eCos FTDI driver has been successfully tested against the following standard FTDI USB serial adapters:

- FTDI CHIPI-X10 (FT231X based)

- FTDI US232R (FT232RL based)
- FTDI US232B (FT232BM based)

In addition an older FT232R and a FT2232C dual channel based devices from manufacturers other than FTDI have also been tested.

Part XXXVI. VirtIO Support

Name

Overview — eCosPro Support for VirtIO

Description

The eCosPro VirtIO package supports access to VirtIO devices. It provides general management of the device and the buffer queues associated with it. Normally a next-level driver will use the facilities provided by this driver to then implement an eCos compliant driver for a particular class of device.

A VirtIO device is described by a cyg_vio_driver structure. Data transfers are described by a cyg_vio_tfr structure. Operations are handled through an API that is used by the class drivers.

VirtIO Device Structure

A VirtIO device is instantiated by creating one of these structures and populating its fields with suitable values. The following fields need to be set; other fields in the structure will be initialized by the VirtIO driver.

base
Base address of the device.

vector
Device interrupt vector. Interrupts are not handled by the VirtIO driver, instead they need to be handled by the parent class driver. See the API description for details.

vector_pri
Interrupt vector priority.

priv
A private pointer for the parent driver. This will usually be a pointer to a data structure that the driver uses to store state for this device.

legacy
If set to 1, this indicates that the device is a legacy device. At present only legacy devices are supported.

pci
If set to 1 this indicates that this is a PCI device. At present PCI devices are not supported.

drv_features
A bit mask corresponding to the driver feature bits defined for this class of driver. This will be set in the DRV_FEATURES field of the device during feature negotiation.

queue_count
The number of queues in the queue array.

queue
A pointer to an array of pointers to cyg_vio_queue structures. Queues are defined using the `VIO_QUEUE(__name, __size)` macro and then collected together into an array which is pointed to by this field.

The following example shows how a VirtIO console driver would be instantiated:

```

// Define driver feature set
#define VIO_CONSOLE_FEATURES            VIRTIO_F_RING_INDIRECT_DESC     | \
                                        VIRTIO_F_NOTIFY_ON_EMPTY        | \
                                        VIRTIO_F_ANY_LAYOUT             | \
                                        VIRTIO_CONSOLE_F_MULTIPORT      | \
                                        VIRTIO_CONSOLE_F_EMERG_WRITE

// Set queue size
#define CONSOLE_QUEUE_SIZE            128

// Define queues. Here we have two console channels and a control channel.
VIO_QUEUE( virtual_console_rxq0, CONSOLE_QUEUE_SIZE );
VIO_QUEUE( virtual_console_txq0, CONSOLE_QUEUE_SIZE );
VIO_QUEUE( virtual_control_rxq, CONSOLE_QUEUE_SIZE );
VIO_QUEUE( virtual_control_txq, CONSOLE_QUEUE_SIZE );
VIO_QUEUE( virtual_console_rxq1, CONSOLE_QUEUE_SIZE );
VIO_QUEUE( virtual_console_txq1, CONSOLE_QUEUE_SIZE );

// Collect queues together into an array
cyg_vio_queue *virtual_console_queues[] = { &virtual_console_rxq0, &virtual_console_txq0,
                                         &virtual_control_rxq, &virtual_control_txq,
                                         &virtual_console_rxq1, &virtual_console_txq1 };

// Declare the driver
cyg_vio_driver console_vio_driver =
{
     // Hardware parameters
    .base               = CYGHWR_HAL_CONSOLE0_BASE,
    .vector             = CYGNUM_HAL_INTERRUPT_CONSOLE0,
    .vector_pri         = 0xa0,

    // Console driver private data
    .priv               = &virtual_console,

    // This is a legacy, non PCI device
    .legacy             = 1,
    .pci                = 0,

    // Set driver features for use in negotiation
    .drv_features       = VIO_CONSOLE_FEATURES,

    // Attach queues.
    .queue_count        = 6,
    .queue              = virtual_console_queues,

};
```

VirtIO Transfer Structure

Data transfers are described using a cyg_vio_tfr structure. The parent driver prepares a transfer object, passes it to the VirtIO driver and receives it back via a callback when the transfer is complete.

A transfer object has the following structure:

```
#define VIO_IOV_MAX             8

struct cyg_vio_tfr
{
    cyg_uint16          queue;          // Queue number
    cyg_uint16          head;           // head descriptor index
    cyg_uint16          iov_len;        // IOV entry count
    cyg_uint32          actual;         // Total actual bytes transferred

    void                (*callback)( cyg_vio_tfr *tfr );
    void                *priv;          // Private data pointer

    struct
    {
        void            *buffer;
        cyg_uint32      size;
        cyg_uint32      flags;
    } iov[VIO_IOV_MAX];
};

#define VIO_IOV_FLAGS_WRITE             CYGHWR_VIRTIO_DESC_FLAGS_WRITE
```

The fields are as follows:

queue
: The index in the queue array of the queue to apply the transfer to.

head
: This is used to store the index of the head buffer descriptor associated with this transfer. It does not need to be set by the client, but may be monitored to detect transfer completion, it will be set to 0xFFFF when the transfer is done.

iov_len
: The number of entries in the *`iov`* field that are in use.

actual
: The actual number of bytes transferred. This is the value of the used queue element length field and therefore depends on the hypervisors device emulation to set it correctly.

callback
: A function that is called when the transfer is completed. The single argument is a pointer to the completed transfer. This will only be called from within the `cyg_vio_poll()`.

priv
: A private pointer that can be used by the parent driver to supply context to the callback.

iov
: An array of buffer pointers with their sizes. The *`flags`* field for each will either be zero, or contain the `VIO_IOV_FLAGS_WRITE` flag. If the flag is zero, then this buffer is for transfer from the VM to the hypervisor, and if set, then the buffer is for transfer from the hypervisor to the VM.

: While the default size of this array is 8, this is not a fixed limit. Larger arrays could be passed by treating a transfer object as an initial substructure of a larger object that contains space for a longer IOV array.

Name

API — Functions

Synopsis

#include <cyg/io/virtio.h>

```
cyg_uint32 cyg_vio_avail(cyg_vio_driver *driver, int queue);

cyg_bool cyg_vio_queue_ready(cyg_vio_driver *driver, int queue);

cyg_bool cyg_vio_submit(cyg_vio_driver *driver, cyg_vio_tfr *tfr);

void cyg_vio_poll(cyg_vio_driver *driver);

void cyg_vio_driver_init(cyg_vio_driver *driver);

void hal_vio_init(void);
```

Description

This API is intended to be used by client drivers to access the VirtIO device and provide the functionality expected of a driver of the given class.

Functions `cyg_vio_avail()` and `cyg_vio_queue_ready()` test the state of the queue. The first returns the number of buffer descriptors available for transfer; it can be used to check that there is enough resource to start a transfer before submitting it. The second is used to check that a queue has completed initialization.

The function `cyg_vio_submit()` submits a transfer to the VirtIO device. All fields in the transfer should be initialized before submission. If the transfer is successfully queued, this function returns `CYG_VIO_DONE`. If the submission fails, a non-zero error code is returned.

The function `cyg_vio_poll()` polls a given driver for completed transfers. If a transfer is complete, then its callback function is called. Calling this poll routine is the only way in which transfer completions are recognized. It is the responsibility of the client driver to arrange to call it. This may be done from a thread context if that exists, or may be done from a DSR if the device interrupt has been enabled. When a callback is called, the only fields in the transfer that will have been updated are the *head* and *actual* fields; so the transfer may be immediately resubmitted to the driver from the callback with no changes if the same transfer is to be repeated.

The function `cyg_vio_driver_init()` is called to initialize the common parts of a VirtIO driver. This function will perform startup negotiation with the hypervisor device and initialize all valid queues. On return, the driver will be ready for submission of transfers. If this function is called for a driver that has already been initialized, it will return immediately, so it may be called from multiple locations safely.

The function `hal_vio_init()` is not supplied by the VirtIO package but is expected to be defined by the variant or platform HAL. The VirtIO package calls this function from a constructor during initialization. This function is responsible for detecting any VirtIO devices, installing base address and interrupt vector values and calling `cyg_vio_driver_init()` for each. Detection may involve searching a memory area for valid VirtIO devices or scanning a PCI bus. If the VirtIO devices are at known fixed addresses then this function should just call `cyg_vio_driver_init()` for each device to be initialized.

Part XXXVII. Wallclock Device Drivers

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 122. Wallclock Support

Name

CYGPKG_IO_WALLCLOCK — eCos Support Wallclock devices

Overview

The wallclock device provides real time stamps, as opposed to the eCos kernel timers which typically just count the number of clock ticks since the hardware was powered up. Depending on the target platform this device may involve interacting with a suitable on-chip device or an external clock chip, or it may be emulated by using the kernel timers.

The wallclock package operates using the standard UNIX epoch of midnight 1st January 1970. When times and dates are expressed in seconds, this is zero point for that count. However, many wallclock devices only have a two digit year field. In order to get a further 30 years duration from this field, and to avoid Y2K issues, many drivers actually store dates starting from the year 2000. It is therefore inavisable to try setting the wallclock to any date before 2000.

Configuration

The Wallclock package contains a number of configuration options, most of which are set by either the wallclock device driver, or the platform HAL.

CYGINT_WALLCLOCK_HW_IMPLEMENTATIONS

> This interface is implemented by the wallclock device driver to signal to this package that a hardware wallclock device is present. If this interface is zero, then this package will implement the wallclock using the kernel timer.

CYGINT_WALLCLOCK_SET_GET_MODE_SUPPORTED

> This interface is implement by the wallclock device driver to signal to this package that the device can set the current value as well as get it and that the set value is preserved when the power is off.

CYGSEM_WALLCLOCK_MODE

> The wallclock driver can be used in one of two modes. Set/get mode allows time to be kept during power off (assuming there's a battery backed clock). Init/get mode is slightly smaller and can be used when there is no battery backed clock - in this mode time 0 is the time of the board power up. The default value of this option depends on whether CYGINT_WALLCLOCK_SET_GET_MODE_SUPPORTED but may be changed by the user.

CYGPKG_WALLCLOCK_EMULATE

> When this option is enabled, a wallclock device will be emulated using the kernel real-time clock. The default value depends on the value of CYGINT_WALLCLOCK_HW_IMPLEMENTATIONS but may be changed by the user.

CYGIMP_WALLCLOCK_NONE

> This option disables the wallclock even if a hardware driver is present. The default value is depends on the value of CYGINT_WALLCLOCK_HW_IMPLEMENTATIONS.

CYGINT_IO_WALLCLOCK_HAS_SCRATCHSPACE

> If the underlying wallclock driver implements this interface, that means that it supports scratch space. This feature exists in some hardware to allow users to store some information in battery backed RAM, alongside the wallclock RTC's data. An API is provided by this package to access it.

CYGINT_IO_WALLCLOCK_HAS_ALARM

> Some wallclock hardware provides alarms which will generate an interrupt when a certain date/time is reached. This interface can be implemented by the underlying wallclock driver to indicate that such support can be used. An API is provided by this package to set and disable these alarms. Note these alarms are wholly separate from eCos kernel alarms.

Wallclock Tests

This package contains a number of test programs. The **wallclock** and **wallclock2** programs test basic functionality of the wallclock device. The **alarm** program tests the functionality of any alarms supported by the device. The **subsec** program tests the functionality and accuracy of device subsecond support if it is present.

Description

The wallclock package exports a C API for interacting directly with the wallclock. This API is a veneer over a C++ API which is used internally within eCos. Applications should generally use the C API. Wallclock support is also integrated into the POSIX and C++ library packages and if these are part of the configuration the APIs provided by these libraries should be used in preference to the API described here. This API will sidestep any mechanisms present in these other packages for maintenance of the current time and may give rise to inconsistencies between the times that different parts of the system percieve.

The main part of the API consists of functions to set and get the current wallclock time. There are three versions of each set and get function which take the time to be set or got in different formats. The functions `cyg_wallclock_get_current_time` and `cyg_wallclock_set_current_time` use a timestamp consisting of seconds since the epoch; no fractions of a second are supported. The functions `cyg_wallclock_get_time_timespec` and `cyg_wallclock_set_time_timespec` use a struct timespec consisting of seconds and nanoseconds values; the nanoseconds value is only used or returned non-zero if the underlying wallclock device supports sub-second resolution. Finally, the `cyg_wallclock_get_time_date` and `cyg_wallclock_set_time_date` use a date and time broken down into its component parts from the year down to nanoseconds; again the nanoseconds argument is only used or returned non-zero if sub-second support is present.

The function `cyg_wallclock_get_info` returns information about the wallclock device. The key may be one of the following values:

CYG_WALLCLOCK_INFO_RES

Resolution in microseconds/tick (NB different from kernel). Returns in "resolution" member of wallclock_info.

CYG_WALLCLOCK_INFO_MAXYEAR

The maximum year supported. This is a rough hint of the exact date. Returned in uint32val.

CYG_WALLCLOCK_INFO_GET_SCRATCH_SIZE

Many modern RTCs have a battery backed scratch space accompanying the RTC. If there is one, this returns its size in bytes in the "uint32val" member of the wallclock_info. If unsupported, either ENOSUPP is returned, or size may be set to 0.

CYG_WALLCLOCK_INFO_GET_NUM_ALARMS

Number of alarms available. Number returned in the "uint32val" member of wallclock_info. If unsupported, either ENOSUPP returned, or uint32val set to 0.

CYG_WALLCLOCK_INFO_GET_ALARM_INTVEC

Must be called with an alarm index number in the "uint32val" member of supplied wallclock_info argument. Will return the interrupt vector number for that alarm in the same "uint32val" member. If there is no alarm or no interrupt for it, ENOSUPP is returned.

CYG_WALLCLOCK_INFO_GET_SUBSECOND_FRACTION

Sub-second fractions supported. If the wallclock driver supports sub-second resolution, this returns in "uint32val" the number of fractions each second is divided into. If the driver does not support sub-seconds, then this will either return ENOSUPP, or "uint32val" will be zero.

CYG_WALLCLOCK_INFO_GET_ALARM_PERIOD_MIN

Since not all RTCs will have support for second granularity alarms this call is used to ascertain the minimum alarm period. Must be called with an alarm index number in the "uint32val" member of supplied wallclock_info argument. Will return in "uint32val" the smallest alarm delta as a microsecond value. If the driver returns `ENOSUPP`, or the value 0, then the default of 1-second granularity can be assumed.

If the wallclock device supports alarms then the functions `cyg_wallclock_set_alarm_timespec`, `cyg_wallclock_set_alarm_date` and `cyg_wallclock_disable_alarm` will be defined and provide support for setting and disabling individual alarms. Expiry of an alarm will cause a given interrupt vector to be raised (as defined bt the `CYG_WALLCLOCK_INFO_GET_ALARM_INTVEC` key). It is the responsibility of the application to attach an ISR and DSR to this vector and handle any subsequent processing. See the **alarm** test program for an example.

If the wallclock device supports scratch space then the functions `cyg_wallclock_read_scratch` and `cyg_wallclock_write_scratch` will be defined to read and write *`len`* bytes at the given `offset` in the scratch space.

Chapter 123. Dallas DS1302 Wallclock Device Driver

Name

CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1302 — eCos Support for the Dallas DS1302 Real-Time Clock

Description

This package CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1302 provides a device driver for the wallclock device in the Dallas DS1302 Real-Time Clock chips. This combines a real-time clock and 31 bytes of battery-backed RAM in a single package. The driver can also be used with any other chips that provide the same interface to the clock hardware.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

The package provides a number of additional functions that are specific to a DS1302:

```
#include <cyg/io/wallclock/ds1302.h>

externC unsigned char cyg_wallclock_ds1302_read_tcs_ds_rs(void);
externC void cyg_wallclock_ds1302_write_tcs_ds_rs(unsigned char val);
externC void cyg_wallclock_ds1302_read_ram(int offset,
                        unsigned char* buf, int len);
externC void cyg_wallclock_ds1302_write_ram(int offset,
                        unsigned char* buf, int len);
```

The _tcs_ds_rs functions allow applications to read and update the trickle charge register in the DS1302. The manufacturer's data sheet should be consulted for further information on this register.

The _ram functions allow applications to read and modify the contents of the 31 bytes of battery-backed RAM. The offset specifies the starting address within the RAM and should be between 0 and 31. The buffer provides the destination or source of the data, and the length gives the number of bytes transferred. Wrap-around is not supported so the sum of the offset and length should also be less than 31. The package's ds1302.c testcase provides example code.

The wallclock package is initialized by a static constructor with a priority immediately after CYG_INIT_DEV_WALLCLOCK. Applications should not call any wallclock-related functions nor any of the DS1302-specific functions before that constructor has run.

Porting

The DS1302 is accessed via a 3-wire bus. At the time of writing there is no generic 3-wire support package within eCos, so instead the wallclock driver expects to bit-bang some GPIO lines. Typically the platform HAL provides appropriate hardware-specific macros for this, via the header file cyg/hal/plf_io.h. The required macros are:

```
HAL_DS1302_CE(_setting_);
HAL_DS1302_SCLK(_setting_);
HAL_DS1302_OUT(_setting_);
HAL_DS1302_IN(_setting_);
```

```
HAL_DS1302_SELECT_OUT(_setting_);
```

The argument to the first three macros will always be 0 or 1 and corresponds to the desired state of the chip-enable, clock, or I/O line. For example, at the start of a transfer the wallclock driver will invoke:

```
    …
    HAL_DS1302_CE(1);
    …
```

Asserting the CE line should activate the DS1302 chip. The `HAL_DS1302_IN` macro is used to sample the state of the I/O line and should set its argument to 0 or 1. The `HAL_DS1302_SELECT_OUT` macro is used to switch the I/O line between output (1) or input (0).

Platform HALs may provide two additional macros:

```
HAL_DS1302_DATA
HAL_DS1302_INIT();
```

`HAL_DS1302_DATA` can be used to define one or more static variables needed by the other macros, for example to hold a shadow copy of the GPIO output register. If defined, `HAL_DS1302_INIT` will be invoked during driver initialization and typically sets up the GPIO lines such that the CE and SCLK lines are outputs.

In addition the DS1302 device driver package `CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1302` should be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Chapter 124. Dallas DS1306 Wallclock Device Driver

Name

CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1306 — eCos Support for the Dallas DS1306 Real-Time Clock

Description

This package CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1306 provides a device driver for the wallclock device in the Dallas DS1306 Real-Time Clock chips. This combines a real-time clock and 96 bytes of battery-backed RAM in a single package. The driver can also be used with any other chips that provide the same interface to the clock hardware.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

The package provides a number of additional functions that are specific to a DS1306:

```
#include <cyg/io/wallclock/ds1306.h>

externC void cyg_wallclock_ds1306_read_regs(int offset,
                                  unsigned char* buf, int len);
externC void cyg_wallclock_ds1306_write_regs(int offset,
                                  const unsigned char* buf, int len);
externC void cyg_wallclock_ds1306_read_ram(int offset,
                                  unsigned char* buf, int len);
externC void cyg_wallclock_ds1306_write_ram(int offset,
                                  const unsigned char* buf, int len);
```

The read_regs and write_regs functions allow direct access to all of the wallclock-related registers including the alarms, the control register 0x0F, the status register 0x10, and the trickle charger register 0x11. The offset should be between 0x00 and 0x1F, specifying the first register that should be read or written. For full details of the DS1306 registers see the manufacturer's data sheet.

The _ram functions allow applications to read and modify the contents of the 96 bytes of battery-backed RAM. The offset specifies the starting address within the RAM and should be between 0x00 and 0x5F. The buffer provides the destination or source of the data, and the length gives the number of bytes transferred. The package's ds1306.c testcase provides example code.

The wallclock package is initialized by a static constructor with a priority immediately after CYG_INIT_DEV_WALLCLOCK. Applications should not call any wallclock-related functions nor any of the DS1306-specific functions before that constructor has run.

Porting

The DS1306 can be either attached to an SPI bus or it can be accessed via a 3-wire interface. The driver supports both modes of operation, with a bit of support from the platform HAL. For SPI, the platform HAL should implement the CDL interface CYGHWR_WALLCLOCK_DALLAS_DS1306_SPI and provided an SPI device instance cyg_spi_wallclock_ds1306. The exact details of this device instantiation will depend on the SPI bus driver. For 3-wire the platform HAL should implement the CDL interface CYGHWR_WALLCLOCK_DALLAS_DS1306_3WIRE and provide a bit-bang function:

```
#include <cyg/io/wallclock/ds1306.h>

cyg_bool
hal_ds1306_bitbang(cyg_ds1306_bitbang_op op)
{
    cyg_bool result = 0;

    switch(op) {
      case CYG_DS1306_BITBANG_INIT: …
      case CYG_DS1306_BITBANG_CE_HIGH: …
      case CYG_DS1306_BITBANG_CE_LOW: …
      case CYG_DS1306_BITBANG_SCLK_HIGH: …
      case CYG_DS1306_BITBANG_SCLK_LOW: …
      case CYG_DS1306_BITBANG_DATA_HIGH: …
      case CYG_DS1306_BITBANG_DATA_LOW: …
      case CYG_DS1306_BITBANG_DATA_READ: …
      case CYG_DS1306_BITBANG_INPUT: …
      case CYG_DS1306_BITBANG_OUTPUT: …
    }
    return result;
}
```

The INIT operation should set the 3-wire bus to its default settings: all lines should be output low. The HIGH and LOW operations should set the specified line to the appropriate level. INPUT switches the data line from an output to an input, and OUTPUT switches it back to an output. READ should return the current state of the data line, and is the only operation for which the return value matters.

In addition the DS1306 device driver package `CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1306` should be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Chapter 125. Dallas DS1307 Wallclock Device Driver

Name

CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1307 — eCos Support for the Dallas DS1307 Serial Real-Time Clock

Description

This package CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1307 provides a device driver for the wallclock device in the Dallas DS1307 Serial Real-Time Clock chips. This combines a real-time clock and 56 bytes of battery-backed RAM in a single package. The driver can also be used with any other chips that provide the same interface to the clock hardware.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

Porting

DS1307 platform support can be implemented in one of two ways. The preferred approach involves the generic I²C API, as defined by the package CYGPKG_IO_I2C. The platform HAL can just provide a cyg_i2c_device structure cyg_i2c_wallclock_ds1307 and implement the CDL interface CYGINT_DEVICES_WALLCLOCK_DALLAS_DS1307_I2C. The DS1307 driver will now use I²C rx and tx operations to interact with the chip.

Alternatively the DS1307 driver can use macros or functions provided by another package to access the chip. This is intended primarily for older platforms that predate the CYGPKG_IO_I2C package. The other package should export a header file containing macros DS_GET and DS_PUT that transfer the eight bytes corresponding to the chip's clock registers. It should also export the name of this header via a #define CYGDAT_DEVS_WALLCLOCK_DS1307_INL in the global configuration header pkgconf/system.h. For full details see the source code.

In addition the DS1307 device driver package CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1307 should be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Chapter 126. Dallas DS1390 Wallclock Device Driver

Name

CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1390 — eCos Support for the Dallas DS1390 Serial Real-Time Clock

Description

This package CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1390 provides a device driver for the wallclock device in the Dallas DS1390 Serial Real-Time Clock chips. The driver can also be used with any other chips that provide the same interface to the clock hardware.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

Porting

The DS1390 driver uses the SPI driver API defined by the package CYGPKG_IO_SPI. A suitable SPI device driver must be available for the target. The platform HAL must provide a cyg_spi_device structure cyg_spi_wallclock_ds1390. The platform HAL should initialize this structure and any associated SPI driver specific struture with the correct phase, polarity and chip select parameters for this device.

In addition the DS1390 device driver package CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1390 should be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Extra API Calls

In addition to the standard wallclock API calls, this driver exports a number of additional functions to permit direct access to additional features of the device. A header, cyg/io/wallclock/ds1390.h is available to define this API.

```
cyg_uint8 cyg_ds1390_read_reg( int addr )
```

Read and return a single 8-bit register from the DS1390, *addr* should be in the range 0x00 to 0x0F.

```
void cyg_ds1390_write_reg( int addr, int val )
```

Write a single 8-bit register to the DS1390, *addr* should be in the range 0x00 to 0x0F and *val* in the range 0x00 to 0xFF.

```
void cyg_ds1390_set_control( cyg_uint8 val )
```

Write the DS1390 control register with the content of *val*.

```
cyg_uint8 cyg_ds1390_get_control( void )
```

Read and return the value of the DS1390 control register.

`void cyg_ds1390_set_status( cyg_uint8 val )`

Write the DS1390 status register with the content of *val*.

`cyg_uint8 cyg_ds1390_get_status( void )`

Read and return the value of the DS1390 control register.

`void cyg_ds1390_set_charger( cyg_uint8 val )`

Write the DS1390 trickle-charge register with the content of *val*.

`cyg_uint8 cyg_ds1390_get_charger( void )`

Read and return the value of the DS1390 trickle-charge register.

`int cyg_wallclock_set_alarm( cyg_uint32 secs )`

Set the DS1390 alarm to trigger when the wallclock time matches the value of *secs*. The DS1390 alarm will match only up to days of the month, so the alarm cannot be set more than one month in the future. This function only initializes the DS1390 to generate the alarm interrupt; it is the responsibility of the caller to attach an ISR to the appropriate vector and unmask it in the interrupt controller.

Chapter 127. Freescale MCFxxxx On-Chip Wallclock Device Driver

Name

CYGPKG_DEVS_WALLCLOCK_MCFxxxx — eCos Support for the Freescale MCFxxxx On-Chip Real-Time Clock

Description

Some members of the Freescale ColdFire range of processors come with an on-chip Real-Time Clock device which can act as an eCos wallclock. The device will not always be appropriate for an application's requirement. Typically it does not have its own low-current battery input so it will only operate when the whole processor is powered up. Hence either the entire system needs to be powered by a battery or have a battery backup. Otherwise the device will lose its settings when the power fails, requiring an application-level recovery mechanism, which means that there is no real advantage to using the RTC rather than a software emulation.

For those scenarios where the on-chip RTC does meet the application's requirements, this package CYGPKG_DEVS_WALLCLOCK_MCFxxxx provides an eCos device driver. The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible device. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

The wallclock driver does not provide any support for other functionality provided by the RTC device such as the alarm or stopwatch. It only manipulates the HOURMIN, SECONDS, DAYS, and CR registers. Applications can access the remaining registers as required without affecting the driver.

The wallclock package is initialized by a static constructor with a priority immediately after CYG_INIT_CLOCK. Applications should not call any wallclock-related functions before that constructor has run.

Porting

The driver requires only minimal porting. The HAL packages, typically the processor HAL, should supply the register definitions and the device base address HAL_MCFxxxx_RTC_BASE. In addition the platform HAL should define the crystal frequency using a #define of HAL_MCFxxxx_RTC_XTAL: legal values are 32768, 32000, and 38400. Finally the driver package CYGPKG_DEVS_WALLCLOCK_MCFxxxx should be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Chapter 128. Intersil ISL1208 Wallclock Device Driver

Name

CYGPKG_DEVICES_WALLCLOCK_INTERSIL_ISL1208 — eCos Support for the Intersil ISL1208 Real-Time Clock

Description

This package CYGPKG_DEVICES_WALLCLOCK_INTERSIL_ISL1208 provides a device driver for the wallclock device in the Intersil ISL1208 Real-Time Clock chips. These combine a real-time clock, alarm functionality, a selectable frequency output, and two bytes of non-volatile memory in a single package. The driver can also be used with any other chips that provide the same interface to the clock hardware.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

The driver does not provide direct access to any of the other functionality provided by the chip. Instead if an application wishes to access the alarms or the non-volatile bytes then it can do so itself, via the generic I²C API. However any such application code does need to synchronize with the wallclock driver to prevent concurrent accesses to the device. The driver exports a mutex lock to allow for this:

```
#include <cyg/io/wallclock/isl1208.h>

extern cyg_drv_mutex_t cyg_isl1208_lock;
```

The mutex should be locked via cyg_drv_mutex_lock to prevent the wallclock driver from accessing the chip, and then unlocked via cyg_drv_mutex_unlock when the driver can safely access the chip again.

The wallclock package is initialized by a static constructor with a priority immediately after CYG_INIT_DEV_WALLCLOCK. Applications should not call any wallclock-related functions before that constructor has run.

Porting

The ISL1208 is accessed via an I²C serial bus, and the driver assumes the presence of the generic I²C support package CYGPKG_IO_I2C and a suitable hardware driver. In addition it requires that some other package, typically the platform HAL, exports a cyg_i2c_device structure cyg_i2c_wallclock_isl1208. The ISL1208 device driver package CYGPKG_DEVICES_WALLCLOCK_INTERSIL_ISL1208 can then be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Chapter 129. Intersil ISL12028 Wallclock Device Driver

Name

CYGPKG_DEVICES_WALLCLOCK_INTERSIL_ISL12028 — eCos Support for the Intersil ISL12028 Real-Time Clock

Description

This package CYGPKG_DEVICES_WALLCLOCK_INTERSIL_ISL12028 provides a device driver for the wallclock device in the Intersil ISL12028 Real-Time Clock chips. These combine a real-time clock, alarm functionality, and a bank of EEPROM in a single package. The driver can also be used with any other chips that provide the same interface to the clock hardware.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

The driver does not provide direct access to any of the other functionality provided by the chip. Instead if an application wishes to access the alarms or the EEPROM memory then it can do so itself, via the generic I²C API. However any such application code does need to synchronize with the wallclock driver to prevent concurrent accesses to the device. The driver exports a mutex lock to allow for this:

```
#include <cyg/io/wallclock/isl12028.h>

extern cyg_drv_mutex_t cyg_isl12028_lock;
```

The mutex should be locked via cyg_drv_mutex_lock to prevent the wallclock driver from accessing the chip, and then unlocked via cyg_drv_mutex_unlock when the driver can safely access the chip again.

The wallclock package is initialized by a static constructor with a priority immediately after CYG_INIT_DEV_WALLCLOCK. Applications should not call any wallclock-related functions before that constructor has run.

Porting

The ISL12028 is accessed via an I²C serial bus, and the driver assumes the presence of the generic I²C support package CYGPKG_IO_I2C and a suitable hardware driver. In addition it requires that some other package, typically the platform HAL, exports a cyg_i2c_device structure cyg_i2c_wallclock_isl12028. The ISL12028 device driver package CYGPKG_DEVICES_WALLCLOCK_INTERSIL_ISL12028 can then be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Chapter 130. ST M41TXX Wallclock Device Driver

Name

CYGPKG_DEVICES_WALLCLOCK_ST_M41TXX — eCos Support for the ST M41TXX Serial Real-Time Clock

Description

This package CYGPKG_DEVICES_WALLCLOCK_ST_M41TXX provides a device driver for the wallclock device in the ST M41TXX Serial Real-Time Clock chips. This is a real-time clock, alarm and watchdog in a single package. eCos only currently supports the real-time clock function.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

Porting

M41TXX platform support is implemented via the generic I²C API, as defined by the package CYGPKG_IO_I2C. The platform HAL can just provide a cyg_i2c_device structure cyg_i2c_wallclock_m41txx. The M41TXX driver will now use I²C rx and tx operations to interact with the chip.

In addition the M41TXX device driver package CYGPKG_DEVICES_WALLCLOCK_ST_M41TXX should be included in the CDL target entry so that it gets loaded automatically whenever eCos is configured for that target.

Chapter 131. ST M48T Wallclock Device Driver

Name

CYGPKG_DEVS_WALLCLOCK_ST_M48Txxx — eCos Support for the ST M48T TimeKeeper SRAM chips and compatibles

Description

This package CYGPKG_DEVS_WALLCLOCK_ST_M48Txxx provides a device driver for the wallclock device in the ST M48T family of TimeKeeper SRAM chips (e.g. the M48T35AV part). These combine an amount of battery-backed SRAM and a real-time clock in a single package. The driver can also be used with any other chips that provide the same interface to the clock hardware.

The package will usually be loaded into the configuration automatically whenever selecting a target which contains a compatible chip. By default it will provide the standard eCos wallclock device, although another implementation such as software emulation may be selected if desired. The only other configuration options related to this package allow users to change the compiler flags. If the application does not actually use the wallclock device, directly or indirectly, then the code should get removed automatically at link-time to ensure that the application does not suffer any unnecessary overheads.

Functionality

This wallclock device driver package implements the standard functionality required by the generic wallclock support CYGPKG_IO_WALLCLOCK. The functionality is not normally accessed directly. Instead it is used by the C library time package to implement standard calls such as time and gmtime. The eCos C library also provides a non-standard function cyg_libc_time_settime for changing the current wallclock setting. In addition RedBoot provides a **date** command which interacts with the wallclock device.

M48T devices provide some support for a calibration value. If the application has some alternative way of getting a reliable time value, for example NTP over a TCP/IP network, then the wallclock can be made to tick slightly faster or slower. The calibration value is a small integer between -31 and +31. A positive value x adds 512x extra cycles every 125829120 actual cycles, speeding up the clock by approximately 10.7x seconds per month. Alternatively a negative value x subtracts 256x cycles, slowing down the clock by 5.35x seconds per month. The package provides two functions for examining and changing the current calibration value:

```
#include <cyg/io/wallclock_m48txxx.h>

externC cyg_int32   cyg_wallclock_m48t_get_calibration(void);
externC void        cyg_wallclock_m48t_set_calibration(cyg_int32);
```

Porting

For most platforms adding support for the M48T wallclock device requires just two steps. The package must be added to the appropriate CDL target entry so that it gets loaded automatically, and selects the relevant ST M48T family device, whenever configuring eCos for that target. Also the platform HAL should specify the location of the clock hardware in the address space, by defining the symbol HAL_WALLCLOCK_M48Txxx_BASE. The definition should go into cyg/hal/hal_io.h or more commonly into a platform-specific header cyg/hal/plf_io.h which gets included automatically by the former. The value should be the address of the control register of the clock device. The driver provides the CYGNUM_DEVS_WALLCLOCK_ST_M48Txxx_OFFSET_CLOCK value which is set to the appropriate offset value for the CYGHWR_DEVS_WALLCLOCK_ST_M48Txxx selected device. For example, given a battery-backed 32K TimeKeeper chip at 0x30000000, the clock hardware will occupy the last eight bytes at 0x30007ff8 and that is the value which should be used, and CYGNUM_DEVS_WALLCLOCK_ST_M48Txxx_OFFSET_CLOCK will have the value 0x7ff8.

The package provides some support for hardware where the clock is mapped into memory in strange ways. The platform HAL can define an additional symbol HAL_WALLCLOCK_M48Txxx_STRIDE and macros HAL_WALLCLOCK_M48Txxx_READ_UINT8 and HAL_WALLCLOCK_M48Txxx_WRITE_UINT8 to change the way in which the driver accesses the hardware. The source code should be consulted for further details of how these work.

If the selected ST M48T device implements the Century bit then the configurarion will define CYGINT_DEVS_WALLCLOCK_ST_M48Txxx_CENTURY_BIT as a non-zero value. The platform can override the CDL device based configuration by defining `HAL_WALLCLOCK_M48Txxx_NO_CENTURY_BIT` which can be used to notify the driver that a compatible device does not support the Century bit, or that the feature should be explicitly disabled.

If the Century bit is not supported the driver will instead use a heuristic for determining the century: if the year register is < 70 then this is treated as relative to 2000; otherwise it is treated as relative to 1900; this gives an effective range of Jan 1st 1970 to Dec 31st 2069.

Part XXXVIII. Watchdog Drivers

Documentation for drivers of this type is often integrated into the eCos board support documentation. You should review the documentation for your target board for details. Standalone and more generic drivers are documented in the following sections.

Table of Contents

Chapter 132. Freescale Kinetis Watchdog Driver

Name

CYGPKG_DEVICES_WATCHDOG_CORTEXM_KINETIS — eCos Support for the Kinetis on-chip Watchdog timer device (WDOG)

Description

The Freescale Kinetis processor provides a Watchdog Timer (WDOG) module. Once the watchdog timer is enabled it will automatically reset the processor unless software resets the timer within the configured period.

The package CYGPKG_DEVICES_WATCHDOG_CORTEXM_KINETIS provides an eCos driver for this device, complementing the generic package CYGPKG_IO_WATCHDOG. The functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

The driver only supports “reset” mode.

Configuration Options

The Kinetis watchdog driver package should be loaded automatically when selecting a platform containing a Kinetis processor, and it should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded and the watchdog explicitly started. Depending on the choice of eCos template it may be necessary to load the CYGPKG_IO_WATCHDOG package. By default the HAL startup for the Kinetis platform disables the watchdog shortly after reset, so even when the I/O watchdog package is loaded the watchdog will not trigger unless the watchdog support is explicitly started by calling watchdog_start.

The package provides four main configuration options.

CYGIMP_WATCHDOG_HARDWARE can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging.

CYGNUM_DEVS_WATCHDOG_CORTEXM_KINETIS_CLK is used to select the clock source used to drive the watchdog timer module. The setting of this variable affects the minimum and maximum values that can be configured for the watchdog timeout.

CYGNUM_DEVS_WATCHDOG_CORTEXM_KINETIS_CLK_PRESCALER can further extend the maximum possible value for the watchdog timeout.

CYGNUM_DEVS_WATCHDOG_CORTEXM_KINETIS_DESIRED_TIMEOUT_US determines the timeout before the hardware watchdog resets the system. The default setting gives a 1-second timeout. The minimum and maximum timeout values are determined by the selected source clock and prescaler values. Depending on the configuration the range can extend from 9 microseconds to 4000 seconds.

Porting

The watchdog device driver does not require any platform-specific support. The only porting effort required is to list CYGPKG_DEVICES_WATCHDOG_CORTEXM_KINETIS as one of the hardware packages in the ecos.db target entry.

Chapter 133. Freescale MCFxxxx SCM Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_MCFxxxx_SCM — eCos Support for the MCFxxxx SCM On-chip Watchdog Device

Description

ColdFire MCFxxxx processors typically come with two on-chip watchdog devices. The main watchdog is not readily usable by eCos: it comes up enabled and, once disabled, it can never be reenabled. Hence in a typical development environment that watchdog device needs to be disabled early on or it will interfere with debugging, and cannot be used again. There is a second watchdog device embedded in the System Control Module which is usable. This package CYGPKG_DEVS_WATCHDOG_MCFxxxx_SCM provides an eCos driver for that device, complementing the generic package CYGPKG_IO_WATCHDOG. The driver functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

Configuration Options

The MCFxxxx SCM watchdog driver package should be loaded automatically when selecting a platform containing a suitable MCFxxxx ColdFire processor. It should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

There are a number of configuration options. The first is CYGIMP_WATCHDOG_HARDWARE, which can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging.

By default the watchdog device is set to reset the system when the timeout expires. It can be configured to raise an interrupt instead by disabling CYGIMP_DEVS_WATCHDOG_MCFxxxx_SCM_RESET. The interrupt ISR will invoke any installed application action handlers.

The watchdog timeout is controlled by CYGNUM_DEVS_WATCHDOG_MCFxxxx_SCM_TICKS. This corresponds to the CWT field in the SCM's CWCR register. It can take a value between 8 and 31, with a default of 28. That means 2^28 peripheral bus clock ticks have to elapse before the watchdog triggers. Typically that means a timeout of a small number of seconds. There is a calculated CDL option CYGNUM_DEVS_WATCHDOG_MCFxxxx_SCM_DELAY which gives the current delay in nanoseconds.

The watchdog device has a bit which turns it read-only, preventing any errant code from accidentally disabling it. By default the driver will set this bit after starting the watchdog. If for some reason the application needs to access the device directly then the option CYGIMP_DEVS_WATCHDOG_MCFxxxx_SCM_WRITE_ONCE should be disabled.

By default the watchdog is set to continue ticking even if the core is halted by an idle thread action or by power management code. This can cause problems if the application code halts the core for an extended period of time, so the behaviour can be changed by disabling CYGIMP_DEVS_WATCHDOG_MCFxxxx_SCM_RUN_WHILE_HALTED.

If the watchdog device is configured to raise interrupts rather than generate a reset then CYGNUM_DEVS_WATCHDOG_MCFxxxx_SCM_ISR_PRIORITY controls the interrupt priority. There are also configuration options allowing developers to tweak the compiler flags used for building this package.

Porting

The watchdog device driver usually does not require any platform-specific support. The processor HAL should provide the device definitions needed by the code. The only porting effort required is to list CYGPKG_DEVS_WATCHDOG_MCFxxxx_SCM as one of the hardware packages in the ecos.db target entry.

Chapter 134. Freescale MCFxxxx Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_MCFxxxx — eCos Support for the MCFxxxx On-chip Watchdog Device

Description

Several members of the MCFxxxx ColdFire family have a simple watchdog device embedded in the System Control Module or SCM. This package CYGPKG_DEVS_WATCHDOG_MCFxxxx provides an eCos device driver for the watchdog device, complementing the generic package CYGPKG_IO_WATCHDOG. The driver functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

The hardware has limited functionality: instead of automatically causing a reset when the watchdog triggers it can only raise an interrupt. By default the watchdog driver installs a non-maskable interrupt with the highest possible priority, and a custom interrupt VSR will immediately perform a reset using the chip's Reset Controller Module. This is not quite as good as a watchdog device which performs the reset automatically: corruption of the interrupt vector table, the interrupt controller, the SCM module, or the VSR code may prevent a reset from occurring. However in most circumstances a watchdog timeout will still result in a full reset. Alternatively the driver can be configured to generate an ordinary interrupt, leaving it up to application code to perform recovery from the timeout.

Configuration Options

The MCFxxxx watchdog driver package should be loaded automatically when selecting a platform containing a suitable ColdFire processor, and it should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

The first configuration option is CYGIMP_WATCHDOG_HARDWARE, which can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging.

If the hardware watchdog is enabled then CYGIMP_DEVS_WATCHDOG_MCFxxxx_ATTEMPT_RESET controls whether the driver will install a non-maskable interrupt VSR which performs a reset, or an ordinary interrupt handler which calls into application code. The default is to attempt the reset.

The watchdog timeout is controlled by CYGNUM_DEVS_WATCHDOG_MCFxxxx_TICKS. It is measured in system clock ticks and only a limited number of values are available: 2^9, 2^{11}, 2^{13}, 2^{15}, 2^{19}, 2^{23}, 2^{27} and 2^{31}. The default is 2^{27} clock ticks. For a processor running at 64MHz that corresponds to just over two seconds. With the same clock 2^{23} ticks would give 0.13 seconds and 2^{31} would give 33 seconds. For convenience there is a calculated configuration option CYGNUM_DEVS_WATCHDOG_MCFxxxx_DELAY which gives the actual delay in nanoseconds.

If the watchdog is configured to generate an ordinary interrupt rather than attempt a reset then CYGNUM_DEVS_WATCHDOG_MCFxxxx_ISR_PRIORITY determines the interrupt priority. The default will be provided by the processor HAL.

Porting

The watchdog device driver usually does not require any platform-specific support. The only porting effort required is to list CYGPKG_DEVS_WATCHDOG_MCFxxxx as one of the hardware packages in the ecos.db target entry. However if the driver has been configured to generate a reset then it will use HAL_VSR_SET to install a custom VSR cyg_mcfxxxx_watchdog_vsr. On platforms where the exception vectors are in flash and hence read-only this will be a problem and the function will have to be placed in the appropriate slot instead of hal_m68k_interrupt_vsr.

Chapter 135. Freescale MCF5272 Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_MCF5272 — eCos Support for the MCF5272 On-chip Watchdog Device

Description

The Freescale MCF5272 ColdFire processor has a built-in watchdog device. Once started it will automatically reset the processor unless software updates the device at regular intervals. The package CYGPKG_DEVS_WATCHDOG_MCF5272provides an eCos driver for this device, complementing the generic package CYGPKG_IO_WATCHDOG. The functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

The watchdog driver only supports reset mode. The hardware can also be configured to raise an interrupt when the watchdog times out, but this mode of operation is not supported.

Configuration Options

The MCF5272 watchdog driver package should be loaded automatically when selecting a platform containing an MCF5272 processor, and it should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

The package provides two main configuration options. CYGIMP_WATCHDOG_HARDWARE can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging. CYGNUM_DEVS_WATCHDOG_MCF5272_TICKS determines the timeout before the hardware watchdog resets the processor. It should be a 15-bit number, with each tick corresponding to 32768 system clock cycles. For a processor operating at 66MHz each tick is approximately 0.5 milliseconds so the default value of 2000 corresponds to a one-second timeout. The maximum value of 32767 gives a timeout of approximately 16 seconds.

Porting

The watchdog device driver does not require any platform-specific support. The only porting effort required is to list CYGPKG_DEVS_WATCHDOG_MCF5272 as one of the hardware packages in the ecos.db target entry.

Chapter 136. Freescale MCF5282 Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_MCF5282 — eCos Support for the MCF5282 On-chip Watchdog Device

Description

The Freescale MCF5282 Coldfire processor has two built-in watchdog devices. The System Control Module or SCM has a simple watchdog device which can only generate an interrupt when the watchdog triggers. The Watchdog Timer Module has a more advanced watchdog device, but unfortunately it has a write-once register which makes it difficult to use in a typical development environment. The package CYGPKG_DEVS_WATCHDOG_MCF5282 provides an eCos device driver for the SCM device, complementing the generic package CYGPKG_IO_WATCHDOG. The functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

By default the watchdog driver installs a non-maskable interrupt with the highest possible priority, and a custom interrupt VSR will immediately perform a reset using the chip's Reset Controller Module. This is not quite as good as a watchdog device which performs the reset automatically: corruption of the interrupt vector table, the interrupt controller, the SCM module, or the VSR code may prevent a reset from occurring. However in most circumstances a watchdog timeout will still result in a full reset. Alternatively the driver can be configured to generate an ordinary interrupt, leaving it up to application code to perform recovery from the timeout.

Configuration Options

The MCF5282 watchdog driver package should be loaded automatically when selecting a platform containing an MCF5282 processor, and it should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

The first configuration option is CYGIMP_WATCHDOG_HARDWARE, which can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging.

If the hardware watchdog is enabled then CYGIMP_DEVS_WATCHDOG_MCF5282_ATTEMPT_RESET controls whether the driver will install a non-maskable interrupt VSR which performs a reset, or an ordinary interrupt handler which calls into application code. The default is to attempt the reset.

The watchdog timeout is controlled by CYGNUM_DEVS_WATCHDOG_MCF5282_TICKS. It is measured in system clock ticks and only a limited number of values are available: 2^9, 2^{11}, 2^{13}, 2^{15}, 2^{19}, 2^{23}, 2^{27} and 2^{31}. The default is 2^{27} clock ticks. For a processor running at 64MHz that corresponds to just over two seconds. With the same clock 2^{23} ticks would give 0.13 seconds and 2^{31} would give 33 seconds.

If the watchdog is configured to generate an ordinary interrupt rather than attempt a reset then CYGNUM_DEVS_WATCHDOG_MCF5282_ISR_PRIORITY determines the interrupt priority. The default will be provided by the processor HAL. On an MCF5282 all interrupt priorities must be unique.

Porting

The watchdog device driver does not require any platform-specific support. The only porting effort required is to list CYGPKG_DEVS_WATCHDOG_MCF5282 as one of the hardware packages in the ecos.db target entry.

Chapter 137. Freescale MCF532x Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_MCF532x — eCos Support for the MCF532x On-chip Watchdog Device

Description

The ColdFire MCF532x family of processors come with two on-chip watchdog devices. The main watchdog is not readily usable by eCos: it comes up enabled and, once disabled, it can never be reenabled. Hence in a typical development environment that watchdog device needs to be disabled early on or it will interfere with debugging, and cannot be used again. There is a second watchdog device embedded in the System Control Module which is usable. This package CYGPKG_DEVS_WATCHDOG_MCF532x provides an eCos driver for that device, complementing the generic package CYGPKG_IO_WATCHDOG. The driver functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

Configuration Options

The MCF532x watchdog driver package should be loaded automatically when selecting a platform containing an MCF532x ColdFire processor, or any other ColdFire with a compatible device. It should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

There are a number of configuration options. The first is CYGIMP_WATCHDOG_HARDWARE, which can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging.

By default the watchdog device is set to reset the system when the timeout expires. It can be configured to raise an interrupt instead by disabling CYGIMP_DEVS_WATCHDOG_MCF532x_RESET. The interrupt ISR will invoke any installed application action handlers.

The watchdog timeout is controlled by CYGNUM_DEVS_WATCHDOG_MCF532x_TICKS. This corresponds to the CWT field in the SCM's CWCR register. It can take a value between 8 and 31, with a default of 27. That means 2^27 clock ticks have to elapse before the watchdog triggers. For a processor operating at 240/80MHz that corresponds to approximately 1.67 seconds. There is also a calculated CDL option CYGNUM_DEVS_WATCHDOG_MCF532x_DELAY which gives the current delay in nanoseconds.

The watchdog device has a bit which turns it read-only, preventing any errant code from accidentally disabling it. By default the driver will set this bit after starting the watchdog. If for some reason the application needs to access the device directly then the option CYGIMP_DEVS_WATCHDOG_MCF532x_WRITE_ONCE should be disabled.

By default the watchdog is set to continue ticking even if the core is halted by an idle thread action or by power management code. This can cause problems if the application code halts the core for an extended period of time, so the behaviour can be changed by disabling CYGIMP_DEVS_WATCHDOG_MCF532x_RUN_WHILE_HALTED.

If the watchdog device is configured to raise interrupts rather than generate a reset then CYGNUM_DEVS_WATCHDOG_MCF532x_ISR_PRIORITY controls the interrupt priority. There are also configuration options allowing developers to tweak the compiler flags used for building this package.

Porting

The watchdog device driver usually does not require any platform-specific support. The only porting effort required is to list CYGPKG_DEVS_WATCHDOG_MCF532x as one of the hardware packages in the ecos.db target entry.

Chapter 138. Nios II Avalon Timer Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_NIOS2_AVALON_TIMER — eCos Support for a Nios II Avalon Timer-based Watchdog Device

Description

A Nios II hardware design can include an Avalon timer which acts as a watchdog device. Once started it will automatically reset the processor unless software updates the device at regular intervals. The package CYGPKG_DEVS_WATCHDOG_NIOS2_AVALON_TIMER provides an eCos driver for this device, complementing the generic package CYGPKG_IO_WATCHDOG. The functionality should be accesssed via the standard eCos watchdog functions.

Configuration Options

The Avalon watchdog driver package should be loaded automatically when creating an eCos configuration for a hardware design which includes a suitable watchdog device, and it should never be necessary to load the package explicitly. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

The package provides a configuration option CYGIMP_WATCHDOG_HARDWARE. This can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging. The package also provides two configuration options for manipulating the compiler flags used to build the driver.

Porting

A hardware design requiring a watchdog should include an Avalon timer labelled “watchdog”. This timer should use the presets for a watchdog device: no writeable period, no readable snapshot, no start/stop control bits, no timeout pulse, system reset on timeout. The watchdog period can be set to any desired value, subject to the constraints of a 32-bit counter and the hardware's input clock. For example if the hardware runs at 100MHz then the watchdog period is limited to at most 42.9 seconds.

The hardware design HAL package should include definitions for HAL_NIOS2_AVALON_TIMER_WATCHDOG_BASE and HAL_NIOS2_AVALON_TIMER_WATCHDOG_PERIOD. In addition the ecos.db target entry should list CYGPKG_DEVS_WATCHDOG_NIOS2_AVALON_TIMER as one of the hardware packages.

Chapter 139. NXP PNX8310 Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_MIPS_PNX8310 — eCos Support for the PNX8310 On-chip Watchdog Device

Description

The NXP PNX8310 processor is based around a PR1910 core. This core supports three timers, one of which can act as a watchdog device. Once the timer is started it will automatically reset the processor unless software resets the timer at regular intervals. The package CYGPKG_DEVS_WATCHDOG_MIPS_PNX8310 provides an eCos driver for this device, complementing the generic package CYGPKG_IO_WATCHDOG. The functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

The watchdog driver only supports reset mode. The hardware can also be configured to raise an interrupt half way through the timeout period, but the driver does not use this functionality. An application can install an interrupt handler on CYGNUM_HAL_ISR_TMR3 if desired.

Configuration Options

The PNX8310 watchdog driver package should be loaded automatically when selecting a platform containing a PNX8310 processor, and it should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

The package provides two main configuration options. CYGIMP_WATCHDOG_HARDWARE can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging. CYGNUM_DEVS_WATCHDOG_MIPS_PNX8310_MILLISECONDS determines the timeout before the hardware watchdog resets the system. The default setting gives a 10-second timeout. The maximum timeout is determined by the CPU clock frequency, approximately 70 seconds for a 120MHz processor.

Porting

The watchdog device driver does not require any platform-specific support. The only porting effort required is to list CYGPKG_DEVS_WATCHDOG_MIPS_PNX8310 as one of the hardware packages in the ecos.db target entry.

Chapter 140. NXP PNX8330 Watchdog Driver

Name

CYGPKG_DEVS_WATCHDOG_MIPS_PNX8330 — eCos Support for the PNX8330 On-chip Watchdog Device

Description

The NXP PNX8330 processor Configuration unit supports three timers, one of which will act as a watchdog device. Once the timer is started it will automatically reset the processor unless software resets the timer at regular intervals. The package CYGPKG_DEVS_WATCHDOG_MIPS_PNX8330 provides an eCos driver for this device, complementing the generic package CYGPKG_IO_WATCHDOG. The functionality should be accessed via the standard eCos watchdog functions watchdog_start, watchdog_reset and watchdog_get_resolution.

The hardware, and thus the watchdog driver, only supports reset mode.

Configuration Options

The PNX8330 watchdog driver package should be loaded automatically when selecting a platform containing a PNX8330 processor, and it should never be necessary to load it explicitly into the configuration. The package is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded. Depending on the choice of eCos template it may be necessary to load the latter.

The package provides two main configuration options. CYGIMP_WATCHDOG_HARDWARE can be used to disable the use of the hardware watchdog and switch to a software emulation provided by the generic watchdog package instead. This may prove useful during debugging. CYGNUM_DEVS_WATCHDOG_MIPS_PNX8330_MILLISECONDS determines the timeout before the hardware watchdog resets the system. The default setting gives a 10-second timeout. The maximum timeout is determined by the CPU clock frequency, approximately 70 seconds for a 120MHz processor.

Porting

The watchdog device driver does not require any platform-specific support. The only porting effort required is to list CYGPKG_DEVS_WATCHDOG_MIPS_PNX8330 as one of the hardware packages in the ecos.db target entry.

Chapter 141. Synthetic Target Watchdog Device

Name

Synthetic Target Watchdog Device — Emulate watchdog hardware in the synthetic target

Overview

Some target hardware comes equipped with a watchdog timer. Application code can start this timer and after a certain period of time, typically a second, the watchdog will trigger. Usually this causes the hardware to reboot. The application can prevent this by regularly resetting the watchdog. An automatic reboot can be very useful when deploying hardware in the field: a hardware glitch could cause the unit to hang; or the software could receive an unexpected sequence of inputs, never seen in the laboratory, causing the system to lock up. Often the hardware is still functional, and a reboot sorts out the problem with only a brief interruption in service.

The synthetic target watchdog package emulates watchdog hardware. During system initialization watchdog device will be instantiated, and the `watchdog.tcl` script will be loaded by the I/O auxiliary. When the eCos application starts the watchdog device, the `watchdog.tcl` script will start checking the state of the eCos application at one second intervals. A watchdog reset call simply involves a message to the I/O auxiliary. If the `watchdog.tcl` script detects that a second has elapsed without a reset then it will send a `SIGPWR` signal to the eCos application, causing the latter to terminate. If gdb is being used to run the application, the user will get a chance to investigate what is happening. This behaviour is different from real hardware in that there is no automatic reboot, but the synthetic target is used only for development purposes, not deployment in the field: if a reboot is desired then this can be achieved very easily by using gdb commands to run another instance of the application.

Installation

Before a synthetic target eCos application can use a watchdog device it is necessary to build and install host-side support. The relevant code resides in the `host` subdirectory of the synthetic target watchdog package, and building it involves the standard **configure**, **make** and **make install** steps. The implementation of the watchdog support does not require any executables, just a Tcl script `watchdog.tcl` and some support files, so the **make** step is a no-op.

There are two main ways of building the host-side software. It is possible to build both the generic host-side software and all package-specific host-side software, including the watchdog support, in a single build tree. This involves using the **configure** script at the toplevel of the eCos repository. For more information on this, see the `README.host` file at the top of the repository. Note that if you have an existing build tree which does not include the synthetic target watchdog support then it will be necessary to rerun the toplevel configure script: the search for appropriate packages happens at configure time.

The alternative is to build just the host-side for this package. This requires a separate build directory, building directly in the source tree is disallowed. The **configure** options are much the same as for a build from the toplevel, and the `README.host` file can be consulted for more details. It is essential that the watchdog support be configured with the same `--prefix` option as other eCos host-side software, especially the I/O auxiliary provided by the architectural synthetic target HAL package, otherwise the I/O auxiliary will be unable to locate the watchdog support.

Target-side Configuration

The watchdog device depends on the generic watchdog support, `CYGPKG_IO_WATCHDOG`: if the generic support is absent then the watchdog device will be inactive. Some templates include this generic package by default, but not all. If the configuration does not include the generic package then it can be added using the eCos configuration tools, for example:

```
$ ecosconfig add CYGPKG_IO_WATCHDOG
```

By default the configuration will use the hardware-specific support, i.e. this package. However the generic watchdog package contains an alternative implementation using the kernel alarm facility, and that implementation can be selected if desired. However usually it will be better to rely on an external watchdog facility as provided by the I/O auxiliary and the `watchdog.tcl` script: if there are serious problems within the application, for example memory corruption, then an internal software-only implementation will not be reliable.

The watchdog resolution is currently fixed to one second: if the device does not receive a reset signal at least once a second then the watchdog will trigger and the eCos application will be terminated with a SIGPWR signal. The current implementation does not allow this resolution to be changed.

On some targets the watchdog device does not perform a hard reset. Instead the device works more or less via the interrupt subsystem, allowing application code to install action routines that will be called when the watchdog triggers. The synthetic target watchdog support effectively does perform a hard reset, by sending a SIGPWR signal to the eCos application, and there is no support for action routines.

The synthetic target watchdog package provides some configuration options for manipulating the compiler flags used for building the target-side code. That code is fairly simple, so for nearly all applications the default flags will suffice.

It should be noted that the watchdog device is subject to selective linking. Unless some code explicitly references the device, for example by calling the start and reset functions, the watchdog support will not appear in the final executable. This is desirable because a watchdog device has no effect until started.

Wallclock versus Elapsed Time

On real hardware the watchdog device uses wallclock time: if the device does not receive a reset signal within a set period of time then the watchdog will trigger. When developing for the synthetic target this is not always appropriate. There may be other processes running, using up some or most of the cpu time. For example, the application may be written such that it will issue a reset after some calculations which are known to complete within half a second, well within the one-second resolution of the watchdog device. However if other Linux processes are running then the synthetic target application may get timesliced, and half a second of computation may take several seconds of wallclock time.

Another problem with using wallclock time is that it interferes with debugging: if the application hits a breakpoint then it is unlikely that the user will manage to restart it in less than a second, and the watchdog will not get reset in time.

To avoid these problems the synthetic target watchdog normally uses consumed cpu time rather than wallclock time. If the application is timesliced or if it is halted inside gdb then it does not consume any cpu time. The application actually has to spend a whole second's worth of cpu cycles without issuing a reset before the watchdog triggers.

However using consumed cpu time is not a perfect solution either. If the application makes blocking system calls then it is not using cpu time. Interaction with the I/O auxiliary involves system calls, but these should take only a short amount of time so their effects can be ignored. If the application makes direct system calls such as `cyg_hal_sys_read` then the system behaviour becomes undefined. In addition by default the idle thread will make blocking `select` system calls, effectively waiting until an interrupt occurs. If an application spends much of its time idle then the watchdog device may take much longer to trigger than expected. It may be desirable to enable the synthetic target HAL configuration option CYGIMP_HAL_IDLE_THREAD_SPIN, causing the idle thread to spin rather than block, at the cost of wasted cpu cycles.

The default is to use consumed cpu time, but this can be changed in the target definition file:

```
synth_device watchdog {
    use wallclock_time
    …
}
```

User Interface

When the synthetic target is run in graphical mode the watchdog device extends the user interface in two ways. The Help menu is extended with an entry for the watchdog-specific documentation. There is also a graphical display of the current state of the watchdog. Initially the watchdog is asleep:

When application code starts the device the watchdog will begin to keep an eye on things (or occasionally both eyes).

If the watchdog triggers the display will change again, and optionally the user can receive an audible alert. The location of the watchdog display within the I/O auxiliary's window can be controlled via a **watchdog_pack** entry in the target definition file. For example the following can be used to put the watchdog display to the right of the central text window:

```
synth_device watchdog {
    watchdog_pack -in .main.e -side top
    …
}
```

The user interface section of the generic synthetic target HAL documentation can be consulted for more information on window packing.

By default the watchdog support will not generate an audible alert when the watchdog triggers, to avoid annoying colleagues. Sound can be enabled in the target definition file, and two suitable files `sound1.au` and `sound2.au` are supplied as standard:

```
synth_device watchdog {
    sound sound1.au
    …
}
```

An absolute path can be specified if desired:

```
synth_device watchdog {
    sound /usr/share/emacs/site-lisp/emacspeak/sounds/default-8k/alarm.au
    …
}
```

Sound facilities are not built into the I/O auxiliary itself, instead an external program is used. The default player is **play**, a front-end to the sox application shipped with some Linux distributions. If another player should be used then this can be specified in the target definition file:

```
synth_device watchdog {
    …
    sound_player my_sound_player
```

The specified program will be run in the background with a single argument, the sound file.

Command Line Arguments

The watchdog support does not use any command line arguments. All configuration is handled through the target definition file.

Hooks

The watchdog support does not provide any hooks for use by other scripts. There is rarely any need for customizing the system's behaviour when a watchdog triggers because those should be rare events, even during application development.

Additional Tcl Procedures

The watchdog support does not provide any additional Tcl procedures or variables for use by other scripts.

Part XXXIX. eCos POSIX compatibility layer

Table of Contents

Chapter 142. POSIX Standard Support

eCos contains support for the POSIX Specification (ISO/IEC 9945-1)[POSIX].

POSIX support is divided between the POSIX and the FILEIO packages. The POSIX package provides support for threads, signals, synchronization, timers and message queues. The FILEIO package provides support for file and device I/O. The two packages may be used together or separately, depending on configuration.

This document takes a functional approach to the POSIX library. Support for a function implies that the data types and definitions necessary to support that function, and the objects it manipulates, are also defined. Any exceptions to this are noted, and unless otherwise noted, implemented functions behave as specified in the POSIX standard.

This document only covers the differences between the eCos implementation and the standard; it does not provide complete documentation. For full information, see the POSIX standard [POSIX]. Online, the Open Group Single Unix Specification [SUS2] provides complete documentation of a superset of POSIX. If you have access to a Unix system with POSIX compatibility, then the manual pages for this will be of use. There are also a number of books available. [Lewine] covers the process, signal, file and I/O functions, while [Lewis1], [Lewis2], [Nichols] and [Norton] cover Pthreads and related topics (see Bibliography, xref). However, many of these books are oriented toward using POSIX in non-embedded systems, so care should be taken in applying them to programming under eCos.

The remainder of this chapter broadly follows the structure of the POSIX Specification. References to the appropriate section of the Standard are included.

Omitted functions marked with “// TBA” are potential candidates for later implementation.

Process Primitives [POSIX Section 3]

Functions Implemented

```
int kill(pid_t pid, int sig);
int pthread_kill(pthread_t thread, int sig);
int sigaction(int sig, const struct sigaction *act, struct sigaction *oact);
int sigqueue(pid_t pid, int sig, const union sigval value);
int sigprocmask(int how, const sigset_t *set, sigset_t *oset);
int pthread_sigmask(int how, const sigset_t *set, sigset_t *oset);
int sigpending(sigset_t *set);
int sigsuspend(const sigset_t *set);
int sigwait(const sigset_t *set, int *sig);
int sigwaitinfo(const sigset_t *set, siginfo_t *info);
int sigtimedwait(const sigset_t *set, siginfo_t *info, const struct timespec *timeout);
int sigemptyset(sigset_t *set);
int sigfillset(sigset_t *set);
int sigaddset(sigset_t *set, int signo);
int sigdelset(sigset_t *set, int signo);
int sigismember(const sigset_t *set, int signo);
unsigned int alarm( unsigned int seconds );
int pause( void );
unsigned int sleep( unsigned int seconds );
```

Functions Omitted

```
pid_t fork(void);
int execl( const char *path, const char *arg, … );
int execv( const char *path, char *const argv[] );
int execle( const char *path, const char *arg, … );
int execve( const char *path, char *const argv[], char *const envp[] );
int execlp( const char *path, const char *arg, … );
int execvp( const char *path, char *const argv[] );
int pthread_atfork( void(*prepare)(void), void (*parent)(void),  void (*child)() );
pid_t wait( int *stat_loc );
pid_t waitpid( pid_t pid, int *stat_loc, int options );
void _exit( int status );
```

Notes

- Signal handling may be enabled or disabled with the CYGPKG_POSIX_SIGNALS option. Since signals are used by other POSIX components, such as timers, disabling signals will disable those components too.
- *kill()* and *sigqueue()* may only take a **pid** argument of zero, which maps to the current process.
- The *SIGEV_THREAD* notification type is not currently implemented.
- Job Control and Memory Protection signals are not supported.
- An extra implementation defined *si_code* value, *SI_EXCEPT*, is defined to distinguish hardware generated exceptions from others.
- Extra signals are defined: _SIGTRAP_, _SIGIOT_, _SIGEMT_, _SIGSYS_ These are largely to maintain compatibility with the signal numbers used by GDB.
- Signal delivery may currently occur at unexpected places in some API functions. Using *longjmp()* to transfer control out of a signal handler may result in the interrupted function not being able to complete properly. This may result in later function calls failing or deadlocking.

Process Environment [POSIX Section 4]

Functions Implemented

```
int uname( struct utsname *name );
time_t time( time_t *tloc );
char *getenv( const char *name );
int isatty( int fd );
long sysconf( int name );
```

Functions Omitted

```
pid_t getpid( void );
pid_t getppid( void );
uid_t getuid( void );
uid_t geteuid( void );
gid_t getgid( void );
gid_t getegid( void );
int setuid( uid_t uid );
int setgid( gid_t gid );
int getgroups( int gidsetsize, gid_t grouplist[] );
char *getlogin( void );
int getlogin_r( char *name, size_t namesize );
pid_t getpgrp( void );
pid_t setsid( void );
int setpgid( pid_t pid, pid_t pgid );
char *ctermid( char *s);
char *ttyname( int fd );                             // TBA
int ttyname_r( int fd, char *name, size_t namesize); // TBA
clock_t times( struct tms *buffer );                 // TBA
```

Notes

- The fields of the *utsname* structure are initialized as follows:

  ```
  sysname “eCos”
  nodename  “”  (gethostname() is currently not available)

  release   Major version number of the kernel
  version       Minor version number of the kernel
  machine “”  (Requires some config tool changes)
  ```

  The sizes of these strings are defined by CYG_POSIX_UTSNAME_LENGTH and CYG_POSIX_UTSNAME_NODENAME_LENGTH. The latter defaults to the value of the former, but may also be set independently to accommodate a longer node name.

- The *time()* function is currently implemented in the C library.

- A set of environment strings may be defined at configuration time with the CYGDAT_LIBC_DEFAULT_ENVIRONMENT option. The application may also define an environment by direct assignment to the **environ** variable.

- At present *isatty()* assumes that any character device is a tty and that all other devices are not ttys. Since the only kind of device that eCos currently supports is serial character devices, this is an adequate distinction.

- All system variables supported by sysconf will yield a value. However, those that are irrelevant to eCos will either return the default minimum defined in `<limits.h>`, or zero.

Files and Directories [POSIX Section 5]

Functions Implemented

```
DIR *opendir( const char *dirname );
struct dirent *readdir( DIR *dirp );
int readdir_r( DIR *dirp, struct dirent *entry, struct dirent **result );
void rewinddir( DIR *dirp );
int closedir( DIR *dirp );
int chdir( const char *path );
char *getcwd( char *buf, size_t size );
int open( const char * path , int oflag , … );
int creat( const char * path, mode_t mode );
int link( const char *existing, const char *new );
int mkdir( const char *path, mode_t mode );
int unlink( const char *path );
int rmdir( const char *path );
int rename( const char *old, const char *new );
int stat( const char *path, struct stat *buf );
int fstat( int fd, struct stat *buf );
int access( const char *path, int amode );
long pathconf(const char *path, int name);
long fpathconf(int fd, int name);
```

Functions Omitted

```
mode_t umask( mode_t cmask );
int mkfifo( const char *path, mode_t mode );
int chmod( const char *path, mode_t mode );                 // TBA
int fchmod( int fd, mode_t mode );                          // TBA
int chown( const char *path, uid_t owner, gid_t group );
int utime( const char *path, const struct utimbuf *times ); // TBA
int ftruncate( int fd, off_t length );                      // TBA
```

Notes

- If a call to `open()` or `creat()` supplies the third _mode_ parameter, it will currently be ignored.
- Most of the functionality of these functions depends on the underlying filesystem.
- Currently *access()* only checks the *F_OK* mode explicitly, the others are all assumed to be true by default.
- The maximum number of open files allowed is supplied by the CYGNUM_FILEIO_NFILE option. The maximum number of file descriptors is supplied by the CYGNUM_FILEIO_NFD option.

Input and Output [POSIX Section 6]

Functions Implemented

```
int dup( int fd );
int dup2( int fd, int fd2 );
int close(int fd);
ssize_t read(int fd, void *buf, size_t nbyte);
ssize_t write(int fd, const void *buf, size_t nbyte);
int fcntl( int fd, int cmd, … );
off_t lseek(int fd, off_t offset, int whence);
int fsync( int fd );
int fdatasync( int fd );
```

Functions Omitted

```
int pipe( int fildes[2] );
int aio_read( struct aiocb *aiocbp );                        // TBA
int aio_write( struct aiocb *aiocbp );                       // TBA
int lio_listio( int mode, struct aiocb *const list[],
                int nent, struct sigevent *sig);             // TBA
int aio_error( struct aiocb *aiocbp );                       // TBA
int aio_return( struct aiocb *aiocbp );                      // TBA
int aio_cancel( int fd, struct aiocb *aiocbp );              // TBA
int aio_suspend( const struct aiocb *const list[],
                 int nent, const struct timespec *timeout );  // TBA
int aio_fsync( int op, struct aiocb *aiocbp );               // TBA
```

Notes

- Only the *F_DUPFD* command of *fcntl()* is currently implemented.
- Most of the functionality of these functions depends on the underlying filesystem.

Device and Class Specific Functions [POSIX Section 7]

Functions Implemented

```
speed_t cfgetospeed( const struct termios *termios_p );
int cfsetospeed( struct termios *termios_p, speed_t speed );
speed_t cfgetispeed( const struct termios *termios_p );
int cfsetispeed( struct termios *termios_p, speed_t speed );
int tcgetattr( int fd, struct termios *termios_p );
int tcsetattr( int fd, int optional_actions,  const struct termios *termios_p );
int tcsendbreak( int fd, int duration );
int tcdrain( int fd );
int tcflush( int fd, int queue_selector );
int tcsendbreak( int fd, int action );
```

Functions Omitted

```
pid_t tcgetpgrp( int fd );
int tcsetpgrp( int fd, pid_t pgrp );
```

Notes

- Only the functionality relevant to basic serial device control is implemented. Only very limited support for canonical input is provided, and then only via the “tty” devices, not the “serial” devices. None of the functionality relevant to job control, controlling terminals and sessions is implemented.
- Only *MIN* = 0 and *TIME* = 0 functionality is provided.
- Hardware flow control is supported if the underlying device driver and serial port support it.
- Support for break, framing and parity errors depends on the functionality of the hardware and device driver.

C Language Services [POSIX Section 8]

Functions Implemented

```
char *setlocale( int category, const char *locale );
int fileno( FILE *stream );
FILE *fdopen( int fd, const char *type );
int getc_unlocked( FILE *stream);
int getchar_unlocked( void );
int putc_unlocked( FILE *stream );
int putchar_unlocked( void );
char *strtok_r( char *s, const char *sep, char **lasts );
char *asctime_r( const struct tm *tm, char *buf );
char *ctime_r( const time_t *clock, char *buf );
struct tm *gmtime_r( const time_t *clock, struct tm *result );
struct tm *localtime_r( const time_t *clock, struct tm *result );
int rand_r( unsigned int *seed );
```

Functions Omitted

```
void flockfile( FILE *file );
int ftrylockfile( FILE *file );
void funlockfile( FILE *file );
int sigsetjmp( sigjmp_buf env, int savemask );      // TBA
void siglongjmp( sigjmp_buf env, int val );         // TBA
void tzset(void);                                   // TBA
```

Notes

- *setlocale()* is implemented in the C library Internationalization package.
- Functions *fileno()* and *fdopen()* are implemented in the C library STDIO package.
- Functions *getc_unlocked()*, *getchar_unlocked()*, *putc_unlocked()* and *putchar_unlocked()* are defined but are currently identical to their non-unlocked equivalents.

- *strtok_r()*, *asctime_r()*, *ctime_r()*, *gmtime_r()*, *localtime_r()* and *rand_r()* are all currently in the C library, alongside their non-reentrant versions.

System Databases [POSIX Section 9]

Functions Implemented

<none>

Functions Omitted

```
struct group *getgrgid( gid_t gid );
int getgrgid( gid_t gid, struct group *grp, char *buffer, size_t bufsize, struct group **result );
struct group *getgrname( const char *name );
int getgrname_r( const char *name,    struct group *grp,      char *buffer,
                 size_t     bufsize,  struct group **result );
struct passwd *getpwuid( uid_t uid );
int getpwuid_r( uid_t   uid,      struct passwd *pwd,         char *buffer,
                size_t  bufsize,  struct passwd **result );
struct passwd *getpwnam( const char *name );
int getpwnam_r( const char *name,    struct passwd *pwd,      char *buffer,
                size_t      bufsize, struct passwd **result );
```

Notes

- None of the functions in this section are implemented.

Data Interchange Format [POSIX Section 10]

This section details *tar* and *cpio* formats. Neither of these is supported by eCos.

Synchronization [POSIX Section 11]

Functions Implemented

```
int sem_init(sem_t *sem, int pshared, unsigned int value);
int sem_destroy(sem_t *sem);
int sem_wait(sem_t *sem);
int sem_trywait(sem_t *sem);
int sem_post(sem_t *sem);
int sem_getvalue(sem_t *sem, int *sval);
int pthread_mutexattr_init( pthread_mutexattr_t *attr);
int pthread_mutexattr_destroy( pthread_mutexattr_t *attr);
int pthread_mutex_init(pthread_mutex_t *mutex, const pthread_mutexattr_t *mutex_attr);
int pthread_mutex_destroy(pthread_mutex_t *mutex);
int pthread_mutex_lock(pthread_mutex_t *mutex);
int pthread_mutex_trylock(pthread_mutex_t *mutex);
int pthread_mutex_timedlock(pthread_mutex_t *mutex, const struct timespec *abstime);
int pthread_mutex_unlock(pthread_mutex_t *mutex);
int pthread_condattr_init(pthread_condattr_t *attr);
int pthread_condattr_destroy(pthread_condattr_t *attr);
int pthread_cond_init(pthread_cond_t *cond, const pthread_condattr_t *attr);
int pthread_cond_destroy(pthread_cond_t *cond);
int pthread_cond_signal(pthread_cond_t *cond);
int pthread_cond_broadcast(pthread_cond_t *cond);
int pthread_cond_wait(pthread_cond_t *cond, pthread_mutex_t *mutex);
int pthread_cond_timedwait(pthread_cond_t *cond, pthread_mutex_t *mutex,
                           const struct timespec *abstime);
```

Functions Omitted

```
sem_t *sem_open(const char *name, int oflag, …);   // TBA
int sem_close(sem_t *sem);          // TBA
int sem_unlink(const char *name);       // TBA
int pthread_mutexattr_getpshared( const pthread_mutexattr_t *attr,
                                  int                       *pshared );
int pthread_mutexattr_setpshared( const pthread_mutexattr_t *attr,
                                  int                       pshared );
int  pthread_condattr_getpshared( const pthread_condattr_t  *attr,
                                  int                       *pshared);
int  pthread_condattr_setpshared( const pthread_condattr_t  *attr,
                                  int                       pshared);
```

Notes

- The presence of semaphores is controlled by the CYGPKG_POSIX_SEMAPHORES option. This in turn causes the _POSIX_SEMAPHORES feature test macro to be defined and the semaphore API to be made available.

- The **pshared** argument to *sem_init()* is not implemented, its value is ignored.

- Functions *sem_open()*, *sem_close()* and *sem_unlink()* are present but always return an error (ENOSYS).

- The exact priority inversion protocols supported may be controlled with the _POSIX_THREAD_PRIO_INHERIT and _POSIX_THREAD_PRIO_PROTECT configuration options.

- {_POSIX_THREAD_PROCESS_SHARED} is not defined, so the **process-shared** mutex and condition variable attributes are not supported, and neither are the functions *pthread_mutexattr_getpshared()*, *pthread_mutexattr_setpshared()*, *pthread_condattr_getpshared()* and *pthread_condattr_setpshared()*.

- Condition variables do not become bound to a particular mutex when *pthread_cond_wait()* is called. Hence different threads may wait on a condition variable with different mutexes. This is at variance with the standard, which requires a condition variable to become (dynamically) bound by the first waiter, and unbound when the last finishes. However, this difference is largely benign, and the cost of policing this feature is non-trivial.

Memory Management [POSIX Section 12]

Functions Implemented

<none>

Functions Omitted

```
int mlockall( int flags );
int munlockall( void );
int mlock( const void *addr, size_t len );
int munlock( const void *addr, size_t len );
void mmap( void *addr, size_t len, int prot, int flags, int fd, off_t off );
int munmap( void *addr, size_t len );
int mprotect( const void *addr, size_t len, int prot );
int msync( void *addr, size_t len, int flags );
int shm_open( const char *name, int oflag, mode_t mode );
int shm_unlink( const char *name );
```

Notes

None of these functions are currently provided. Some may be implemented in a restricted form in the future.

Execution Scheduling [POSIX Section 13]

Functions Implemented

```
int sched_yield(void);
int sched_get_priority_max(int policy);
int sched_get_priority_min(int policy);
int sched_rr_get_interval(pid_t pid, struct timespec *t);
int pthread_attr_setscope(pthread_attr_t *attr, int scope);
int pthread_attr_getscope(const pthread_attr_t *attr, int *scope);
int pthread_attr_setinheritsched(pthread_attr_t *attr, int inherit);
int pthread_attr_getinheritsched(const pthread_attr_t *attr, int *inherit);
int pthread_attr_setschedpolicy(pthread_attr_t *attr, int policy);
int pthread_attr_getschedpolicy(const pthread_attr_t *attr, int *policy);
int pthread_attr_setschedparam(pthread_attr_t *attr, const struct sched_param *param);
int pthread_attr_getschedparam(const pthread_attr_t *attr, struct sched_param *param);
int pthread_setschedparam(pthread_t thread, int policy, const struct sched_param *param);
int pthread_getschedparam(pthread_t thread, int *policy, struct sched_param *param);
int pthread_mutexattr_setprotocol(pthread_mutexattr_t *attr, int protocol);
int pthread_mutexattr_getprotocol(pthread_mutexattr_t *attr, int *protocol);
int pthread_mutexattr_setprioceiling(pthread_mutexattr_t *attr, int prioceiling);
int pthread_mutexattr_getprioceiling(pthread_mutexattr_t *attr, int *prioceiling);
int pthread_mutex_setprioceiling(pthread_mutex_t *mutex, int prioceiling, int *old_ceiling);
int pthread_mutex_getprioceiling(pthread_mutex_t *mutex, int *prioceiling);
```

Functions Omitted

```
int sched_setparam(pid_t pid, const struct sched_param *param);
int sched_getparam(pid_t pid, struct sched_param *param);
int sched_setscheduler(pid_t pid, int policy, const struct sched_param *param);
int sched_getscheduler(pid_t pid);
```

Notes

- The functions *sched_setparam()*, *sched_getparam()*, *sched_setscheduler()* and *sched_getscheduler()* are present but always return an error.
- The scheduler policy *SCHED_OTHER* is equivalent to *SCHED_RR*.
- Only *PTHREAD_SCOPE_SYSTEM* is supported as a **contentionscope** attribute.
- The default thread scheduling attributes are:

  ```
  contentionscope         PTHREAD_SCOPE_SYSTEM
  inheritsched            PTHREAD_INHERIT_SCHED
  schedpolicy             SCHED_OTHER
  chedparam.sched        0
  ```

- Mutex priority inversion protection is controlled by a number of kernel configuration options. If CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL_INHERIT is defined then {_POSIX_THREAD_PRIO_INHERIT} will be defined and PTHREAD_PRIO_INHERIT may be set as the protocol in a *pthread_mutexattr_t* object. If CYGSEM_KERNEL_SYNCH_MUTEX_PRIORITY_INVERSION_PROTOCOL_CEILING is defined then {_POSIX_THREAD_PRIO_PROTECT} will be defined and PTHREAD_PRIO_PROTECT may be set as the protocol in a *pthread_mutexattr_t* object.

- The default attribute values set by *pthread_mutexattr_init()* is to set the protocol attribute to PTHREAD_PRIO_NONE and the prioceiling attribute to zero.

Clocks and Timers [POSIX Section 14]

Functions Implemented

```
int clock_settime( clockid_t clock_id,
const struct timespec *tp);
int clock_gettime( clockid_t clock_id, struct timespec *tp);
int clock_getres( clockid_t clock_id, struct timespec *tp);
int timer_create( clockid_t clock_id, struct sigevent *evp, timer_t *timer_id);
int timer_delete( timer_t timer_id );
int timer_settime( timer_t                  timerid,
                   int                      flags,
                   const struct itimerspec  *value,
                   struct itimerspec        *ovalue );
int timer_gettime( timer_t timerid, struct itimerspec *value );
int timer_getoverrun( timer_t timerid );
int nanosleep( const struct timespec *rqtp, struct timespec *rmtp);
int gettimeofday(struct timeval *tv, struct timezone* tz);
```

Functions Omitted

<none>

Notes

- Currently *timer_getoverrun()* only reports timer notifications that are delayed in the timer subsystem. If they are delayed in the signal subsystem, due to signal masks for example, this is not counted as an overrun.

- The option CYGPKG_POSIX_TIMERS allows the timer support to be enabled or disabled, and causes _POSIX_TIMERS to be defined appropriately. This will cause other parts of the POSIX system to have limited functionality.

Message Passing [POSIX Section 15]

Functions Implemented

```
mqd_t mq_open( const char *name, int  oflag, … );
int mq_close( mqd_t  mqdes );
int mq_unlink( const char *name );
int mq_send( mqd_t mqdes, const char *msg_ptr,  size_t msg_len, unsigned int msg_prio );
ssize_t mq_receive( mqd_t mqdes, char *msg_ptr, size_t msg_len, unsigned int *msg_prio );
int mq_setattr( mqd_t mqdes, const struct mq_attr *mqstat, struct mq_attr *omqstat );
int mq_getattr( mqd_t mqdes, struct mq_attr *mqstat );
int mq_notify( mqd_t mqdes, const struct sigevent *notification );
```

From POSIX 1003.1d draft:

```
int mq_send( mqd_t        mqdes,
             const char   *msg_ptr,
             size_t       msg_len,
             unsigned int msg_prio,
             const struct timespec *abs_timeout );

ssize_t mq_receive( mqd_t         mqdes,
                    char          *msg_ptr,
                    size_t        msg_len,
                    unsigned int  *msg_prio,
                    const struct timespec *abs_timeout );
```

Functions Omitted

<none>

Notes

- The presence of message queues is controlled by the CYGPKG_POSIX_MQUEUES option. Setting this will cause [_POSIX_MESSAGE_PASSING] to be defined and the message queue API to be made available.
- Message queues are not currently filesystem objects. They live in their own name and descriptor spaces.

Thread Management [POSIX Section 16]

Functions Implemented

```
int pthread_attr_init(pthread_attr_t *attr);
int pthread_attr_destroy(pthread_attr_t *attr);
int pthread_attr_setdetachstate(pthread_attr_t *attr, int detachstate);
int pthread_attr_getdetachstate(const pthread_attr_t *attr, int *detachstate);
int pthread_attr_setstackaddr(pthread_attr_t *attr,  void *stackaddr);
int pthread_attr_getstackaddr(const pthread_attr_t *attr, void **stackaddr);
int pthread_attr_setstacksize(pthread_attr_t *attr, size_t stacksize);
int pthread_attr_getstacksize(const pthread_attr_t *attr, size_t *stacksize);
int pthread_create( pthread_t             *thread,
                    const pthread_attr_t  *attr,
                    void                  *(*start_routine)(void *),
                    void                  *arg);
pthread_t pthread_self( void );
int pthread_equal(pthread_t thread1, pthread_t thread2);
void pthread_exit(void *retval);
int pthread_join(pthread_t thread, void **thread_return);
int pthread_detach(pthread_t thread);
int pthread_once(pthread_once_t *once_control, void (*init_routine)(void));
```

Functions Omitted

<none>

Notes

- The presence of thread support as a whole is controlled by the the CYGPKG_POSIX_PTHREAD configuration option. Note that disabling this will also disable many other features of the POSIX package, since these are intimately bound up with the thread mechanism.
- The default (non-scheduling) thread attributes are:

  ```
  detachstate             PTHREAD_CREATE_JOINABLE
  stackaddr               unset
  stacksize               unset
  ```

- Dynamic thread stack allocation is only provided if there is an implementation of *malloc()* configured (i.e. a package implements the CYGINT_MEMALLOC_MALLOC_ALLOCATORS interface). If there is no malloc() available, then the thread creator must supply a stack. If only a stack address is supplied then the stack is assumed to be PTHREAD_STACK_MIN bytes long.

This size is seldom useful for any but the most trivial of threads. If a different sized stack is used, both the stack address and stack size must be supplied.

- The value of PTHREAD_THREADS_MAX is supplied by the CYGNUM_POSIX_PTHREAD_THREADS_MAX option. This defines the maximum number of threads allowed. The POSIX standard requires this value to be at least 64, and this is the default value set.
- When the POSIX package is installed, the thread that calls *main()* is initialized as a POSIX thread. The priority of that thread is controlled by the CYGNUM_POSIX_MAIN_DEFAULT_PRIORITY option.

Thread-Specific Data [POSIX Section 17]

Functions Implemented

```
int pthread_key_create(pthread_key_t *key, void (*destructor)(void *));
int pthread_setspecific(pthread_key_t key, const void *pointer);
void *pthread_getspecific(pthread_key_t key);
int pthread_key_delete(pthread_key_t key);
```

Functions Omitted

<none>

Notes

- The value of PTHREAD_DESTRUCTOR_ITERATIONS is provided by the CYGNUM_POSIX_PTHREAD_DESTRUCTOR_ITERATIONS option. This controls the number of times that a key destructor will be called while the data item remains non-NULL.
- The value of PTHREAD_KEYS_MAX is provided by the CYGNUM_POSIX_PTHREAD_KEYS_MAX option. This defines the maximum number of per-thread data items supported. The POSIX standard calls for this to be a minimum of 128, which is rather large for an embedded system. The default value for this option is set to 128 for compatibility but it should be reduced to a more usable value.

Thread Cancellation [POSIX Section 18]

Functions Implemented

```
int pthread_cancel(pthread_t thread);
int pthread_setcancelstate(int state, int *oldstate);
int pthread_setcanceltype(int type, int *oldtype);
void pthread_testcancel(void);
void pthread_cleanup_push( void (*routine)(void *), void *arg);
void pthread_cleanup_pop( int execute);
```

Functions Omitted

<none>

Notes

Asynchronous cancellation is only partially implemented. In particular, cancellation may occur in unexpected places in some functions. It is strongly recommended that only synchronous cancellation be used.

Non-POSIX Functions

In addition to the standard POSIX functions defined above, the following non-POSIX functions are defined in the FILEIO package.

General I/O Functions

```
int ioctl(int fd, CYG_ADDRWORD com, CYG_ADDRWORD data);
int select(int nfd, fd_set *in, fd_set *out, fd_set *ex, struct timeval *tv);
```

Socket Functions

```
int socket( int domain, int type, int protocol);
int bind(int s, const struct sockaddr *sa, unsigned int len);
int listen(int s, int len);
int accept(int s, struct sockaddr *sa, socklen_t *addrlen);
int connect(int s, const struct sockaddr *sa, socklen_t len);
int getpeername(int s, struct sockaddr *sa, socklen_t *len);
int getsockname(int s, struct sockaddr *sa, socklen_t *len);
int setsockopt(int s, int level, int optname, const void *optval, socklen_t optlen);
int getsockopt(int s, int level, int optname, void *optval, socklen_t *optlen);
ssize_t recvmsg(int s, struct msghdr *msg, int flags);
ssize_t recvfrom(int s, void *buf, size_t len, int flags, struct sockaddr *from, socklen_t *fromlen);
ssize_t recv(int s, void *buf, size_t len, int flags);
ssize_t sendmsg(int s, const struct msghdr *msg, int flags);
ssize_t sendto(int                    s,
               const void             *buf,
               size_t                 len,
               int                    flags,
               const struct sockaddr  *to,
               socklen_t              tolen);
ssize_t send(int s, const void *buf, size_t len, int flags);
int shutdown(int s, int how);
```

Notes

- The precise behaviour of these functions depends mainly on the functionality of the underlying filesystem or network stack to which they are applied.

Part XL. µITRON

Table of Contents

Chapter 143. µITRON API

Introduction to µITRON

The µITRON specification defines a highly flexible operating system architecture designed specifically for application in embedded systems. The specification addresses features which are common to the majority of processor architectures and deliberately avoids virtualization which would adversely impact real-time performance. The µITRON specification may be implemented on many hardware platforms and provides significant advantages by reducing the effort involved in understanding and porting application software to new processor architectures.

Several revisions of the µITRON specification exist. In this release, *eCos* supports the µITRON version 3.02 specification, with complete “Standard functionality” (level S), plus many “Extended” (level E) functions. An exception is get_tid() which has µITRON 4 semantics. The definitive reference on µITRON is Dr. Sakamura,s book: *µITRON 3.0, An Open and Portable Real-Time Operating System for Embedded Systems*. The book can be purchased from the IEEE Press, and an ASCII version of the standard can be found online at http://www.t-engine.org/specifications#d.

µITRON and *eCos*

The *eCos* kernel implements the functionality used by the µITRON compatibility subsystem. The configuration of the kernel influences the behavior of µITRON programs.

In particular, the default configuration has time slicing (also known as round-robin scheduling) switched on; this means that a task can be moved from RUN state to READY state at any time, in order that one of its peers may run. This is not strictly conformant to the µITRON specification, which states that timeslicing may be implemented by periodically issuing a rot_rdq(0) call from within a periodic task or cyclic handler; otherwise it is expected that a task runs until it is pre-empted in consequence of synchronization or communication calls it makes, or the effects of an interrupt or other external event on a higher priority task cause that task to become READY. To disable timeslicing functionality in the kernel and µITRON compatibility environment, please disable the CYGSEM_KERNEL_SCHED_TIMESLICE configuration option in the kernel package. A description of kernel scheduling is in Kernel Overview.

For another example, the semantics of task queueing when waiting on a synchronization object depend solely on the way the underlying kernel is configured. As discussed above, the multi-level queue scheduler is the only one which is µITRON compliant, and it queues waiting tasks in FIFO order. Future releases of that scheduler might be configurable to support priority ordering of task queues. Other schedulers might be different again: for example the bitmap scheduler can be used with the µITRON compatibility layer, even though it only allows one task at each priority and as such is not µITRON compliant, but it supports only priority ordering of task queues. So which queueing scheme is supported is not really a property of the µITRON compatibility layer; it depends on the kernel.

In this version of the µITRON compatibility layer, the calls to disable and enable scheduling and interrupts (dis_dsp(), ena_dsp(), loc_cpu() and unl_cpu()) call underlying kernel functions; in particular, the xxx_dsp() functions lock the scheduler entirely, which prevents dispatching of DSRs; functions implemented by DSRs include clock counters and alarm timers. Thus time “stops” while dispatching is disabled with dis_dsp().

Like all parts of the *eCos* system, the detailed semantics of the µITRON layer are dependent on its configuration and the configuration of other components that it uses. The µITRON configuration options are all defined in the file pkgconf/uitron.h, and can be set using the configuration tool or editing the .ecc file in your build directory by hand.

An important configuration option for the µITRON compatibility layer is “Option: Return Error Codes for Bad Params” (CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS), which allows a lot of the error checking code in the µITRON compatibility layer to be removed. Of course this leaves a program open to undetected errors, so it should only be used once an application is fully debugged and tested. Its benefits include reduced code size and faster execution. However, it affects the API significantly, in that with this option enabled, bad calls do not return errors, but cause an assert failure (if that is itself enabled) or malfunction internally. There is discussion in more detail about this in each section below.

We now give a brief description of the µITRON functions which are implemented in this release. Note that all C and C++ source files should have the following `#include` statement:

```
#include <cyg/compat/uitron/uit_func.h>
```

Task Management Functions

The following functions are fully supported in this release:

```
ER sta_tsk(
  ID tskid,
  INT stacd )
```

```
void ext_tsk( void )
```

```
void exd_tsk( void )
```

```
ER dis_dsp( void )
```

```
ER ena_dsp( void )
```

```
ER chg_pri(
  ID tskid,
  PRI tskpri )
```

```
ER rot_rdq(
  PRI tskpri )
```

```
ER get_tid(
  ID *p_tskid )
```

```
ER ref_tsk(
  T_RTSK *pk_rtsk,
  ID tskid )
```

```
ER ter_tsk(
  ID tskid )
```

```
ER rel_wai(
  ID tskid )
```

The following two functions are supported in this release, when enabled with the configuration option `CYGPKG_UITRON_TASKS_CREATE_DELETE` with some restrictions:

```
ER cre_tsk(
  ID tskid,
  T_CTSK *pk_ctsk )
```

```
ER del_tsk(
  ID tskid )
```

These functions are restricted as follows:

Because of the static initialization facilities provided for system objects, a task is allocated stack space statically in the configuration. So while tasks can be created and deleted, the same stack space is used for that task (task ID number) each time. Thus the stack size (pk_ctsk->stksz) requested in `cre_tsk()` is checked for being less than that which was statically allocated, and otherwise ignored. This ensures that the new task will have enough stack to run. For this reason `del_tsk()` does not in any sense free the memory that was in use for the task's stack.

The task attributes (pk_ctsk->tskatr) are ignored; current versions of *eCos* do not need to know whether a task is written in assembler or C/C++ so long as the procedure call standard appropriate to the CPU is followed.

Extended information (pk_ctsk->exinf) is ignored.

Error checking

For all these calls, an invalid task id (tskid) (less than 1 or greater than the number of configured tasks) only returns E_ID when bad params return errors (`CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` is enabled, see above).

Similarly, the following conditions are only checked for, and only return errors if `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` is enabled:

- pk_crtk in `cre_tsk()` is a valid pointer, otherwise return E_PAR
- `ter_tsk()` or `rel_wai()` on the calling task returns E_OBJ
- the CPU is not locked already in `dis_dsp()` and `ena_dsp()` ; returns E_CTX
- priority level in `chg_pri()` and `rot_rdq()` is checked for validity, E_PAR
- return value pointer in `get_tid()` and `ref_tsk()` is a valid pointer, or E_PAR

The following conditions are checked for, and return error codes if appropriate, regardless of the setting of `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` :

- When create and delete functions `cre_tsk()` and `del_tsk()` are supported, all calls which use a valid task ID number check that the task exists; if not, E_NOEXS is returned
- When supported, `cre_tsk()` : the task must not already exist; otherwise E_OBJ
- When supported, `cre_tsk()` : the requested stack size must not be larger than that statically configured for the task; see the configuration options “Static initializers”, and “Default stack size”. Else E_NOMEM
- When supported, `del_tsk()` : the underlying *eCos* thread must not be running - this would imply either a bug or some program bypassing the µITRON compatibility layer and manipulating the thread directly. E_OBJ
- `sta_tsk()` : the task must be dormant, else E_OBJ
- `ter_tsk()` : the task must not be dormant, else E_OBJ
- `chg_pri()` : the task must not be dormant, else E_OBJ
- `rel_wai()` : the task must be in `WAIT` or `WAIT-SUSPEND` state, else E_OBJ

Task-Dependent Synchronization Functions

These functions are fully supported in this release:

```
ER sus_tsk(
    ID tskid )
```

```
ER rsm_tsk(
    ID tskid )
```

```
ER frsm_tsk(
    ID tskid )
```

```
ER slp_tsk( void )
```

```
ER tslp_tsk(
    TMO tmout )
```

```
ER wup_tsk(
    ID tskid )
```

```
ER can_wup(
    INT *p_wupcnt,    ID tskid )
```

Error checking

The following conditions are only checked for, and only return errors if CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS is enabled (see the configuration option “Return Error Codes for Bad Params”):

- invalid tskid; less than 1 or greater than CYGNUM_UITRON_TASKS returns E_ID
- wup_tsk() , sus_tsk() , rsm_tsk() , frsm_tsk() on the calling task returns E_OBJ
- dispatching is enabled in tslp_tsk() and slp_tsk() , or E_CTX
- tmout must be positive, otherwise E_PAR
- return value pointer in can_wup() is a valid pointer, or E_PAR

The following conditions are checked for, and can return error codes, regardless of the setting of CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS:

- When create and delete functions cre_tsk() and del_tsk() are supported, all calls which use a valid task ID number check that the task exists; if not, E_NOEXS is returned
- sus_tsk() : the task must not be dormant, else E_OBJ
- frsm/rsm_tsk() : the task must be suspended, else E_OBJ
- tslp/slp_tsk() : return codes E_TMOUT, E_RLWAI and E_DLT are returned depending on the reason for terminating the sleep
- wup_tsk() and can_wup() : the task must not be dormant, or E_OBJ is returned

Synchronization and Communication Functions

These functions are fully supported in this release:

```
ER sig_sem(
    ID semid )
```

```
ER wai_sem(
    ID semid )
```

```
ER preq_sem(
    ID semid )
```

```
ER twai_sem(
    ID semid,    TMO tmout )
```

```
ER ref_sem(
    T_RSEM *pk_rsem ,    ID semid )
```

```
ER set_flg(
    ID flgid,    UINT setptn )
```

```
ER clr_flg(
    ID flgid,    UINT clrptn )
```

```
ER wai_flg(
    UINT *p_flgptn,    ID flgid ,
    UINT waiptn ,    UINT wfmode )
```

```
ER pol_flg(
    UINT *p_flgptn,    ID flgid ,
    UINT waiptn ,    UINT wfmode )
```

```
ER twai_flg(
    UINT *p_flgptn    ID flgid ,
    UINT waiptn ,    UINT wfmode,    TMO tmout )
```

```
ER ref_flg(
    T_RFLG *pk_rflg,    ID flgid )
```

```
ER snd_msg(
    ID mbxid,    T_MSG *pk_msg )
```

```
ER rcv_msg(
    T_MSG **ppk_msg,    ID mbxid )
```

```
ER prcv_msg(
    T_MSG **ppk_msg,    ID mbxid )
```

```
ER trcv_msg(
    T_MSG **ppk_msg,    ID mbxid ,    TMO tmout )
```

```
ER ref_mbx(
    T_RMBX *pk_rmbx,    ID mbxid )
```

The following functions are supported in this release (with some restrictions) if enabled with the appropriate configuration option for the object type (for example `CYGPKG_UITRON_SEMAS_CREATE_DELETE`):

```
ER cre_sem(
    ID semid,    T_CSEM *pk_csem )
```

```
ER del_sem(
    ID semid )
```

```
ER cre_flg(
    ID flgid,    T_CFLG *pk_cflg )
```

```
ER del_flg(
    ID flgid )
```

```
ER cre_mbx(
    ID mbxid,    T_CMBX *pk_cmbx )
```

```
ER del_mbx(
    ID mbxid )
```

In general the queueing order when waiting on a synchronization object depends on the underlying kernel configuration. The multi-level queue scheduler is required for strict µITRON conformance and it queues tasks in FIFO order, so requests to create an object with priority queueing of tasks (`pk_cxxx->xxxatr = TA_TPRI`) are rejected with E_RSATR. Additional undefined bits in the attributes fields must be zero.

In general, extended information (pk_cxxx->exinf) is ignored.

For semaphores, the initial semaphore count (pk_csem->isemcnt) is supported; the new semaphore's count is set. The maximum count is not supported, and is not in fact defined in type pk_csem.

For flags, multiple tasks are allowed to wait. Because single task waiting is a subset of this, the W bit (TA_WMUL) of the flag attributes is ignored; all other bits must be zero. The initial flag value is supported.

For mailboxes, the buffer count is defined statically by kernel configuration option `CYGNUM_KERNEL_SYNCH_MBOX_QUEUE_SIZE`; therefore the buffer count field is not supported and is not in fact defined in type pk_cmbx. Queueing of messages is FIFO ordered only, so TA_MPRI (in pk_cmbx->mbxatr) is not supported.

Error checking

The following conditions are only checked for, and only return errors if `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` is enabled:

- invalid object id; less than 1 or greater than `CYGNUM_UITRON_TASKS/SEMAS/MBOXES` as appropriate returns E_ID
- dispatching is enabled in any call which can sleep, or E_CTX
- tmout must be positive, otherwise E_PAR
- pk_cxxx pointers in `cre_xxx()` must be valid pointers, or E_PAR
- return value pointer in `ref_xxx()` is valid pointer, or E_PAR
- flag wait pattern must be non-zero, and mode must be valid, or E_PAR
- return value pointer in flag wait calls is a valid pointer, or E_PAR

The following conditions are checked for, and can return error codes, regardless of the setting of `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` :

- When create and delete functions `cre_xxx()` and `del_xxx()` are supported, all calls which use a valid object ID number check that the object exists. If not, E_NOEXS is returned.
- In create functions `cre_xxx()` , when supported, if the object already exists, then E_OBJ
- In any call which can sleep, such as `twai_sem()` : return codes E_TMOUT, E_RLWAI, E_DLT or of course E_OK are returned depending on the reason for terminating the sleep
- In polling functions such as `preq_sem()` return codes E_TMOUT or E_OK are returned depending on the state of the synchronization object
- In creation functions, the attributes must be compatible with the selected underlying kernel configuration: in `cre_sem()` `pk_csem->sematr` must be equal to `TA_TFIFO` else E_RSATR.
- In `cre_flg()` `pk_cflg->flgatr` must be either `TA_WMUL` or `TA_WSGL` else `E_RSATR`.
- In `cre_mbx()` `pk_cmbx->mbxatr` must be `TA_TFIFO + TA_MFIFO` else E_RSATR.

Extended Synchronization and Communication Functions

None of these functions are supported in this release.

Interrupt management functions

These functions are fully supported in this release:

```
void   ret_int( void )
```

```
ER loc_cpu( void )
```

```
ER unl_cpu( void )
```

```
ER dis_int(
    UINT eintno )
```

```
ER ena_int(
    UINT eintno )
```

```
void  ret_wup(
    ID tskid )
```

```
ER iwup_tsk(
    ID tskid )
```

```
ER isig_sem(
    ID semid )
```

```
ER iset_flg(
    ID flgid ,
    UID setptn )
```

```
ER isend_msg(
    ID mbxid ,
    T_MSG *pk_msg )
```

Note that `ret_int()` and the `ret_wup()` are implemented as macros, containing a “return” statement.

Also note that `ret_wup()` and the `ixxx_yyy()` style functions will only work when called from an ISR whose associated DSR is `cyg_uitron_dsr()`, as specified in include file `<cyg/compat/uitron/uit_ifnc.h>`, which defines the `ixxx_yyy()` style functions also.

If you are writing interrupt handlers more in the *eCos* style, with separate ISR and DSR routines both of your own devising, do not use these special functions from a DSR: use plain `xxx_yyy()` style functions (with no ’i, prefix) instead, and do not call any µITRON functions from the ISR at all.

The following functions are not supported in this release:

```
ER def_int(
    UINT dintno,
  T_DINT *pk_dint )
```

```
ER chg_iXX(
    UINT iXXXX )
```

```
ER ref_iXX(
    UINT * p_iXXXX )
```

These unsupported functions are all Level C (CPU dependent). Equivalent functionality is available via other *eCos*-specific APIs.

Error checking

The following conditions are only checked for, and only return errors if `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` is enabled:

- `loc/unl_cpu()` : these must only be called in a µITRON task context, else E_CTX.
- `dis/ena_int()` : the interrupt number must be in range as specified by the platform HAL in qustion, else E_PAR.

Memory pool Management Functions

These functions are fully supported in this release:

```
ER get_blf(
    VP *p_blf,    ID mpfid )
```

```
ER pget_blf(
    VP *p_blf,    ID mpfid )
```

```
ER tget_blf(
    VP *p_blf,    ID mpfid,    TMO tmout )
```

```
ER rel_blf(
    ID mpfid,    VP blf )
```

```
ER ref_mpf(
    T_RMPF *pk_rmpf,    ID mpfid )
```

```
ER get_blk(
    VP *p_blk,    ID mplid,    INT blksz )
```

```
ER pget_blk(
    VP *p_blk,    ID mplid,    INT blksz )
```

```
ER tget_blk(
    VP *p_blk,    ID mplid,    INT blksz,    TMO tmout )
```

```
ER rel_blk(
    ID mplid,    VP blk )
```

```
ER ref_mpl(
    T_RMPL *pk_rmpl,    ID mplid )
```

Note that of the memory provided for a particular pool to manage in the static initialization of the memory pool objects, some memory will be used to manage the pool itself. Therefore the number of blocks * the blocksize will be less than the total memory size.

The following functions are supported in this release, when enabled with `CYGPKG_UITRON_MEMPOOLVAR_CREATE_DELETE` or `CYGPKG_UITRON_MEMPOOLFIXED_CREATE_DELETE` as appropriate, with some restrictions:

```
ER cre_mpl(
    ID mplid,    T_CMPL *pk_cmpl )
```

```
ER del_mpl(
    ID mplid )
```

```
ER cre_mpf(
    ID mpfid,    T_CMPF *pk_cmpf )
```

```
ER del_mpf(
    ID mpfid )
```

Because of the static initialization facilities provided for system objects, a memory pool is allocated a region of memory to manage statically in the configuration. So while memory pools can be created and deleted, the same area of memory is used for that memory pool (memory pool ID number) each time. The requested variable pool size (pk_cmpl->mplsz) or the number of fixed-size blocks (pk_cmpf->mpfcnt) times the block size (pk_cmpf->blfsz) are checked for fitting within the statically allocated memory area, so if a create call succeeds, the resulting pool will be at least as large as that requested. For this reason `del_mpl()` and `del_mpf()` do not in any sense free the memory that was managed by the deleted pool for use by other pools; it may only be managed by a pool of the same object id.

For both fixed and variable memory pools, the queueing order when waiting on a synchronization object depends on the underlying kernel configuration. The multi-level queue scheduler is required for strict µITRON conformance and it queues tasks in FIFO order, so requests to create an object with priority queueing of tasks (pk_cxxx->xxxatr = TA_TPRI) are rejected with E_RSATR. Additional undefined bits in the attributes fields must be zero.

In general, extended information (pk_cxxx->exinf) is ignored.

Error checking

The following conditions are only checked for, and only return errors if `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` is enabled:

- invalid object id; less than 1 or greater than `CYGNUM_UITRON_MEMPOOLVAR/MEMPOOLFIXED` as appropriate returns E_ID
- dispatching is enabled in any call which can sleep, or E_CTX
- tmout must be positive, otherwise E_PAR
- pk_cxxx pointers in `cre_xxx()` must be valid pointers, or E_PAR
- return value pointer in `ref_xxx()` is a valid pointer, or E_PAR
- return value pointers in get block routines is a valid pointer, or E_PAR
- blocksize request in get variable block routines is greater than zero, or E_PAR

The following conditions are checked for, and can return error codes, regardless of the setting of `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS`:

- When create and delete functions `cre_xxx()` and `del_xxx()` are supported, all calls which use a valid object ID number check that the object exists. If not, E_NOEXS is returned.
- When create functions `cre_xxx()` are supported, if the object already exists, then E_OBJ
- In any call which can sleep, such as `get_blk()` : return codes E_TMOUT, E_RLWAI, E_DLT or of course E_OK are returned depending on the reason for terminating the sleep
- In polling functions such as `pget_blk()` return codes E_TMOUT or E_OK are returned depending on the state of the synchronization object
- In creation functions, the attributes must be compatible with the selected underlying kernel configuration: in `cre_mpl()` `pk_cmpl->mplatr` must be equal to `TA_TFIFO` else E_RSATR.
- In `cre_mpf()` `pk_cmpf->mpfatr` must be equal to `TA_TFIFO` else E_RSATR.
- In creation functions, the requested size of the memory pool must not be larger than that statically configured for the pool else E_RSATR; see the configuration option “Option: Static initializers”. In `cre_mpl()` `pk_cmpl->mplsz` is the field of interest
- In `cre_mpf()` the product of `pk_cmpf->blfsz` and `pk_cmpf->mpfcnt` must be smaller than the memory statically configured for the pool else E_RSATR
- In functions which return memory to the pool `rel_blk()` and `rel_blf()` , if the free fails, for example because the memory did not come from that pool originally, then E_PAR is returned

Time Management Functions

These functions are fully supported in this release:

```
ER set_tim(
    SYSTIME *pk_tim )
```

Caution

Setting the time may cause erroneous operation of the kernel, for example a task performing a wait with a time-out may never awaken.

```
ER get_tim(
    SYSTIME *pk_tim )
```

```
ER dly_tsk(
    DLYTIME dlytim )
```

```
ER def_cyc(
    HNO cycno,    T_DCYC *pk_dcyc )
```

```
ER act_cyc(
    HNO cycno,    UINT cycact )
```

```
ER ref_cyc(
    T_RCYC *pk_rcyc,    HNO cycno )
```

```
ER def_alm(
    HNO almno,    T_DALM *pk_dalm )
```

```
ER ref_alm(
    T_RALM *pk_ralm,    HNO almno )
```

```
void ret_tmr( void )
```

Error checking

The following conditions are only checked for, and only return errors if `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` is enabled:

- invalid handler number; less than 1 or greater than `CYGNUM_UITRON_CYCLICS/ALARMS` as appropriate, or E_PAR
- dispatching is enabled in `dly_tsk()` , or E_CTX
- dlytim must be positive or zero, otherwise E_PAR
- return value pointer in `ref_xxx()` is a valid pointer, or E_PAR
- params within pk_dalm and pk_dcyc must be valid, or E_PAR
- cycact in `act_cyc()` must be valid, or E_PAR
- handler must be defined in `ref_xxx()` and `act_cyc()` , or E_NOEXS
- parameter pointer must be a good pointer in `get_tim()` and `set_tim()` , otherwise E_PAR is returned

The following conditions are checked for, and can return error codes, regardless of the setting of `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` :

- `dly_tsk()` : return code E_RLWAI is returned depending on the reason for terminating the sleep

System Management Functions

These functions are fully supported in this release:

```
ER get_ver(
    T_VER *pk_ver )
```

```
ER ref_sys(
    T_RSYS *pk_rsys )
```

```
ER ref_cfg(
    T_RCFG *pk_rcfg )
```

Note that the information returned by each of these calls may be configured to match the user's own versioning system, and the values supplied by the default configuration may be inappropriate.

These functions are not supported in this release:

```
ER def_svc(
    FN s_fncd,
    T_DSVC *pk_dsvc )
```

```
ER def_exc(
    UINT exckind,
    T_DEXC *pk_dexc )
```

Error checking

The following conditions are only checked for, and only return errors if `CYGSEM_UITRON_BAD_PARAMS_RETURN_ERRORS` is enabled:

- return value pointer in all calls is a valid pointer, or E_PAR

Network Support Functions

None of these functions are supported in this release.

µITRON Configuration FAQ

Q: How are µITRON objects created?

For each type of uITRON object (tasks, semaphores, flags, mboxes, mpf, mpl) these two quantities are controlled by configuration:

- The *maximum* number of this type of object.
- The number of these objects which exist *initially*.

This is assuming that for the relevant object type, *create* and *delete* operations are enabled; enabled is the default. For example, the option `CYGPKG_UITRON_MBOXES_CREATE_DELETE` controls whether the functions `cre_mbx()` and `del_mbx()` exist in the API. If not, then the maximum number of mboxes is the same as the initial number of mboxes, and so on for all µITRON object types.

Mboxes have no initialization, so there are only a few, simple configuration options:

- `CYGNUM_UITRON_MBOXES` is the total number of mboxes that you can have in the system. By default this is 4, so you can use mboxes 1,2,3 and 4. You cannot create mboxes outside this range; trying to `cre_mbx(5,...)` will return an error.
- `CYGNUM_UITRON_MBOXES_INITIALLY` is the number of mboxes created automatically for you, during startup. By default this is 4, so all 4 mboxes exist already, and an attempt to create one of these eg. `cre_mbx(3,...)` will return an error because the mbox in quesion already exists. You can delete a pre-existing mbox, and then re-create it.

If you change `CYGNUM_UITRON_MBOXES_INITIALLY`, for example to 0, no mboxes are created automatically for you during startup. Any attempt to use an mbox without creating it will return E_NOEXS because the mbox does not exist. You can create an mbox, say `cre_mbx(3,...)` and then use it, say `snd_msg(3,&foo)`, and all will be well.

Q: How are µITRON objects initialized?

Some object types have optional initialization. Semaphores are an example. You could have `CYGNUM_UITRON_SEMAS`=10 and `CYGNUM_UITRON_SEMAS_INITIALLY`=5 which means you can use semaphores 1-5 straight off, but you must create semaphores 6-10 before you can use them. If you decide not to initialize semaphores, semaphores 1-5 will have an initial count of zero. If you decide to initialize them, you must supply a dummy initializer for semaphores 6-10 also. For example, in terms of the configuration output in `pkgconf/uitron.h`:

```
   #define CYGDAT_UITRON_SEMA_INITIALIZERS \
        CYG_UIT_SEMA(  1 ),     \
        CYG_UIT_SEMA(  0 ),     \
        CYG_UIT_SEMA(  0 ),     \
        CYG_UIT_SEMA( 99 ),     \
        CYG_UIT_SEMA(  1 ),     \
        CYG_UIT_SEMA_NOEXS,     \
        CYG_UIT_SEMA_NOEXS,     \
        CYG_UIT_SEMA_NOEXS,     \
        CYG_UIT_SEMA_NOEXS,     \
        CYG_UIT_SEMA_NOEXS
```

Semaphore 1 will have initial count 1, semaphores 2 and 3 will be zero, number 4 will be 99 initially, 5 will be one and numbers 6 though 10 do not exist initially.

Aside: this is how the definition of the symbol would appear in the configuration header file `pkgconf/uitron.h` — unfortunately editing such a long, multi-line definition is somewhat cumbersome in the GUI config tool in current releases. The macros `CYG_UIT_SEMA()` — to create a semaphore initializer — and `CYG_UIT_SEMA_NOEXS` — to invoke a dummy initializer — are provided in in the environment to help with this. Similar macros are provided for other object types. The resulting #define symbol is used in the context of a C++ array initializer, such as:

```
Cyg_Counting_Semaphore2 cyg_uitron_SEMAS[ CYGNUM_UITRON_SEMAS ] = {
  CYGDAT_UITRON_SEMA_INITIALIZERS
};
```

which is eventually macro-processed to give

```
Cyg_Counting_Semaphore2 cyg_uitron_SEMAS[ 10 ] = {
  Cyg_Counting_Semaphore2( ( 1 ) ),
  Cyg_Counting_Semaphore2( ( 0 ) ),
  Cyg_Counting_Semaphore2( ( 0 ) ),
  Cyg_Counting_Semaphore2( ( 99 ) ),
  Cyg_Counting_Semaphore2( ( 1 ) ),
  Cyg_Counting_Semaphore2(0),
  Cyg_Counting_Semaphore2(0),
  Cyg_Counting_Semaphore2(0),
  Cyg_Counting_Semaphore2(0),
  Cyg_Counting_Semaphore2(0),
};
```

so you can see how it is necessary to include the dummy entries in that definition, otherwise the resulting code will not compile correctly.

If you choose `CYGNUM_UITRON_SEMAS_INITIALLY`=0 it is meaningless to initialize them, for they must be created and so initialized then, before use.

Q: What about µITRON tasks?

Some object types require initialization. Tasks are an example of this. You must provide a task with a priority, a function to enter when the task starts, a name (for debugging purposes), and some memory to use for the stack. For example (again in terms of the resulting definitions in `pkgconf/uitron.h`):

```
#define CYGNUM_UITRON_TASKS 4           // valid task ids are 1,2,3,4
#define CYGNUM_UITRON_TASKS_INITIALLY 4 // they all exist at start

#define CYGDAT_UITRON_TASK_EXTERNS            \
extern "C" void startup( unsigned int );      \
extern "C" void worktask( unsigned int );     \
extern "C" void lowtask( unsigned int );        \
static char stack1[ CYGNUM_UITRON_STACK_SIZE ], \
            stack2[ CYGNUM_UITRON_STACK_SIZE ], \
            stack3[ CYGNUM_UITRON_STACK_SIZE ], \
            stack4[ CYGNUM_UITRON_STACK_SIZE ];

#define CYGDAT_UITRON_TASK_INITIALIZERS \
 CYG_UIT_TASK("main task", 8, startup,  &stack1, sizeof( stack1 )), \
 CYG_UIT_TASK("worker 2" , 9, worktask, &stack2, sizeof( stack2 )), \
 CYG_UIT_TASK("worker 3" , 9, worktask, &stack3, sizeof( stack3 )), \
 CYG_UIT_TASK("low task" ,20, lowtask,  &stack4, sizeof( stack4 )), \
```

So this example has all four tasks statically configured to exist, ready to run, from the start of time. The “main task” runs a routine called `startup()` at priority 8. Two “worker” tasks run both a priority 9, and a “low priority” task runs at priority 20 to do useful non-urgent background work.

```
Task ID | Exists at | Function | Priority | Stack   | Stack
 number |  startup  |  entry   |          | address | size
--------+-----------+----------+----------+---------+----------
   1    |    Yes    |  startup |    8     | &stack1 | CYGNUM…
   2    |    Yes    | worktask |    9     | &stack2 | CYGNUM…
   3    |    Yes    | worktask |    9     | &stack3 | CYGNUM…
   4    |    Yes    |  lowtask |   20     | &stack4 | CYGNUM…
--------+-----------+----------+----------+---------+----------
```

Q: How can I create µITRON tasks in the program?

You must provide free slots in the task table in which to create new tasks, by configuring the number of tasks existing initially to be smaller than the total. For a task ID which does not initially exist, it will be told what routine to call, and what priority it is, when the task is created. But you must still set aside memory for the task to use for its stack, and give it a name during initialization. For example:

```
#define CYGNUM_UITRON_TASKS 4           // valid task ids are 1-4
#define CYGNUM_UITRON_TASKS_INITIALLY 1 // only task #1 exists

#define CYGDAT_UITRON_TASK_EXTERNS \
extern "C" void startup( unsigned int ); \
static char stack1[ CYGNUM_UITRON_STACK_SIZE ], \
            stack2[ CYGNUM_UITRON_STACK_SIZE ], \
            stack3[ CYGNUM_UITRON_STACK_SIZE ], \
            stack4[ CYGNUM_UITRON_STACK_SIZE ];

#define CYGDAT_UITRON_TASK_INITIALIZERS \
   CYG_UIT_TASK( "main", 8, startup, &stack1, sizeof( stack1 ) ), \
   CYG_UIT_TASK_NOEXS( "slave",      &stack2, sizeof( stack2 ) ), \
   CYG_UIT_TASK_NOEXS( "slave2",     &stack3, sizeof( stack3 ) ), \
   CYG_UIT_TASK_NOEXS( "slave3",     &stack4, sizeof( stack4 ) ), \
```

So tasks numbered 2,3 and 4 have been given their stacks during startup, though they do not yet exist in terms of `cre_tsk()` and `del_tsk()` so you can create tasks 2–4 at runtime.

```
Task ID | Exists at | Function | Priority | Stack   | Stack
 number |  startup  |  entry   |          | address | size
--------+-----------+----------+----------+---------+----------
   1    |    Yes    |  startup |    8     | &stack1 | CYGNUM…
   2    |    No     |   N/A    |   N/A    | &stack2 | CYGNUM…
   3    |    No     |   N/A    |   N/A    | &stack3 | CYGNUM…
   4    |    No     |   N/A    |   N/A    | &stack4 | CYGNUM…
--------+-----------+----------+----------+---------+----------
```

(you must have at least one task at startup in order that the system can actually run; this is not so for other uITRON object types)

Q: Can I have different stack sizes for µITRON tasks?

Simply set aside different amounts of memory for each task to use for its stack. Going back to a typical default setting for the µITRON tasks, the definitions in `pkgconf/uitron.h` might look like this:

```
#define CYGDAT_UITRON_TASK_EXTERNS \
extern "C" void task1( unsigned int ); \
extern "C" void task2( unsigned int ); \
extern "C" void task3( unsigned int ); \
extern "C" void task4( unsigned int ); \
static char stack1[ CYGNUM_UITRON_STACK_SIZE ], \
            stack2[ CYGNUM_UITRON_STACK_SIZE ], \
            stack3[ CYGNUM_UITRON_STACK_SIZE ], \
            stack4[ CYGNUM_UITRON_STACK_SIZE ];

#define CYGDAT_UITRON_TASK_INITIALIZERS \
  CYG_UIT_TASK( "t1", 1, task1, &stack1, CYGNUM_UITRON_STACK_SIZE ), \
  CYG_UIT_TASK( "t2", 2, task2, &stack2, CYGNUM_UITRON_STACK_SIZE ), \
  CYG_UIT_TASK( "t3", 3, task3, &stack3, CYGNUM_UITRON_STACK_SIZE ), \
  CYG_UIT_TASK( "t4", 4, task4, &stack4, CYGNUM_UITRON_STACK_SIZE )
```

Note that `CYGNUM_UITRON_STACK_SIZE` is used to control the size of the stack objects themselves, and to tell the system what size stack is being provided.

Suppose instead stack sizes of 2000, 1000, 800 and 800 were required: this could be achieved by using the GUI config tool to edit these options, or editting the `.ecc` file to get these results in `pkgconf/uitron.h`:

```
#define CYGDAT_UITRON_TASK_EXTERNS \
extern "C" void task1( unsigned int ); \
extern "C" void task2( unsigned int ); \
extern "C" void task3( unsigned int ); \
extern "C" void task4( unsigned int ); \
static char stack1[ 2000 ], \
            stack2[ 1000 ], \
            stack3[  800 ], \
            stack4[  800 ];

#define CYGDAT_UITRON_TASK_INITIALIZERS \
      CYG_UIT_TASK( "t1", 1, task1, &stack1, sizeof( stack1 ) ), \
      CYG_UIT_TASK( "t2", 2, task2, &stack2, sizeof( stack2 ) ), \
      CYG_UIT_TASK( "t3", 3, task3, &stack3, sizeof( stack3 ) ), \
      CYG_UIT_TASK( "t4", 4, task4, &stack4, sizeof( stack4 ) )
```

Note that the sizeof() operator has been used to tell the system what size stacks are provided, rather than quoting a number (which is difficult for maintenance) or the symbol `CYGNUM_UITRON_STACK_SIZE` (which is wrong).

We recommend using (if available in your release) the stacksize symbols provided in the architectural HAL for your target, called `CYGNUM_HAL_STACK_SIZE_TYPICAL` and `CYGNUM_HAL_STACK_SIZE_MINIMUM`. So a better (more portable) version of the above might be:

```
#define CYGDAT_UITRON_TASK_EXTERNS \
extern "C" void task1( unsigned int ); \
extern "C" void task2( unsigned int ); \
extern "C" void task3( unsigned int ); \
extern "C" void task4( unsigned int ); \
static char stack1[ CYGNUM_HAL_STACK_SIZE_TYPICAL + 1200 ], \
            stack2[ CYGNUM_HAL_STACK_SIZE_TYPICAL +  200 ], \
            stack3[ CYGNUM_HAL_STACK_SIZE_TYPICAL        ], \
            stack4[ CYGNUM_HAL_STACK_SIZE_TYPICAL        ];

#define CYGDAT_UITRON_TASK_INITIALIZERS \
      CYG_UIT_TASK( "t1", 1, task1, &stack1, sizeof( stack1 ) ), \
      CYG_UIT_TASK( "t2", 2, task2, &stack2, sizeof( stack2 ) ), \
      CYG_UIT_TASK( "t3", 3, task3, &stack3, sizeof( stack3 ) ), \
      CYG_UIT_TASK( "t4", 4, task4, &stack4, sizeof( stack4 ) )
```

Part XLI. TCP/IP Stack Support for eCos

The Common Networking for eCos package provides support for a complete TCP/IP networking stack. The design allows for the actual stack to be modular allowing for different implementations to be provided. Currently only one version based on FreeBSD is available, with the earlier OpenBSD implementation (circa 2000) deprecated and withdrawn from current eCosPro releases.

For resource-constrained systems, the lightweight networking stack lwip (see Part XLIV, “lwIP - the lightweight IP stack for eCosPro”) has been ported to eCos and supports the IP, TCP, UDP, ICMP, IGMP, ARP, DHCP, AutoIP, DNS, SNMP, SLIP and PPP protocols. lwip was designed from the outset to have a low memory footprint and gains many of its lightweight properties from being highly configurable, making it an excellent eCos add-on package.

Table of Contents

Chapter 144. Ethernet Driver Design

Currently, the networking stack only supports ethernet based networking.

The network drivers use a two-layer design. One layer is hardware independent and contains all the stack specific code. The other layer is platform dependent and communicates with the hardware independent layer via a very simple API. In this way, hardware device drivers can actually be used with other stacks, if the same API can be provided by that stack. We designed the drivers this way to encourage the development of other stacks in eCos while allowing re-use of the actual hardware specific code.

More comprehensive documentation of the ethernet device driver and the associated API can be found in the eCos generic ethernet device driver documentation. The driver and API is the same as the minimal debug stack used by the RedBoot application. See the RedBoot documentation for further information.

Chapter 145. Sample Code

Many examples using the networking support are provided. These are arranged as eCos test programs, primarily for use in verifying the package, but they can also serve as useful frameworks for program design. We have taken a KISS approach to building programs which use the network. A single include file <`network.h`> is all that is required to access the stack. A complete, annotated test program can be found at `net/common/`*`VERSION`*`/tests/ftp_test.c`, with its associated files.

Chapter 146. Configuring IP Addresses

Each interface (“eth0” and “eth1”) has independent configuration of its setup. Each can be set up manually (in which case you must write code to do this), or by using BOOTP/DHCP, or explicitly, with configured values. If additional interfaces are added, these must be configured manually.

The configurable values are:

- IP address
- netmask
- broadcast address
- gateway/router
- server address.

Server address is the DHCP server if applicable, but in addition, many test cases use it as “the machine to talk to” in whatever manner the test exercises the protocol stack.

The initialization is invoked by calling the C routine:

```
void init_all_network_interfaces(void);
```

Additionally, if the system is configured to support IPv6 then each interface may have an address assigned which is a composite of a 64 bit prefix and the 32 bit IPv4 address for that interface. The prefix is controlled by the CDL setting CYGHWR_NET_DRIVER_ETH0_IPV6_PREFIX for “eth0”, etc. This is a CDL booldata type, allowing this address to be suppressed if not desired.

Alternatively, the system can configure its IPv6 address using router solicitation. When the CDL option CYGOPT_NET_IPV6_ROUTING_THREAD is enabled, `init_all_network_interface` will start a thread which sends out router solicit messages, process router advertisements and thus configure an IPv6 address to the interface.

Refer to the test cases, …`/packages/net/common/`*`VERSION`*`/tests/ftp_test.c` for example usage, and the source files in …`/packages/net/common/`*`VERSION`*`/src/bootp_support.c` and `network_support.c` to see what that call does.

This assumes that the MAC address (also known as ESA or Ethernet Station Address) is already defined in the serial EEPROM or however the particular target implements this; support for setting the MAC address is hardware dependent.

DHCP support is active by default, and there are configuration options to control it. Firstly, in the top level of the “Networking” configuration tree, “Use full DHCP instead of BOOTP” enables DHCP, and it contains an option to have the system provide a thread to renew DHCP leases and manage lease expiry. Secondly, the individual interfaces “eth0” and “eth1” each have new options within the “Use BOOTP/DHCP to initialize ’*ethX*,” to select whether to use DHCP rather than BOOTP.

You should not configure the network stack to use BOOTP/DHCP if you are using RedBoot, have configured it also to use BOOTP/DHCP, and are connected via GDB to it over the network. Otherwise the TCP/IP stacks in both RedBoot and the eCos application are likely to be given the same IP address, which will cause problems.

Note that you are completely at liberty to ignore this startup code and its configuration in building your application. `init_all_network_interfaces()` is provided for three main purposes:

- For use by eCos's own test programs.
- As an easy “get you going” utility for newcomers to eCos.

- As readable example code from which further development might start.

If your application has different requirements for bringing up available network interfaces, setting up routes, determining IP addresses and the like from the defaults that the example code provides, you can write your own initialization code to use whatever sequence of `ioctl()` function calls carries out the desired setup. Analogously, in larger systems, a sequence of “ifconfig” invocations is used; these mostly map to `ioctl()` calls to manipulate the state of the interface in question.

By default the supplied `init_all_network_interfaces()` code can configure up to two ethernet interfaces. An alternative implementation is available that can configure more interfaces. This code is used by enabling the `CYGPKG_NET_DRIVER_INIT_NEW` option; this is enabled by default if more than two interfaces are configured but may also be enabled by the user. At preseent support is limited to four interfaces, but can be extended with minimal changes to the CDL and code to any number of interfaces. The alternative code is functionally equivalent to the default, but uses more memory and is therefore not used by default.

Chapter 147. Tests and Demonstrations

Loopback tests

By default, only tests which can execute on any target will be built. These therefore do not actually use external network interfaces (though they may configure and initialize them) but are limited to testing via the loopback interface.

```
ping_lo_test     - ping test of the loopback address
tcp_lo_select    - simple test of select with TCP via loopback
tcp_lo_test      - trivial TCP test via loopback
udp_lo_test      - trivial UDP test via loopback
multi_lo_select  - test of multiple select() calls simultaneously
```

Building the Network Tests

To build further network tests, ensure that the configuration option CYGPKG_NET_BUILD_TESTS is set in your build and then make the tests in the usual way. Alternatively (with that option set) use the following command after building the eCos library, if you wish to build *only* the network tests:

```
make -C net/common/VERSION/ tests
```

This should give test executables in `install/tests/net/common/VERSION/tests` including the following:

```
socket_test      - trivial test of socket creation API
mbuf_test        - trivial test of mbuf allocation API
ftp_test         - simple FTP test, connects to “server”
ping_test        - pings “server” and non-existent host to test timeout
dhcp_test        - ping test, but also relinquishes and
                   reacquires DHCP leases periodically
flood            - a flood ping test; use with care
tcp_echo         - data forwarding program for performance test
nc_test_master   - network characterization master
nc_test_slave    - network characterization slave
server_test      - a very simple server example
tftp_client_test - performs a tftp get and put from/to “server”
tftp_server_test - runs a tftp server for a short while
set_mac_address  - set MAC address(es) of interfaces in NVRAM
bridge           - contributed network bridge code
nc6_test_master  - IPv4/IPv6 network characterization master
nc6_test_slave   - IPv4/IPv6 network characterization slave
ga_server_test   - a very simple IPv4/IPv6 server example
```

Standalone Tests

```
socket_test      - trivial test of socket creation API
mbuf_test        - trivial test of mbuf allocation API
```

These two do not communicate over the net; they just perform simple API tests then exit.

```
ftp_test         - simple FTP test, connects to “server”
```

This test initializes the interface(s) then connects to the FTP server on the “server” machine for for each active interface in turn, confirms that the connection was successful, disconnects and exits. This tests interworking with the server.

```
ping_test        - pings “server” and non-existent host to test timeout
```

This test initializes the interface(s) then pings the server machine in the standard way, then pings address “32 up” from the server in the expectation that there is no machine there. This confirms that the successful ping is not a false positive, and tests the receive timeout. If there is such a machine, of course the 2nd set of pings succeeds, confirming that we can talk to a machine not previously mentioned by configuration or by bootp. It then does the same thing on the other interface, eth1.

If IPv6 is enabled, the program will also ping to the address it last received a router advertisement from. Also a ping will be made to that address plus 32, in a similar way the the IPv4 case.

```
dhcp_test        - ping test, but also manipulates DHCP leases
```

This test is very similar to the ping test, but in addition, provided the network package is not configured to do this automatically, it manually relinquishes and reclaims DHCP leases for all available interfaces. This tests the external API to DHCP. See section below describing this.

```
flood            - a flood ping test; use with care
```

This test performs pings on all interfaces as quickly as possible, and only prints status information periodically. Flood pinging is bad for network performance; so do not use this test on general purpose networks unless protected by a switch.

Performance Test

```
tcp_echo         - data forwarding program for performance test
```

tcp_echo is one part of the standard performance test we use. The other parts are host programs `tcp_source` and `tcp_sink`. To make these (under your *HOST* system) cd to the tests source directory in the eCos repository and type “`make -f make.host`” - this should build `tcp_source` and `tcp_sink`.

The host program “`tcp_source`” sends data to the target. On the target, “`tcp_echo`” sends it onwards to “`tcp_sink`” running on your host. So the target must receive and send on all the data that `tcp_source` sends it; the time taken for this is measured and the data rate is calculated.

To invoke the test, first start `tcp_echo` on the target board and wait for it to become quiescent - it will report work to calibrate a CPU load which can be used to simulate real operating conditions for the stack.

Then on your host machine, in one terminal window, invoke `tcp_sink` giving it the IP address (or hostname) of one interface of the target board. For example “`tcp_sink 10.130.39.66`”. `tcp_echo` on the target will print something like “`SINK connection from 10.130.39.13:1143`” when `tcp_sink` is correctly invoked.

Next, in another host terminal window, invoke `tcp_source`, giving it the IP address (or hostname) of an interface of the target board, and optionally a background load to apply to the target while the test runs. For example, “`tcp_source 194.130.39.66`” to run the test with no additional target CPU load, or “`tcp_source 194.130.39.66 85`” to load it up to 85% used. The target load must be a multiple of 5. `tcp_echo` on the target will print something like “`SOURCE connection from 194.130.39.13:1144`” when tcp_source is correctly invoked.

You can connect tcp_sink to one target interface and tcp_source to another, or both to the same interface. Similarly, you can run `tcp_sink` and `tcp_source` on the same host machine or different ones. TCP/IP and ARP look after them finding one another, as intended.

```
nc_test_master   - network characterization master
nc_test_slave    - network characterization slave
```

These tests talk to each other to measure network performance. They can each run on either a test target or a host computer given some customization to your local environment. As provided, `nc_test_slave` must run on the test target, and `nc_test_master` must be run on a host computer, and be given the test target's IP address or hostname.

The tests print network performance for various packet sizes over UDP and TCP, versus various additional CPU loads on the target.

The programs below are additional forms which support both IPv4 and IPv6 addressing:

```
        nc6_test_slave
        nc6_test_master
```

Interactive Tests

```
server_test - a very simple server example
```

This test simply awaits a connection on port 7734 and after accepting a connection, gets a packet (with a timeout of a few seconds) and prints it.

The connection is then closed. We then loop to await the next connection, and so on. To use it, telnet to the target on port 7734 then type something (quickly!)

```
% telnet 172.16.19.171 7734
Hello target board
```

and the test program will print something like:

```
connection from 172.16.19.13:3369
buf = "Hello target board"
```

```
ga_server_test - another very simple server example
```

This is a variation on the *ga_server_test* test with the difference being that it uses the `getaddrinfo` function to set up its addresses. On a system with IPv6 enabled, it will listen on port 7734 for a TCP connection via either IPv4 or IPv6.

```
tftp_client_test - performs a tftp get and put from/to “server”
```

This is only partially interactive. You need to set things up on the “server” in order for this to work, and you will need to look at the server afterwards to confirm that all was well.

For each interface in turn, this test attempts to read by tftp from the server, a file called `tftp_get` and prints the status and contents it read (if any). It then writes the same data to a file called `tftp_put` on the same server.

In order for this to succeed, both files must already exist. The TFTP protocol does not require that a WRQ request _create_ a file, just that it can write it. The TFTP server on Linux certainly will only allow writes to an existing file, given the appropriate permission. Thus, you need to have these files in place, with proper permission, before running the test.

The conventional place for the tftp server to operate in LINUX is /tftpboot/; you will likely need root privileges to create files there. The data contents of `tftp_get` can be anything you like, but anything very large will waste lots of time printing it on the test,s stdout, and anything above 32kB will cause a buffer overflow and unpredictable failure.

Creating an empty tftp_put file (eg. by copying /dev/null to it) is neatest. So before the test you should have something like:

```
-rw-rw-rw- 1 root        1076 May  1 11:39 tftp_get
-rw-rw-rw- 1 root           0 May  1 15:52 tftp_put
```

note that both files have public permissions wide open. After running the test, `tftp_put` should be a copy of `tftp_get`.

```
-rw-rw-rw-  1 root       1076 May  1 11:39 tftp_get
-rw-rw-rw-  1 root       1076 May  1 15:52 tftp_put
```

If the configuration contains IPv6 support, the test program will also use IPv6. It will attempt to put/get the files listed above from the address it last received a routers solicit from.

```
tftp_server_test - runs a tftp server for a short while
```

This test is truly interactive, in that you can use a standard tftp application to get and put files from the server, during the 5 minutes that it runs. The dummy filesystem which underlies the server initially contains one file, called “uu” which contains part of a familiar text and some padding. It also accommodates creation of 3 further files of up to 1Mb in size and names of up to 256 bytes. Exceeding these limits will cause a buffer overflow and unpredictable failure.

The dummy filesystem is an implementation of the generic API which allows a true filesystem to be attached to the tftp server in the network stack.

We have been testing the tftp server by running the test on the target board, then using two different host computers connecting to the different target interfaces, putting a file from each, getting the “uu” file, and getting the file from the other computer. This verifies that data is preserved during the transfer as well as interworking with standard tftp applications.

Maintenance Tools

```
set_mac_address - set MAC address(es) of interfaces in NVRAM
```

This program makes an example `ioctl()` call SIOCSIFHWADDR “Socket IO Set InterFace HardWare ADDRess” to set the MAC address on targets where this is supported and enabled in the configuration. You must edit the source to choose a MAC address and further edit it to allow this very dangerous operation. Not all ethernet drivers support this operation, because most ethernet hardware does not support it — or it comes pre-set from the factory. *Do not use this program.*

Chapter 148. Support Features

TFTP

The TFTP client and server are described in `tftp_support.h`;

The TFTP client has and new and an older, deprecated, API. The new API works for both IPv4 and IPv6 where as the deprecated API is IPv4 only.

The new API is as follows:

```
int tftp_client_get(const char * const  filename,
                    const char * const  server,
                    const int           port,
                    char                *buf,
                    int                 len,
                    const int           mode,
                    int * const         err);

int tftp_client_put(const char * const  filename,
                    const char * const  server,
                    const int           port,
                    const char          *buf,
                    int                 len,
                    const int           mode,
                    int *const          err);
```

Currently `server` can only be a numeric IPv4 or IPv6 address. The resolver is currently not used, but it is planned to add this feature (patches welcome). If `port` is zero the client connects to the default TFTP port on the server. Otherwise the specified port is used.

The deprecated API is:

```
int tftp_get(const char * const               filename,
             const struct sockaddr_in * const server,
             char                             *buf,
             int                              len,
             const int                        mode,
             int * const                      error);

int tftp_put(const char * const               filename,
             const struct sockaddr_in * const server,
             const char                       *buffer,
             int                              len,
             const int                        mode,
             int * const                      err);
```

The `server` should contain the address of the server to contact. If the `sin_port` member of the structure is zero the default TFTP port is used. Otherwise the specified port is used.

Both API's report errors in the same way. The functions return a value of -1 and `*err` will be set to one of the following values:

```
#define TFTP_ENOTFOUND   1   /* file not found                    */
#define TFTP_EACCESS     2   /* access violation                  */
#define TFTP_ENOSPACE    3   /* disk full or allocation exceeded  */
#define TFTP_EBADOP      4   /* illegal TFTP operation            */
#define TFTP_EBADID      5   /* unknown transfer ID               */
#define TFTP_EEXISTS     6   /* file already exists               */
#define TFTP_ENOUSER     7   /* no such user                      */
#define TFTP_TIMEOUT     8   /* operation timed out               */
#define TFTP_NETERR      9   /* some sort of network error        */
#define TFTP_INVALID    10   /* invalid parameter                 */
```

```
#define TFTP_PROTOCOL   11   /* protocol violation                */
#define TFTP_TOOLARGE   12   /* file is larger than buffer        */
```

If there are no errors the return value is the number of bytes transfered.

The server is more complex. It requires a filesystem implementation to be supplied by the user, and attached to the tftp server by means of a vector of function pointers:

```
struct tftpd_fileops {
             int (*open)(const char *, int);
             int (*close)(int);
             int (*write)(int, const void *, int);
             int (*read)(int, void *, int);
};
```

These functions have the obvious semantics. The structure describing the filesystem is an argument to the `tftpd_start`:

```
int tftp_start(int port,
               struct tftpd_fileops *ops);
```

The first argument is the port to use for the server. If this port number is zero, the default TFTP port number will be used. The return value from `tftpd_start` is a handle which can be passed to `tftpd_stop`. This will kill the tftpd thread. Note that this is not a clean shutdown. The thread will simply be killed. `tftpd_stop` will attempt to close the sockets the thread was listening on and free some of its allocated memory. But if the thread was actively transferreing data at the time `tftpd_stop` is called, it is quite likely some memory and a socket will be leaked. Use this function with caution (or implement a clean shutdown and please contribute the code back :-).

There are two CDL configuration options that control how many servers on how many different ports tftp can be started. CYGSEM_NET_TFTPD_MULTITHREADED, when enabled, allows multiple tftpd threads to operate on the same port number. With only one thread, while the thread is active transferring data, new requests for transfers will not be served until the active transfer is complete. When multiple threads are started on the same port, multiple transfers can take place simultaneous, up to the number of threads started. However a semaphore is required to synchronise the threads. This semaphore is required per port. The CDL option CYGNUM_NET_TFTPD_MULTITHREADED_PORTS controls how many different port numbers multithreaded servers can service.

If CYGSEM_NET_TFTPD_MULTITHREADED is not enabled, only one thread may be run per port number. But this removes the need for a semaphore and so CYGNUM_NET_TFTPD_MULTITHREADED_PORTS is not required and unlimited number of ports can be used.

It should be noted that the TFTPD does not perform any form of file locking. When multiple servers are active, it is assumed the underlying filesystem will refuse to open the same file multiple times, operate correctly with simultaneous read/writes to the same file, or if you are unlucky, corrupt itself beyond all repair.

When IPv6 is enabled the tftpd thread will listen for requests from both IPv4 and IPv6 addresses.

As discussed in the description of the tftp_server_test above, an example filesystem is provided in `net/common/`*`VERSION`*`/src/tftp_dummy_file.c` for use by the tftp server test. The dummy filesystem is not a supported part of the network stack, it exists purely for demonstration purposes.

DHCP

This API publishes a routine to maintain DHCP state, and a semaphore that is signalled when a lease requires attention: this is your clue to call the aforementioned routine.

The intent with this API is that a simple DHCP client thread, which maintains the state of the interfaces, can go as follows: (after `init_all_network_interfaces()` is called from elsewhere)

```
while ( 1 ) {
    while ( 1 ) {
        cyg_semaphore_wait( &dhcp_needs_attention );
        if ( ! dhcp_bind() ) // a lease expired
            break; // If we need to re-bind
    }
    dhcp_down(); // tear down unbound interfaces
    init_all_network_interfaces(); // re-initialize
}
```

and if the application does not want to suffer the overhead of a separate thread and its stack for this, this functionality can be placed in the app,s server loop in an obvious fashion. That is the goal of breaking out these internal elements. For example, some server might be arranged to poll DHCP from time to time like this:

```
while ( 1 ) {
    init_all_network_interfaces();
    open-my-listen-sockets();
    while ( 1 ) {
        serve-one-request();
        // sleeps if no connections, but not forever;
        // so this loop is polled a few times a minute...
        if ( cyg_semaphore_trywait( &dhcp_needs_attention )) {
            if ( ! dhcp_bind() ) {
               close-my-listen-sockets();
               dhcp_down();
               break;
            }
        }
    }
}
```

If the configuration option CYGOPT_NET_DHCP_DHCP_THREAD is defined, then eCos provides a thread as described initially. Independent of this option, initialization of the interfaces still occurs in `init_all_network_interfaces()` and your startup code can call that. It will start the DHCP management thread if configured. If a lease fails to be renewed, the management thread will shut down all interfaces and attempt to initialize all the interfaces again from scratch. This may cause chaos in the app, which is why managing the DHCP state in an application aware thread is actually better, just far less convenient for testing.

If the configuration option CYGOPT_NET_DHCP_OPTION_HOST_NAME is defined, then the TAG_HOST_NAME DHCP option will be included in any DHCP lease requests. The text for the hostname is set by calling `dhcp_set_hostname()`. Any DHCP lease requests made prior to calling `dhcp_set_hostname()` will not include the TAG_HOST_NAME DHCP option. The configuration option CYGNUM_NET_DHCP_OPTION_HOST_NAME_LEN controls the maximum length allowed for the hostname. This permits the hostname text to be determined at run-time. Setting the hostname to the empty string will have the effect of disabling the TAG_HOST_NAME DHCP option.

If the configuration option CYGOPT_NET_DHCP_OPTION_DHCP_CLIENTID_MAC is defined, then the TAG_DHCP_CLIENTID DHCP option will be included in any DHCP lease requests. The client ID used will be the current MAC address of the network interface.

The option CYGOPT_NET_DHCP_PARM_REQ_LIST_ADDITIONAL allows additional DHCP options to be added to the request sent to the DHCP server. This option should be set to a comma separated list of options.

The option CYGOPT_NET_DHCP_PARM_REQ_LIST_REPLACE is similar to CYGOPT_NET_DHCP_PARM_REQ_LIST_ADDITIONAL but in this case it completely replaces the default list of options with the configured set of comma separated options.

Chapter 149. TCP/IP Library Reference

getdomainname

```
GETDOMAINNAME(3)         BSD Library Functions Manual         GETDOMAINNAME(3)

NAME
     getdomainname, setdomainname -- get/set YP domain name of current host

SYNOPSIS
     #include <unistd.h>

     int
     getdomainname(char *name, size_t namelen);

     int
     setdomainname(const char *name, size_t namelen);

DESCRIPTION
     The getdomainname() function returns the YP domain name for the current
     processor, as previously set by setdomainname().  The parameter namelen
     specifies the size of the name array.  If insufficient space is provided,
     the returned name is truncated.  The returned name is always null termi-
     nated.

     setdomainname() sets the domain name of the host machine to be name,
     which has length namelen.  This call is restricted to the superuser and
     is normally used only when the system is bootstrapped.

RETURN VALUES
     If the call succeeds a value of 0 is returned.  If the call fails, a
     value of -1 is returned and an error code is placed in the global vari-
     able errno.

ERRORS
     The following errors may be returned by these calls:

     [EFAULT]           The name or namelen parameter gave an invalid address.

     [EPERM]            The caller tried to set the domain name and was not
                        the superuser.

SEE ALSO
     domainname(1), gethostid(3), gethostname(3), sysctl(3), sysctl(8), yp(8)

BUGS
     Domain names are limited to MAXHOSTNAMELEN (from <sys/param.h>) charac-
     ters, currently 256.  This includes the terminating NUL character.

     If the buffer passed to getdomainname() is too small, other operating
     systems may not guarantee termination with NUL.

HISTORY
     The getdomainname function call appeared in SunOS 3.x.

BSD                               May 6, 1994                              BSD
```

gethostname

```
GETHOSTNAME(3)           BSD Library Functions Manual           GETHOSTNAME(3)

NAME
     gethostname, sethostname -- get/set name of current host
```

```
SYNOPSIS
     #include <unistd.h>

     int
     gethostname(char *name, size_t namelen);

     int
     sethostname(const char *name, size_t namelen);

DESCRIPTION
     The gethostname() function returns the standard host name for the current
     processor, as previously set by sethostname().  The parameter namelen
     specifies the size of the name array.  If insufficient space is provided,
     the returned name is truncated.  The returned name is always null termi-
     nated.

     sethostname() sets the name of the host machine to be name, which has
     length namelen.  This call is restricted to the superuser and is normally
     used only when the system is bootstrapped.

RETURN VALUES
     If the call succeeds a value of 0 is returned.  If the call fails, a
     value of -1 is returned and an error code is placed in the global vari-
     able errno.

ERRORS
     The following errors may be returned by these calls:

     [EFAULT]           The name or namelen parameter gave an invalid address.

     [EPERM]            The caller tried to set the hostname and was not the
                        superuser.

SEE ALSO
     hostname(1), getdomainname(3), gethostid(3), sysctl(3), sysctl(8), yp(8)

STANDARDS
     The gethostname() function call conforms to X/Open Portability Guide
     Issue 4, Version 2 (``XPG4.2'').

HISTORY
     The gethostname() function call appeared in 4.2BSD.

BUGS
     Host names are limited to MAXHOSTNAMELEN (from <sys/param.h>) characters,
     currently 256.  This includes the terminating NUL character.

     If the buffer passed to gethostname() is smaller than MAXHOSTNAMELEN,
     other operating systems may not guarantee termination with NUL.

BSD                              June 4, 1993                              BSD
```

byteorder

```
BYTEORDER(3)             BSD Library Functions Manual             BYTEORDER(3)

NAME
     htonl, htons, ntohl, ntohs, htobe32, htobe16, betoh32, betoh16, htole32,
     htole16, letoh32, letoh16, swap32, swap16 -- convert values between dif-
     ferent byte orderings

SYNOPSIS
     #include <sys/types.h>
     #include <machine/endian.h>
     u_int32_t
     htonl(u_int32_t host32);

     u_int16_t
     htons(u_int16_t host16);

     u_int32_t
     ntohl(u_int32_t net32);

     u_int16_t
     ntohs(u_int16_t net16);

     u_int32_t
     htobe32(u_int32_t host32);

     u_int16_t
     htobe16(u_int16_t host16);

     u_int32_t
     betoh32(u_int32_t big32);

     u_int16_t
     betoh16(u_int16_t big16);

     u_int32_t
     htole32(u_int32_t host32);

     u_int16_t
     htole16(u_int16_t host16);

     u_int32_t
     letoh32(u_int32_t little32);

     u_int16_t
     letoh16(u_int16_t little16);

     u_int32_t
     swap32(u_int32_t val32);

     u_int16_t
     swap16(u_int16_t val16);

DESCRIPTION
     These routines convert 16- and 32-bit quantities between different byte
     orderings.  The ``swap'' functions reverse the byte ordering of the given
     quantity, the others converts either from/to the native byte order used
     by the host to/from either little- or big-endian (a.k.a network) order.

     Apart from the swap functions, the names can be described by this form:
     {src-order}to{dst-order}{size}.  Both {src-order} and {dst-order} can
     take the following forms:

           h    Host order.
           n    Network order (big-endian).
           be   Big-endian (most significant byte first).
           le   Little-endian (least significant byte first).

     One of the specified orderings must be `h'.  {size} will take these
     forms:

           l  Long (32-bit, used in conjunction with forms involving `n').
           s  Short (16-bit, used in conjunction with forms involving `n').
           16
              16-bit.
           32
              32-bit.
     The swap functions are of the form: swap{size}.

     Names involving `n' convert quantities between network byte order and
     host byte order.  The last letter (`s' or `l') is a mnemonic for the tra-
     ditional names for such quantities, short and long, respectively.  Today,
     the C concept of short and long integers need not coincide with this tra-
     ditional misunderstanding.  On machines which have a byte order which is
     the same as the network order, routines are defined as null macros.

     The functions involving either ``be'', ``le'', or ``swap'' use the num-
     bers 16 and 32 for specifying the bitwidth of the quantities they operate
     on.  Currently all supported architectures are either big- or little-
     endian so either the ``be'' or ``le'' variants are implemented as null
     macros.

     The routines mentioned above which have either {src-order} or {dst-order}
     set to `n' are most often used in conjunction with Internet addresses and
     ports as returned by gethostbyname(3) and getservent(3).

SEE ALSO
     gethostbyname(3), getservent(3)

HISTORY
     The byteorder functions appeared in 4.2BSD.

BUGS
     On the vax, alpha, i386, and so far mips, bytes are handled backwards
     from most everyone else in the world.  This is not expected to be fixed
     in the near future.

BSD                              June 4, 1993                              BSD

ETHERS(3)                BSD Library Functions Manual                ETHERS(3)

NAME
     ether_aton, ether_ntoa, ether_addr, ether_ntohost, ether_hostton,
     ether_line -- get ethers entry

SYNOPSIS
     #include <netinet/if_ether.h>

     char *
     ether_ntoa(struct ether_addr *e);

     struct ether_addr *
     ether_aton(char *s);

     int
     ether_ntohost(char *hostname, struct ether_addr *e);

     int
     ether_hostton(char *hostname, struct ether_addr *e);

     int
     ether_line(char *l, struct ether_addr *e, char *hostname);

DESCRIPTION
     Ethernet addresses are represented by the following structure:

           struct ether_addr {
                   u_int8_t  ether_addr_octet[6];
           };

     The ether_ntoa() function converts this structure into an ASCII string of
     the form ``xx:xx:xx:xx:xx:xx'', consisting of 6 hexadecimal numbers sepa-
     rated by colons.  It returns a pointer to a static buffer that is reused
     for each call.  The ether_aton() converts an ASCII string of the same
     form and to a structure containing the 6 octets of the address.  It
     returns a pointer to a static structure that is reused for each call.

     The ether_ntohost() and ether_hostton() functions interrogate the data-
     base mapping host names to Ethernet addresses, /etc/ethers.  The
     ether_ntohost() function looks up the given Ethernet address and writes
     the associated host name into the character buffer passed.  This buffer
     should be MAXHOSTNAMELEN characters in size.  The ether_hostton() func-
     tion looks up the given host name and writes the associated Ethernet
     address into the structure passed.  Both functions return zero if they
     find the requested host name or address, and -1 if not.

     Each call reads /etc/ethers from the beginning; if a `+' appears alone on
     a line in the file, then ether_hostton() will consult the ethers.byname
     YP map, and ether_ntohost() will consult the ethers.byaddr YP map.

     The ether_line() function parses a line from the /etc/ethers file and
     fills in the passed struct ether_addr and character buffer with the Eth-
     ernet address and host name on the line.  It returns zero if the line was
     successfully parsed and -1 if not.  The character buffer should be
     MAXHOSTNAMELEN characters in size.

FILES
     /etc/ethers

SEE ALSO
     ethers(5)

HISTORY
     The ether_ntoa(), ether_aton(), ether_ntohost(), ether_hostton(), and
     ether_line() functions were adopted from SunOS and appeared in NetBSD 0.9
     b.

BUGS
     The data space used by these functions is static; if future use requires
     the data, it should be copied before any subsequent calls to these func-
     tions overwrite it.

BSD                            December 16, 1993                           BSD

getaddrinfo

```
GETADDRINFO(3)           BSD Library Functions Manual           GETADDRINFO(3)

NAME
     getaddrinfo, freeaddrinfo, gai_strerror -- nodename-to-address transla-
     tion in protocol-independent manner

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>
     #include <netdb.h>

     int
     getaddrinfo(const char *nodename, const char *servname,
         const struct addrinfo *hints, struct addrinfo **res);

     void
     freeaddrinfo(struct addrinfo *ai);

     char *
     gai_strerror(int ecode);
```

```
DESCRIPTION
     The getaddrinfo() function is defined for protocol-independent nodename-
     to-address translation.  It performs the functionality of
     gethostbyname(3) and getservbyname(3), but in a more sophisticated man-
     ner.

     The addrinfo structure is defined as a result of including the <netdb.h>
     header:

     struct addrinfo {                                                  *
          int     ai_flags;     /* AI_PASSIVE, AI_CANONNAME, AI_NUMERICHOST */
          int     ai_family;    /* PF_xxx */
          int     ai_socktype;  /* SOCK_xxx */
          int     ai_protocol;  /* 0 or IPPROTO_xxx for IPv4 and IPv6 */
          size_t  ai_addrlen;   /* length of ai_addr */
          char   *ai_canonname; /* canonical name for nodename */
          struct sockaddr  *ai_addr; /* binary address */
          struct addrinfo  *ai_next; /* next structure in linked list */
     };

     The nodename and servname arguments are pointers to NUL-terminated
     strings or NULL.  One or both of these two arguments must be a non-null
     pointer.  In the normal client scenario, both the nodename and servname
     are specified.  In the normal server scenario, only the servname is spec-
     ified.  A non-null nodename string can be either a node name or a numeric
     host address string (i.e., a dotted-decimal IPv4 address or an IPv6 hex
     address).  A non-null servname string can be either a service name or a
     decimal port number.

     The caller can optionally pass an addrinfo structure, pointed to by the
     third argument, to provide hints concerning the type of socket that the
     caller supports.  In this hints structure all members other than
     ai_flags, ai_family, ai_socktype, and ai_protocol must be zero or a null
     pointer.  A value of PF_UNSPEC for ai_family means the caller will accept
     any protocol family.  A value of 0 for ai_socktype means the caller will
     accept any socket type.  A value of 0 for ai_protocol means the caller
     will accept any protocol.  For example, if the caller handles only TCP
     and not UDP, then the ai_socktype member of the hints structure should be
     set to SOCK_STREAM when getaddrinfo() is called.  If the caller handles
     only IPv4 and not IPv6, then the ai_family member of the hints structure
     should be set to PF_INET when getaddrinfo() is called.  If the third
     argument to getaddrinfo() is a null pointer, this is the same as if the
     caller had filled in an addrinfo structure initialized to zero with
     ai_family set to PF_UNSPEC.

     Upon successful return a pointer to a linked list of one or more addrinfo
     structures is returned through the final argument.  The caller can
     process each addrinfo structure in this list by following the ai_next
     pointer, until a null pointer is encountered.  In each returned addrinfo
     structure the three members ai_family, ai_socktype, and ai_protocol are
     the corresponding arguments for a call to the socket() function.  In each
     addrinfo structure the ai_addr member points to a filled-in socket
     address structure whose length is specified by the ai_addrlen member.

     If the AI_PASSIVE bit is set in the ai_flags member of the hints struc-
     ture, then the caller plans to use the returned socket address structure
     in a call to bind().  In this case, if the nodename argument is a null
     pointer, then the IP address portion of the socket address structure will
     be set to INADDR_ANY for an IPv4 address or IN6ADDR_ANY_INIT for an IPv6
     address.

     If the AI_PASSIVE bit is not set in the ai_flags member of the hints
     structure, then the returned socket address structure will be ready for a
     call to connect() (for a connection-oriented protocol) or either
     connect(), sendto(), or sendmsg() (for a connectionless protocol).  In
     this case, if the nodename argument is a null pointer, then the IP
     address portion of the socket address structure will be set to the loop-
```

```
       back address.

       If the AI_CANONNAME bit is set in the ai_flags member of the hints struc-
       ture, then upon successful return the ai_canonname member of the first
       addrinfo structure in the linked list will point to a NUL-terminated
       string containing the canonical name of the specified nodename.

       If the AI_NUMERICHOST bit is set in the ai_flags member of the hints
       structure, then a non-null nodename string must be a numeric host address
       string.  Otherwise an error of EAI_NONAME is returned.  This flag pre-
       vents any type of name resolution service (e.g., the DNS) from being
       called.

       The arguments to getaddrinfo() must sufficiently be consistent and unam-
       biguous.  Here are pitfall cases you may encounter:

       +   getaddrinfo() will raise an error if members of the hints structure
           are not consistent.  For example, for internet address families,
           getaddrinfo() will raise an error if you specify SOCK_STREAM to
           ai_socktype while you specify IPPROTO_UDP to ai_protocol.

       +   If you specify a servname which is defined only for certain
           ai_socktype, getaddrinfo() will raise an error because the arguments
           are not consistent.  For example, getaddrinfo() will raise an error
           if you ask for ``tftp'' service on SOCK_STREAM.

       +   For internet address families, if you specify servname while you set
           ai_socktype to SOCK_RAW, getaddrinfo() will raise an error, because
           service names are not defined for the internet SOCK_RAW space.

       +   If you specify a numeric servname, while leaving ai_socktype and
           ai_protocol unspecified, getaddrinfo() will raise an error.  This is
           because the numeric servname does not identify any socket type, and
           getaddrinfo() is not allowed to glob the argument in such case.

       All of the information returned by getaddrinfo() is dynamically allo-
       cated: the addrinfo structures, the socket address structures, and canon-
       ical node name strings pointed to by the addrinfo structures.  To return
       this information to the system the function freeaddrinfo() is called.
       The addrinfo structure pointed to by the ai argument is freed, along with
       any dynamic storage pointed to by the structure.  This operation is
       repeated until a NULL ai_next pointer is encountered.

       To aid applications in printing error messages based on the EAI_xxx codes
       returned by getaddrinfo(), gai_strerror() is defined.  The argument is
       one of the EAI_xxx values defined earlier and the return value points to
       a string describing the error.  If the argument is not one of the EAI_xxx
       values, the function still returns a pointer to a string whose contents
       indicate an unknown error.

     Extension for scoped IPv6 address
       The implementation allows experimental numeric IPv6 address notation with
       scope identifier.  By appending the percent character and scope identi-
       fier to addresses, you can fill sin6_scope_id field for addresses.  This
       would make management of scoped address easier, and allows cut-and-paste
       input of scoped address.

       At this moment the code supports only link-local addresses with the for-
       mat.  Scope identifier is hardcoded to name of hardware interface associ-
       ated with the link.  (such as ne0).  Example would be like
       ``fe80::1%ne0'', which means ``fe80::1 on the link associated with ne0
       interface''.

       The implementation is still very experimental and non-standard.  The cur-
       rent implementation assumes one-by-one relationship between interface and
       link, which is not necessarily true from the specification.
```

```
EXAMPLES
     The following code tries to connect to ``www.kame.net'' service ``http''.
     via stream socket.  It loops through all the addresses available, regard-
     less from address family.  If the destination resolves to IPv4 address,
     it will use AF_INET socket.  Similarly, if it resolves to IPv6, AF_INET6
     socket is used.  Observe that there is no hardcoded reference to particu-
     lar address family.  The code works even if getaddrinfo returns addresses
     that are not IPv4/v6.

           struct addrinfo hints, *res, *res0;
           int error;
           int s;
           const char *cause = NULL;

           memset(&hints, 0, sizeof(hints));
           hints.ai_family = PF_UNSPEC;
           hints.ai_socktype = SOCK_STREAM;
           error = getaddrinfo("www.kame.net", "http", &hints, &res0);
           if (error) {
                   errx(1, "%s", gai_strerror(error));
                   /*NOTREACHED*/
           }
           s = -1;
           for (res = res0; res; res = res->ai_next) {
                   s = socket(res->ai_family, res->ai_socktype,
                       res->ai_protocol);
                   if (s < 0) {
                           cause = "socket";
                           continue;
                   }

                   if (connect(s, res->ai_addr, res->ai_addrlen) < 0) {
                           cause = "connect";
                           close(s);
                           s = -1;
                           continue;
                   }

                   break;  /* okay we got one */
           }
           if (s < 0) {
                   err(1, cause);
                   /*NOTREACHED*/
           }
           freeaddrinfo(res0);

     The following example tries to open a wildcard listening socket onto ser-
     vice ``http'', for all the address families available.

           struct addrinfo hints, *res, *res0;
           int error;
           int s[MAXSOCK];
           int nsock;
           const char *cause = NULL;

           memset(&hints, 0, sizeof(hints));
           hints.ai_family = PF_UNSPEC;
           hints.ai_socktype = SOCK_STREAM;
           hints.ai_flags = AI_PASSIVE;
           error = getaddrinfo(NULL, "http", &hints, &res0);
           if (error) {
                   errx(1, "%s", gai_strerror(error));
                   /*NOTREACHED*/
           }
           nsock = 0;
           for (res = res0; res && nsock < MAXSOCK; res = res->ai_next) {
                   s[nsock] = socket(res->ai_family, res->ai_socktype,
                       res->ai_protocol);
                   if (s[nsock] < 0) {
                           cause = "socket";
                           continue;
                   }

                   if (bind(s[nsock], res->ai_addr, res->ai_addrlen) < 0) {
                           cause = "bind";
                           close(s[nsock]);
                           continue;
                   }
                   (void) listen(s[nsock], 5);

                   nsock++;
           }
           if (nsock == 0) {
                   err(1, cause);
                   /*NOTREACHED*/
           }
           freeaddrinfo(res0);

DIAGNOSTICS
     Error return status from getaddrinfo() is zero on success and non-zero on
     errors.  Non-zero error codes are defined in <netdb.h>, and as follows:

     EAI_ADDRFAMILY  Address family for nodename not supported.
     EAI_AGAIN       Temporary failure in name resolution.
     EAI_BADFLAGS    Invalid value for ai_flags.
     EAI_FAIL        Non-recoverable failure in name resolution.
     EAI_FAMILY      ai_family not supported.
     EAI_MEMORY      Memory allocation failure.
     EAI_NODATA      No address associated with nodename.
     EAI_NONAME      nodename nor servname provided, or not known.
     EAI_SERVICE     servname not supported for ai_socktype.
     EAI_SOCKTYPE    ai_socktype not supported.
     EAI_SYSTEM      System error returned in errno.

     If called with proper argument, gai_strerror() returns a pointer to a
     string describing the given error code.  If the argument is not one of
     the EAI_xxx values, the function still returns a pointer to a string
     whose contents indicate an unknown error.

GETHOSTBYNAME(3)         BSD Library Functions Manual         GETHOSTBYNAME(3)

NAME
     gethostbyname, gethostbyname2, gethostbyaddr, gethostent, sethostent,
     endhostent, hstrerror, herror -- get network host entry

SYNOPSIS
     #include <netdb.h>
     extern int h_errno;

     struct hostent *
     gethostbyname(const char *name);

     struct hostent *
     gethostbyname2(const char *name, int af);

     struct hostent *
     gethostbyaddr(const char *addr, int len, int af);

     struct hostent *
     gethostent(void);

     void
     sethostent(int stayopen);

     void
     endhostent(void);

     void
     herror(const char *string);

     const char *
     hstrerror(int err);

DESCRIPTION
     The gethostbyname() and gethostbyaddr() functions each return a pointer
     to an object with the following structure describing an internet host
     referenced by name or by address, respectively.  This structure contains
     either information obtained from the name server (i.e., resolver(3) and
     named(8)), broken-out fields from a line in /etc/hosts, or database
     entries supplied by the yp(8) system.  resolv.conf(5) describes how the
     particular database is chosen.

     struct  hostent {
             char    *h_name;        /* official name of host */
             char    **h_aliases;    /* alias list */
             int     h_addrtype;     /* host address type */
             int     h_length;       /* length of address */
             char    **h_addr_list;  /* list of addresses from name server */
     };
     #define h_addr  h_addr_list[0]  /* address, for backward compatibility */

     The members of this structure are:

     h_name       Official name of the host.

     h_aliases    A zero-terminated array of alternate names for the host.

     h_addrtype   The type of address being returned.

     h_length     The length, in bytes, of the address.
     h_addr_list  A zero-terminated array of network addresses for the host.
                  Host addresses are returned in network byte order.

     h_addr       The first address in h_addr_list; this is for backward com-
                  patibility.

     The function gethostbyname() will search for the named host in the cur-
     rent domain and its parents using the search lookup semantics detailed in
     resolv.conf(5) and hostname(7).

     gethostbyname2() is an advanced form of gethostbyname() which allows
     lookups in address families other than AF_INET, for example AF_INET6.

     The gethostbyaddr() function will search for the specified address of
     length len in the address family af.  The only address family currently
     supported is AF_INET.

     The sethostent() function may be used to request the use of a connected
     TCP socket for queries.  If the stayopen flag is non-zero, this sets the
     option to send all queries to the name server using TCP and to retain the
     connection after each call to gethostbyname() or gethostbyaddr().  Other-
     wise, queries are performed using UDP datagrams.

     The endhostent() function closes the TCP connection.

     The herror() function prints an error message describing the failure.  If
     its argument string is non-null, it is prepended to the message string
     and separated from it by a colon (`:') and a space.  The error message is
     printed with a trailing newline.  The contents of the error message is
     the same as that returned by hstrerror() with argument h_errno.

FILES
     /etc/hosts
     /etc/resolv.conf

DIAGNOSTICS
     Error return status from gethostbyname(), gethostbyname2(), and
     gethostbyaddr() is indicated by return of a null pointer.  The external
     integer h_errno may then be checked to see whether this is a temporary
     failure or an invalid or unknown host.

     The variable h_errno can have the following values:

     HOST_NOT_FOUND  No such host is known.

     TRY_AGAIN       This is usually a temporary error and means that the
                     local server did not receive a response from an authori-
                     tative server.  A retry at some later time may succeed.

     NO_RECOVERY     Some unexpected server failure was encountered.  This is
                     a non-recoverable error.

     NO_DATA         The requested name is valid but does not have an IP
                     address; this is not a temporary error.  This means that
                     the name is known to the name server but there is no
                     address associated with this name.  Another type of
                     request to the name server using this domain name will
                     result in an answer; for example, a mail-forwarder may be
                     registered for this domain.

SEE ALSO
     resolver(3), getaddrinfo(3), getnameinfo(3), hosts(5), resolv.conf(5),
     hostname(7), named(8)

CAVEAT
     If the search routines in resolv.conf(5) decide to read the /etc/hosts
     file, gethostent() and other functions will read the next line of the
     file, re-opening the file if necessary.

     The sethostent() function opens and/or rewinds the file /etc/hosts.  If
     the stayopen argument is non-zero, the file will not be closed after each
     call to gethostbyname(), gethostbyname2(), or gethostbyaddr().

     The endhostent() function closes the file.

HISTORY
     The herror() function appeared in 4.3BSD.  The endhostent(),
     gethostbyaddr(), gethostbyname(), gethostent(), and sethostent() func-
     tions appeared in 4.2BSD.

BUGS
     These functions use static data storage; if the data is needed for future
     use, it should be copied before any subsequent calls overwrite it.  Only
     the Internet address formats are currently understood.

     YP does not support any address families other than AF_INET and uses the
     traditional database format.

BSD                             March 13, 1997                             BSD

getifaddrs

```
GETIFADDRS(3)            BSD Library Functions Manual            GETIFADDRS(3)

NAME
     getifaddrs -- get interface addresses

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>
     #include <ifaddrs.h>

     int
     getifaddrs(struct ifaddrs **ifap);

     void
     freeifaddrs(struct ifaddrs *ifap);

DESCRIPTION
     The getifaddrs() function stores a reference to a linked list of the net-
     work interfaces on the local machine in the memory referenced by ifap.
     The list consists of ifaddrs structures, as defined in the include file
     <ifaddrs.h>.  The ifaddrs structure contains at least the following
     entries:

         struct ifaddrs   *ifa_next;         /* Pointer to next struct */
         char             *ifa_name;         /* Interface name */
         u_int             ifa_flags;        /* Interface flags */
         struct sockaddr  *ifa_addr;         /* Interface address */
         struct sockaddr  *ifa_netmask;      /* Interface netmask */
         struct sockaddr  *ifa_broadaddr;    /* Interface broadcast address */
         struct sockaddr  *ifa_dstaddr;      /* P2P interface destination */
         void             *ifa_data;         /* Address specific data */

     ifa_next
             Contains a pointer to the next structure on the list.  This field
             is set to NULL in last structure on the list.

     ifa_name
             Contains the interface name.

     ifa_flags
```

```
             Contains the interface flags, as set by ifconfig(8).

     ifa_addr
             References either the address of the interface or the link level
             address of the interface, if one exists, otherwise it is NULL.
             (The sa_family field of the ifa_addr field should be consulted to
             determine the format of the ifa_addr address.)

     ifa_netmask
             References the netmask associated with ifa_addr, if one is set,
             otherwise it is NULL.

     ifa_broadaddr
             This field, which should only be referenced for non-P2P inter-
             faces, references the broadcast address associated with ifa_addr,
             if one exists, otherwise it is NULL.

     ifa_dstaddr
             References the destination address on a P2P interface, if one
             exists, otherwise it is NULL.

     ifa_data
             References address family specific data.  For AF_LINK addresses
             it contains a pointer to the struct if_data (as defined in
             include file <net/if.h>) which contains various interface
             attributes and statistics.  For all other address families, it
             contains a pointer to the struct ifa_data (as defined in include
             file <net/if.h>) which contains per-address interface statistics.

     The data returned by getifaddrs() is dynamically allocated and should be
     freed using freeifaddrs() when no longer needed.

RETURN VALUES
     Upon successful completion, a value of 0 is returned.  Otherwise, a value
     of -1 is returned and errno is set to indicate the error.

ERRORS
     The getifaddrs() may fail and set errno for any of the errors specified
     for the library routines ioctl(2), socket(2), malloc(3), or sysctl(3).

BUGS
     If both <net/if.h> and <ifaddrs.h> are being included, <net/if.h> must be
     included before <ifaddrs.h>.

SEE ALSO
     ioctl(2), socket(2), sysctl(3), networking(4), ifconfig(8)

HISTORY
     The getifaddrs() function first appeared in BSDI BSD/OS.  The function is
     supplied on OpenBSD since OpenBSD 2.7.

                               September 3, 2013

getnameinfo

```
GETNAMEINFO(3)           BSD Library Functions Manual           GETNAMEINFO(3)

NAME
     getnameinfo -- address-to-nodename translation in protocol-independent
     manner

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>
     #include <netdb.h>
     int
     getnameinfo(const struct sockaddr *sa, socklen_t salen, char *host,
         size_t hostlen, char *serv, size_t servlen, int flags);

DESCRIPTION
     The getnameinfo() function is defined for protocol-independent address-
     to-nodename translation.  Its functionality is a reverse conversion of
     getaddrinfo(3), and implements similar functionality with
     gethostbyaddr(3) and getservbyport(3) in more sophisticated manner.

     This function looks up an IP address and port number provided by the
     caller in the DNS and system-specific database, and returns text strings
     for both in buffers provided by the caller.  The function indicates suc-
     cessful completion by a zero return value; a non-zero return value indi-
     cates failure.

     The first argument, sa, points to either a sockaddr_in structure (for
     IPv4) or a sockaddr_in6 structure (for IPv6) that holds the IP address
     and port number.  The salen argument gives the length of the sockaddr_in
     or sockaddr_in6 structure.

     The function returns the nodename associated with the IP address in the
     buffer pointed to by the host argument.  The caller provides the size of
     this buffer via the hostlen argument.  The service name associated with
     the port number is returned in the buffer pointed to by serv, and the
     servlen argument gives the length of this buffer.  The caller specifies
     not to return either string by providing a zero value for the hostlen or
     servlen arguments.  Otherwise, the caller must provide buffers large
     enough to hold the nodename and the service name, including the terminat-
     ing null characters.

     Unfortunately most systems do not provide constants that specify the max-
     imum size of either a fully-qualified domain name or a service name.
     Therefore to aid the application in allocating buffers for these two
     returned strings the following constants are defined in <netdb.h>:

     #define NI_MAXHOST    MAXHOSTNAMELEN
     #define NI_MAXSERV    32

     The first value is actually defined as the constant MAXDNAME in recent
     versions of BIND's <arpa/nameser.h> header (older versions of BIND define
     this constant to be 256) and the second is a guess based on the services
     listed in the current Assigned Numbers RFC.

     The final argument is a flag that changes the default actions of this
     function.  By default the fully-qualified domain name (FQDN) for the host
     is looked up in the DNS and returned.  If the flag bit NI_NOFQDN is set,
     only the nodename portion of the FQDN is returned for local hosts.

     If the flag bit NI_NUMERICHOST is set, or if the host's name cannot be
     located in the DNS, the numeric form of the host's address is returned
     instead of its name (e.g., by calling inet_ntop() instead of
     gethostbyaddr()).  If the flag bit NI_NAMEREQD is set, an error is
     returned if the host's name cannot be located in the DNS.

     If the flag bit NI_NUMERICSERV is set, the numeric form of the service
     address is returned (e.g., its port number) instead of its name.  The two
     NI_NUMERICxxx flags are required to support the -n flag that many com-
     mands provide.

     A fifth flag bit, NI_DGRAM, specifies that the service is a datagram ser-
     vice, and causes getservbyport() to be called with a second argument of
     "udp" instead of its default of "tcp".  This is required for the few
     ports (512-514) that have different services for UDP and TCP.

     These NI_xxx flags are defined in <netdb.h>.
```

```
   Extension for scoped IPv6 address
     The implementation allows experimental numeric IPv6 address notation with
     scope identifier.  IPv6 link-local address will appear as string like
     ``fe80::1%ne0'', if NI_WITHSCOPEID bit is enabled in flags argument.
     Refer to getaddrinfo(3) for the notation.

EXAMPLES
     The following code tries to get numeric hostname, and service name, for
     given socket address.  Observe that there is no hardcoded reference to
     particular address family.

           struct sockaddr *sa;    /* input */
           char hbuf[NI_MAXHOST], sbuf[NI_MAXSERV];

           if (getnameinfo(sa, sa->sa_len, hbuf, sizeof(hbuf), sbuf,
               sizeof(sbuf), NI_NUMERICHOST | NI_NUMERICSERV)) {
                   errx(1, "could not get numeric hostname");
                   /*NOTREACHED*/
           }
           printf("host=%s, serv=%s\n", hbuf, sbuf);

     The following version checks if the socket address has reverse address
     mapping.

           struct sockaddr *sa;    /* input */
           char hbuf[NI_MAXHOST];

           if (getnameinfo(sa, sa->sa_len, hbuf, sizeof(hbuf), NULL, 0,
               NI_NAMEREQD)) {
                   errx(1, "could not resolve hostname");
                   /*NOTREACHED*/
           }
           printf("host=%s\n", hbuf);

DIAGNOSTICS
     The function indicates successful completion by a zero return value; a
     non-zero return value indicates failure.  Error codes are as below:

     EAI_AGAIN          The name could not be resolved at this time.  Future
                        attempts may succeed.

     EAI_BADFLAGS       The flags had an invalid value.

     EAI_FAIL           A non-recoverable error occurred.

     EAI_FAMILY         The address family was not recognized or the address
                        length was invalid for the specified family.

     EAI_MEMORY         There was a memory allocation failure.

     EAI_NONAME         The name does not resolve for the supplied parameters.
                        NI_NAMEREQD is set and the host's name cannot be
                        located, or both nodename and servname were null.

     EAI_SYSTEM         A system error occurred.  The error code can be found
                        in errno.

     Addresses, internet draft, draft-ietf-ipngwg-scopedaddr-format-02.txt,
     work in progress material.
     Craig Metz, "Protocol Independence Using the Sockets API", Proceedings of
     the freenix track: 2000 USENIX annual technical conference, June 2000.

HISTORY
     The implementation first appeared in WIDE Hydrangea IPv6 protocol stack
     kit.

STANDARDS
     The getaddrinfo() function is defined IEEE POSIX 1003.1g draft specifica-
     tion, and documented in ``Basic Socket Interface Extensions for IPv6''
     (RFC2553).

BUGS
     The current implementation is not thread-safe.

     The text was shamelessly copied from RFC2553.

     OpenBSD intentionally uses different NI_MAXHOST value from what RFC2553
     suggests, to avoid buffer length handling mistakes.

BSD                             May 25, 1995                             BSD
```

getnetent

```
GETNETENT(3)             BSD Library Functions Manual             GETNETENT(3)

NAME
     getnetent, getnetbyaddr, getnetbyname, setnetent, endnetent -- get net-
     work entry

SYNOPSIS
     #include <netdb.h>

     struct netent *
     getnetent(void);

     struct netent *
     getnetbyname(char *name);

     struct netent *
     getnetbyaddr(in_addr_t net, int type);

     void
     setnetent(int stayopen);

     void
     endnetent(void);

DESCRIPTION
     The getnetent(), getnetbyname(), and getnetbyaddr() functions each return
     a pointer to an object with the following structure containing the bro-
     ken-out fields of a line in the network database, /etc/networks.

           struct  netent {
                   char            *n_name;        /* official name of net */
                   char            **n_aliases;    /* alias list */
                   int             n_addrtype;     /* net number type */
                   in_addr_t       n_net;          /* net number */
           };

     The members of this structure are:

     n_name      The official name of the network.

     n_aliases   A zero-terminated list of alternate names for the network.
     n_addrtype  The type of the network number returned; currently only
                 AF_INET.

     n_net       The network number.  Network numbers are returned in machine
                 byte order.

     The getnetent() function reads the next line of the file, opening the
     file if necessary.

     The setnetent() function opens and rewinds the file.  If the stayopen
     flag is non-zero, the net database will not be closed after each call to
     getnetbyname() or getnetbyaddr().

     The endnetent() function closes the file.

     The getnetbyname() and getnetbyaddr() functions search the domain name
     server if the system is configured to use one.  If the search fails, or
     no name server is configured, they sequentially search from the beginning
     of the file until a matching net name or net address and type is found,
     or until EOF is encountered.  Network numbers are supplied in host order.

FILES
     /etc/networks

DIAGNOSTICS
     Null pointer (0) returned on EOF or error.

SEE ALSO
     resolver(3), networks(5)

HISTORY
     The getnetent(), getnetbyaddr(), getnetbyname(), setnetent(), and
     endnetent() functions appeared in 4.2BSD.

BUGS
     The data space used by these functions is static; if future use requires
     the data, it should be copied before any subsequent calls to these func-
     tions overwrite it.  Only Internet network numbers are currently under-
     stood.  Expecting network numbers to fit in no more than 32 bits is
     naive.

BSD                             March 13, 1997                             BSD
```

getprotoent

```
GETPROTOENT(3)           BSD Library Functions Manual           GETPROTOENT(3)

NAME
     getprotoent, getprotobynumber, getprotobyname, setprotoent, endprotoent
     -- get protocol entry

SYNOPSIS
     #include <netdb.h>

     struct protoent *
     getprotoent(void);

     struct protoent *
     getprotobyname(char *name);

     struct protoent *
     getprotobynumber(int proto);

     void
     setprotoent(int stayopen);
     void
     endprotoent(void);

DESCRIPTION
     The getprotoent(), getprotobyname(), and getprotobynumber() functions
     each return a pointer to an object with the following structure contain-
     ing the broken-out fields of a line in the network protocol database,
     /etc/protocols.

           struct  protoent {
                   char    *p_name;        /* official name of protocol */
                   char    **p_aliases;    /* alias list */
                   int     p_proto;        /* protocol number */
           };

     The members of this structure are:

     p_name     The official name of the protocol.

     p_aliases  A zero-terminated list of alternate names for the protocol.

     p_proto    The protocol number.

     The getprotoent() function reads the next line of the file, opening the
     file if necessary.

     The setprotoent() function opens and rewinds the file.  If the stayopen
     flag is non-zero, the net database will not be closed after each call to
     getprotobyname() or getprotobynumber().

     The endprotoent() function closes the file.

     The getprotobyname() and getprotobynumber() functions sequentially search
     from the beginning of the file until a matching protocol name or protocol
     number is found, or until EOF is encountered.

RETURN VALUES
     Null pointer (0) returned on EOF or error.

FILES
     /etc/protocols

SEE ALSO
     protocols(5)

HISTORY
     The getprotoent(), getprotobynumber(), getprotobyname(), setprotoent(),
     and endprotoent() functions appeared in 4.2BSD.

BUGS
     These functions use a static data space; if the data is needed for future
     use, it should be copied before any subsequent calls overwrite it.  Only
     the Internet protocols are currently understood.

BSD                             June 4, 1993                             BSD
```

getrrsetbyname

```
GETRRSETBYNAME(3)        BSD Library Functions Manual        GETRRSETBYNAME(3)

NAME
     getrrsetbyname -- retrieve DNS records

SYNOPSIS
```

```
     #include <netdb.h>

     int
     getrrsetbyname(const char *hostname, unsigned int rdclass,
         unsigned int rdtype, unsigned int flags, struct rrsetinfo **res);

     int
     freerrset(struct rrsetinfo **rrset);

DESCRIPTION
     getrrsetbyname() gets a set of resource records associated with a
     hostname, class and type.  hostname is a pointer a to null-terminated
     string.  The flags field is currently unused and must be zero.

     After a successful call to getrrsetbyname(), *res is a pointer to an
     rrsetinfo structure, containing a list of one or more rdatainfo struc-
     tures containing resource records and potentially another list of
     rdatainfo structures containing SIG resource records associated with
     those records.  The members rri_rdclass and rri_rdtype are copied from
     the parameters.  rri_ttl and rri_name are properties of the obtained
     rrset.  The resource records contained in rri_rdatas and rri_sigs are in
     uncompressed DNS wire format.  Properties of the rdataset are represented
     in the rri_flags bitfield. If the RRSET_VALIDATED bit is set, the data
     has been DNSSEC validated and the signatures verified.

     The following structures are used:

     struct  rdatainfo {
             unsigned int            rdi_length;     /* length of data */
             unsigned char           *rdi_data;      /* record data */
     };

     struct  rrsetinfo {
             unsigned int            rri_flags;      /* RRSET_VALIDATED … */
             unsigned int            rri_rdclass;    /* class number */
             unsigned int            rri_rdtype;     /* RR type number */
             unsigned int            rri_ttl;        /* time to live */
             unsigned int            rri_nrdatas;    /* size of rdatas array */
             unsigned int            rri_nsigs;      /* size of sigs array */
             char                    *rri_name;      /* canonical name */
             struct rdatainfo        *rri_rdatas;    /* individual records */
             struct rdatainfo        *rri_sigs;      /* individual signatures */
     };

     All of the information returned by getrrsetbyname() is dynamically allo-
     cated: the rrsetinfo and rdatainfo structures, and the canonical host
     name strings pointed to by the rrsetinfostructure. Memory allocated for
     the dynamically allocated structures created by a successful call to
     getrrsetbyname() is released by freerrset().  rrset is a pointer to a
     struct rrset created by a call to getrrsetbyname().

     If the EDNS0 option is activated in resolv.conf(3), getrrsetbyname() will
     request DNSSEC authentication using the EDNS0 DNSSEC OK (DO) bit.

RETURN VALUES
     getrrsetbyname() returns zero on success, and one of the following error
     codes if an error occurred:

     ERRSET_NONAME    the name does not exist
     ERRSET_NODATA    the name exists, but does not have data of the desired
                      type
     ERRSET_NOMEMORY  memory could not be allocated
     ERRSET_INVAL     a parameter is invalid
     ERRSET_FAIL      other failure

AUTHORS
     Jakob Schlyter <jakob@openbsd.org>

HISTORY
     getrrsetbyname() first appeared in OpenBSD 3.0.  The API first appeared
     in ISC BIND version 9.

BUGS
     The data in *rdi_data should be returned in uncompressed wire format.
     Currently, the data is in compressed format and the caller can't uncom-
     press since it doesn't have the full message.

CAVEATS
     The RRSET_VALIDATED flag in rri_flags is set if the AD (autenticated
     data) bit in the DNS answer is set. This flag should not be trusted
     unless the transport between the nameserver and the resolver is secure
     (e.g. IPsec, trusted network, loopback communication).

BSD                              Oct 18, 2000                              BSD

getservent

```
GETSERVENT(3)            BSD Library Functions Manual            GETSERVENT(3)

NAME
     getservent, getservbyport, getservbyname, setservent, endservent -- get
     service entry

SYNOPSIS
     #include <netdb.h>

     struct servent *
     getservent(void);

     struct servent *
     getservbyname(char *name, char *proto);

     struct servent *
     getservbyport(int port, char *proto);

     void
     setservent(int stayopen);

     void
     endservent(void);

DESCRIPTION
     The getservent(), getservbyname(), and getservbyport() functions each
     return a pointer to an object with the following structure containing the
     broken-out fields of a line in the network services database,
     /etc/services.

           struct  servent {
                   char    *s_name;        /* official name of service */
                   char    **s_aliases;    /* alias list */
                   int     s_port;         /* port service resides at */
                   char    *s_proto;       /* protocol to use */
           };

     The members of this structure are:

     s_name     The official name of the service.

     s_aliases  A zero-terminated list of alternate names for the service.
     s_port     The port number at which the service resides.  Port numbers
                are returned in network byte order.

     s_proto    The name of the protocol to use when contacting the service.

     The getservent() function reads the next line of the file, opening the
     file if necessary.

     The setservent() function opens and rewinds the file.  If the stayopen
     flag is non-zero, the net database will not be closed after each call to
     getservbyname() or getservbyport().

     The endservent() function closes the file.

     The getservbyname() and getservbyport() functions sequentially search
     from the beginning of the file until a matching protocol name or port
     number (specified in network byte order) is found, or until EOF is
     encountered.  If a protocol name is also supplied (non-null), searches
     must also match the protocol.

FILES
     /etc/services

DIAGNOSTICS
     Null pointer (0) returned on EOF or error.

SEE ALSO
     getprotoent(3), services(5)

HISTORY
     The getservent(), getservbyport(), getservbyname(), setservent(), and
     endservent() functions appeared in 4.2BSD.

BUGS
     These functions use static data storage; if the data is needed for future
     use, it should be copied before any subsequent calls overwrite it.
     Expecting port numbers to fit in a 32-bit quantity is probably naive.

BSD                             January 12, 1994                           BSD
```

if_nametoindex

```
IF_NAMETOINDEX(3)        BSD Library Functions Manual        IF_NAMETOINDEX(3)

NAME
     if_nametoindex, if_indextoname, if_nameindex, if_freenameindex -- convert
     interface index to name, and vice versa

SYNOPSIS
     #include <net/if.h>

     unsigned int
     if_nametoindex(const char *ifname);

     char *
     if_indextoname(unsigned int ifindex, char *ifname);

     struct if_nameindex *
     if_nameindex(void);

     void
     if_freenameindex(struct if_nameindex *ptr);

DESCRIPTION
     These functions map interface indexes to interface names (such as
     ``lo0''), and vice versa.
     The if_nametoindex() function converts an interface name specified by the
     ifname argument to an interface index (positive integer value).  If the
     specified interface does not exist, 0 will be returned.

     if_indextoname() converts an interface index specified by the ifindex
     argument to an interface name.  The ifname argument must point to a buf-
     fer of at least IF_NAMESIZE bytes into which the interface name corre-
     sponding to the specified index is returned.  (IF_NAMESIZE is also
     defined in <net/if.h> and its value includes a terminating null byte at
     the end of the interface name.)  This pointer is also the return value of
     the function.  If there is no interface corresponding to the specified
     index, NULL is returned.

     if_nameindex() returns an array of if_nameindex structures.
     if_nametoindex is also defined in <net/if.h>, and is as follows:

     struct if_nameindex {
         unsigned int   if_index;  /* 1, 2, … */
         char          *if_name;   /* null terminated name: "le0", … */
     };

     The end of the array of structures is indicated by a structure with an
     if_index of 0 and an if_name of NULL.  The function returns a null
     pointer on error.  The memory used for this array of structures along
     with the interface names pointed to by the if_name members is obtained
     dynamically.  This memory is freed by the if_freenameindex() function.

     if_freenameindex() takes a pointer that was returned by if_nameindex() as
     argument (ptr), and it reclaims the region allocated.

DIAGNOSTICS
     if_nametoindex() returns 0 on error, positive integer on success.
     if_indextoname() and if_nameindex() return NULL on errors.

INET(3)                  BSD Library Functions Manual                  INET(3)

NAME
     inet_addr, inet_aton, inet_lnaof, inet_makeaddr, inet_netof,
     inet_network, inet_ntoa, inet_ntop, inet_pton -- Internet address manipu-
     lation routines

SYNOPSIS
     #include <sys/socket.h>
     #include <netinet/in.h>
     #include <arpa/inet.h>

     in_addr_t
     inet_addr(const char *cp);

     int
     inet_aton(const char *cp, struct in_addr *addr);

     in_addr_t
     inet_lnaof(struct in_addr in);

     struct in_addr
     inet_makeaddr(unsigned long net, unsigned long lna);

     in_addr_t
     inet_netof(struct in_addr in);

     in_addr_t
     inet_network(const char *cp);

     char *
     inet_ntoa(struct in_addr in);

     const char *
     inet_ntop(int af, const void *src, char *dst, size_t size);

     int
     inet_pton(int af, const char *src, void *dst);

DESCRIPTION
     The routines inet_aton(), inet_addr() and inet_network() interpret char-
     acter strings representing numbers expressed in the Internet standard `.'
     notation.  The inet_pton() function converts a presentation format
     address (that is, printable form as held in a character string) to net-
     work format (usually a struct in_addr or some other internal binary rep-
     resentation, in network byte order).  It returns 1 if the address was
     valid for the specified address family, or 0 if the address wasn't
     parseable in the specified address family, or -1 if some system error
     occurred (in which case errno will have been set).  This function is
     presently valid for AF_INET and AF_INET6.  The inet_aton() routine inter-
     prets the specified character string as an Internet address, placing the
     address into the structure provided.  It returns 1 if the string was suc-
     cessfully interpreted, or 0 if the string was invalid.  The inet_addr()
     and inet_network() functions return numbers suitable for use as Internet
     addresses and Internet network numbers, respectively.

     The function inet_ntop() converts an address from network format (usually
     a struct in_addr or some other binary form, in network byte order) to
     presentation format (suitable for external display purposes).  It returns
     NULL if a system error occurs (in which case, errno will have been set),
     or it returns a pointer to the destination string.  The routine
     inet_ntoa() takes an Internet address and returns an ASCII string repre-
     senting the address in `.' notation.  The routine inet_makeaddr() takes
     an Internet network number and a local network address and constructs an
     Internet address from it.  The routines inet_netof() and inet_lnaof()
     break apart Internet host addresses, returning the network number and
     local network address part, respectively.

     All Internet addresses are returned in network order (bytes ordered from
     left to right).  All network numbers and local address parts are returned
     as machine format integer values.

INTERNET ADDRESSES (IP VERSION 4)
     Values specified using the `.' notation take one of the following forms:

           a.b.c.d
           a.b.c
           a.b
           a

     When four parts are specified, each is interpreted as a byte of data and
     assigned, from left to right, to the four bytes of an Internet address.
     Note that when an Internet address is viewed as a 32-bit integer quantity
     on a system that uses little-endian byte order (such as the Intel 386,
     486 and Pentium processors) the bytes referred to above appear as
     ``d.c.b.a''.  That is, little-endian bytes are ordered from right to
     left.

     When a three part address is specified, the last part is interpreted as a
     16-bit quantity and placed in the rightmost two bytes of the network
     address.  This makes the three part address format convenient for speci-
     fying Class B network addresses as ``128.net.host''.

     When a two part address is supplied, the last part is interpreted as a
     24-bit quantity and placed in the rightmost three bytes of the network
     address.  This makes the two part address format convenient for specify-
     ing Class A network addresses as ``net.host''.

     When only one part is given, the value is stored directly in the network
     address without any byte rearrangement.

     All numbers supplied as ``parts'' in a `.' notation may be decimal,
     octal, or hexadecimal, as specified in the C language (i.e., a leading 0x
     or 0X implies hexadecimal; otherwise, a leading 0 implies octal; other-
     wise, the number is interpreted as decimal).

INTERNET ADDRESSES (IP VERSION 6)
     In order to support scoped IPv6 addresses, getaddrinfo(3) and
     getnameinfo(3) are recommended rather than the functions presented here.

     The presentation format of an IPv6 address is given in [RFC1884 2.2]:

     There are three conventional forms for representing IPv6 addresses as
     text strings:

     1.   The preferred form is x:x:x:x:x:x:x:x, where the 'x's are the hexa-
          decimal values of the eight 16-bit pieces of the address.  Examples:

                FEDC:BA98:7654:3210:FEDC:BA98:7654:3210
                1080:0:0:0:8:800:200C:417A

          Note that it is not necessary to write the leading zeros in an indi-
          vidual field, but there must be at least one numeral in every field
          (except for the case described in 2.).

     2.   Due to the method of allocating certain styles of IPv6 addresses, it
          will be common for addresses to contain long strings of zero bits.
          In order to make writing addresses

          containing zero bits easier a special syntax is available to com-
          press the zeros.  The use of ``::'' indicates multiple groups of 16
          bits of zeros.  The ``::'' can only appear once in an address.  The
          ``::'' can also be used to compress the leading and/or trailing
          zeros in an address.

          For example the following addresses:

                1080:0:0:0:8:800:200C:417A  a unicast address
                FF01:0:0:0:0:0:0:43         a multicast address
                0:0:0:0:0:0:0:1             the loopback address
                0:0:0:0:0:0:0:0             the unspecified addresses

          may be represented as:

                1080::8:800:200C:417A       a unicast address
                FF01::43                    a multicast address
                ::1                         the loopback address
                ::                          the unspecified addresses

     3.   An alternative form that is sometimes more convenient when dealing
          with a mixed environment of IPv4 and IPv6 nodes is
          x:x:x:x:x:x:d.d.d.d, where the 'x's are the hexadecimal values of
          the six high-order 16-bit pieces of the address, and the 'd's are
          the decimal values of the four low-order 8-bit pieces of the address
          (standard IPv4 representation).  Examples:

                0:0:0:0:0:0:13.1.68.3
                0:0:0:0:0:FFFF:129.144.52.38

          or in compressed form:

                ::13.1.68.3
                ::FFFF:129.144.52.38

DIAGNOSTICS
     The constant INADDR_NONE is returned by inet_addr() and inet_network()
     for malformed requests.

SEE ALSO
     byteorder(3), gethostbyname(3), getnetent(3), inet_net(3), hosts(5),
     networks(5)

STANDARDS
     The inet_ntop and inet_pton functions conforms to the IETF IPv6 BSD API
     and address formatting specifications.  Note that inet_pton does not
     accept 1-, 2-, or 3-part dotted addresses; all four parts must be speci-
     fied.  This is a narrower input set than that accepted by inet_aton.

HISTORY
     The inet_addr, inet_network, inet_makeaddr, inet_lnaof and inet_netof
     functions appeared in 4.2BSD.  The inet_aton and inet_ntoa functions
     appeared in 4.3BSD.  The inet_pton and inet_ntop functions appeared in
     BIND 4.9.4.

BUGS
     The value INADDR_NONE (0xffffffff) is a valid broadcast address, but
     inet_addr() cannot return that value without indicating failure.  Also,
     inet_addr() should have been designed to return a struct in_addr.  The
     newer inet_aton() function does not share these problems, and almost all
     existing code should be modified to use inet_aton() instead.

     The problem of host byte ordering versus network byte ordering is confus-
     ing.

     The string returned by inet_ntoa() resides in a static memory area.

BSD                              June 18, 1997                             BSD

inet6_option_space

```
INET6_OPTION_SPACE(3)    BSD Library Functions Manual    INET6_OPTION_SPACE(3)

NAME
     inet6_option_space, inet6_option_init, inet6_option_append,
     inet6_option_alloc, inet6_option_next, inet6_option_find -- IPv6 Hop-by-
     Hop and Destination Options manipulation

SYNOPSIS
     #include <netinet/in.h>

     int
     inet6_option_space(int nbytes);

     int
     inet6_option_init(void *bp, struct cmsghdr **cmsgp, int type);

     int
     inet6_option_append(struct cmsghdr *cmsg, const u_int8_t *typep,
         int multx, int plusy);
     u_int8_t *
     inet6_option_alloc(struct cmsghdr *cmsg, int datalen, int multx,
         int plusy);;

     int
     inet6_option_next(const struct cmsghdr *cmsg, u_int8_t **tptrp);

     int
     inet6_option_find(const struct cmsghdr *cmsg, u_int8_t **tptrp,
         int type);

DESCRIPTION
     Building and parsing the Hop-by-Hop and Destination options is compli-
     cated due to alignment constranints, padding and ancillary data manipula-
     tion.  RFC2292 defines a set of functions to help the application.  The
     function prototypes for these functions are all in the <netinet/in.h>
     header.

   inet6_option_space
     inet6_option_space() returns the number of bytes required to hold an
     option when it is stored as ancillary data, including the cmsghdr struc-
     ture at the beginning, and any padding at the end (to make its size a
     multiple of 8 bytes).  The argument is the size of the structure defining
     the option, which must include any pad bytes at the beginning (the value
     y in the alignment term ``xn + y''), the type byte, the length byte, and
     the option data.

     Note: If multiple options are stored in a single ancillary data object,
     which is the recommended technique, this function overestimates the
     amount of space required by the size of N-1 cmsghdr structures, where N
     is the number of options to be stored in the object.  This is of little
     consequence, since it is assumed that most Hop-by-Hop option headers and
     Destination option headers carry only one option (appendix B of
     [RFC-2460]).

   inet6_option_init
     inet6_option_init() is called once per ancillary data object that will
     contain either Hop-by-Hop or Destination options.  It returns 0 on suc-
     cess or -1 on an error.

     bp is a pointer to previously allocated space that will contain the
     ancillary data object.  It must be large enough to contain all the indi-
     vidual options to be added by later calls to inet6_option_append() and
     inet6_option_alloc().

     cmsgp is a pointer to a pointer to a cmsghdr structure.  *cmsgp is ini-
     tialized by this function to point to the cmsghdr structure constructed
     by this function in the buffer pointed to by bp.

     type is either IPV6_HOPOPTS or IPV6_DSTOPTS.  This type is stored in the
     cmsg_type member of the cmsghdr structure pointed to by *cmsgp.

   inet6_option_append
     This function appends a Hop-by-Hop option or a Destination option into an
     ancillary data object that has been initialized by inet6_option_init().
     This function returns 0 if it succeeds or -1 on an error.

     cmsg is a pointer to the cmsghdr structure that must have been initial-
     ized by inet6_option_init().

     typep is a pointer to the 8-bit option type.  It is assumed that this
     field is immediately followed by the 8-bit option data length field,
     which is then followed immediately by the option data.  The caller ini-
     tializes these three fields (the type-length-value, or TLV) before call-
     ing this function.
     The option type must have a value from 2 to 255, inclusive.  (0 and 1 are
     reserved for the Pad1 and PadN options, respectively.)

     The option data length must have a value between 0 and 255, inclusive,
     and is the length of the option data that follows.

     multx is the value x in the alignment term ``xn + y''.  It must have a
     value of 1, 2, 4, or 8.

     plusy is the value y in the alignment term ``xn + y''.  It must have a
     value between 0 and 7, inclusive.

   inet6_option_alloc
     This function appends a Hop-by-Hop option or a Destination option into an
     ancillary data object that has been initialized by inet6_option_init().
     This function returns a pointer to the 8-bit option type field that
     starts the option on success, or NULL on an error.

     The difference between this function and inet6_option_append() is that
     the latter copies the contents of a previously built option into the
     ancillary data object while the current function returns a pointer to the
     space in the data object where the option's TLV must then be built by the
     caller.

     cmsg is a pointer to the cmsghdr structure that must have been initial-
     ized by inet6_option_init().

     datalen is the value of the option data length byte for this option.
     This value is required as an argument to allow the function to determine
     if padding must be appended at the end of the option.  (The
     inet6_option_append() function does not need a data length argument since
     the option data length must already be stored by the caller.)

     multx is the value x in the alignment term ``xn + y''.  It must have a
     value of 1, 2, 4, or 8.

     plusy is the value y in the alignment term ``xn + y''.  It must have a
     value between 0 and 7, inclusive.

   inet6_option_next
     This function processes the next Hop-by-Hop option or Destination option
     in an ancillary data object.  If another option remains to be processed,
     the return value of the function is 0 and *tptrp points to the 8-bit
     option type field (which is followed by the 8-bit option data length,
     followed by the option data).  If no more options remain to be processed,
     the return value is -1 and *tptrp is NULL.  If an error occurs, the
     return value is -1 and *tptrp is not NULL.

     cmsg is a pointer to cmsghdr structure of which cmsg_level equals
     IPPROTO_IPV6 and cmsg_type equals either IPV6_HOPOPTS or IPV6_DSTOPTS.

     tptrp is a pointer to a pointer to an 8-bit byte and *tptrp is used by
     the function to remember its place in the ancillary data object each time
     the function is called.  The first time this function is called for a
     given ancillary data object, *tptrp must be set to NULL.

     Each time this function returns success, *tptrp points to the 8-bit
     option type field for the next option to be processed.

   inet6_option_find
     This function is similar to the previously described inet6_option_next()
     function, except this function lets the caller specify the option type to
     be searched for, instead of always returning the next option in the
     ancillary data object.  cmsg is a pointer to cmsghdr structure of which
     cmsg_level equals IPPROTO_IPV6 and cmsg_type equals either IPV6_HOPOPTS
     or IPV6_DSTOPTS.
     tptrp is a pointer to a pointer to an 8-bit byte and *tptrp is used by
     the function to remember its place in the ancillary data object each time
     the function is called.  The first time this function is called for a
     given ancillary data object, *tptrp must be set to NULL.  ~ This function
     starts searching for an option of the specified type beginning after the
     value of *tptrp.  If an option of the specified type is located, this
     function returns 0 and *tptrp points to the 8- bit option type field for
     the option of the specified type.  If an option of the specified type is
     not located, the return value is -1 and *tptrp is NULL.  If an error
     occurs, the return value is -1 and *tptrp is not NULL.

DIAGNOSTICS
     inet6_option_init() and inet6_option_append() return 0 on success or -1
     on an error.

     inet6_option_alloc() returns NULL on an error.

     On errors, inet6_option_next() and inet6_option_find() return -1 setting
     *tptrp to non NULL value.

EXAMPLES
     RFC2292 gives comprehensive examples in chapter 6.

     int
     inet6_rthdr_segments(const struct cmsghdr *cmsg);

     struct in6_addr *
     inet6_rthdr_getaddr(struct cmsghdr *cmsg, int index);

     int
     inet6_rthdr_getflags(const struct cmsghdr *cmsg, int index);

DESCRIPTION
     RFC2292 IPv6 advanced API defines eight functions that the application
     calls to build and examine a Routing header.  Four functions build a
     Routing header:

     inet6_rthdr_space() return #bytes required for ancillary data

     inet6_rthdr_init() initialize ancillary data for Routing header

     inet6_rthdr_add() add IPv6 address & flags to Routing header

     inet6_rthdr_lasthop() specify the flags for the final hop

     Four functions deal with a returned Routing header:

     inet6_rthdr_reverse() reverse a Routing header

     inet6_rthdr_segments() return #segments in a Routing header

     inet6_rthdr_getaddr() fetch one address from a Routing header

     inet6_rthdr_getflags() fetch one flag from a Routing header

     The function prototypes for these functions are all in the <netinet/in.h>
     header.

   inet6_rthdr_space
     This function returns the number of bytes required to hold a Routing
     header of the specified type containing the specified number of segments
     (addresses).  For an IPv6 Type 0 Routing header, the number of segments
     must be between 1 and 23, inclusive.  The return value includes the size
     of the cmsghdr structure that precedes the Routing header, and any
     required padding.

     If the return value is 0, then either the type of the Routing header is
     not supported by this implementation or the number of segments is invalid
     for this type of Routing header.

     Note: This function returns the size but does not allocate the space
     required for the ancillary data.  This allows an application to allocate
     a larger buffer, if other ancillary data objects are desired, since all
     the ancillary data objects must be specified to sendmsg(2) as a single
     msg_control buffer.

   inet6_rthdr_init
     This function initializes the buffer pointed to by bp to contain a
     cmsghdr structure followed by a Routing header of the specified type.
     The cmsg_len member of the cmsghdr structure is initialized to the size
     of the structure plus the amount of space required by the Routing header.
     The cmsg_level and cmsg_type members are also initialized as required.

     The caller must allocate the buffer and its size can be determined by
     calling inet6_rthdr_space().
     Upon success the return value is the pointer to the cmsghdr structure,
     and this is then used as the first argument to the next two functions.
     Upon an error the return value is NULL.

   inet6_rthdr_add
     This function adds the address pointed to by addr to the end of the Rout-
     ing header being constructed and sets the type of this hop to the value
     of flags.  For an IPv6 Type 0 Routing header, flags must be either
     IPV6_RTHDR_LOOSE or IPV6_RTHDR_STRICT.

     If successful, the cmsg_len member of the cmsghdr structure is updated to
     account for the new address in the Routing header and the return value of
     the function is 0.  Upon an error the return value of the function is -1.

   inet6_rthdr_lasthop
     This function specifies the Strict/Loose flag for the final hop of a
     Routing header.  For an IPv6 Type 0 Routing header, flags must be either
     IPV6_RTHDR_LOOSE or IPV6_RTHDR_STRICT.

     The return value of the function is 0 upon success, or -1 upon an error.

     Notice that a Routing header specifying N intermediate nodes requires N+1
     Strict/Loose flags.  This requires N calls to inet6_rthdr_add() followed
     by one call to inet6_rthdr_lasthop().

   inet6_rthdr_reverse
     This function takes a Routing header that was received as ancillary data
     (pointed to by the first argument, in) and writes a new Routing header
     that sends datagrams along the reverse of that route.  Both arguments are
     allowed to point to the same buffer (that is, the reversal can occur in
     place).

     The return value of the function is 0 on success, or -1 upon an error.

   inet6_rthdr_segments
     This function returns the number of segments (addresses) contained in the
     Routing header described by cmsg.  On success the return value is between
     1 and 23, inclusive.  The return value of the function is -1 upon an
     error.

   inet6_rthdr_getaddr
     This function returns a pointer to the IPv6 address specified by index
     (which must have a value between 1 and the value returned by
     inet6_rthdr_segments()) in the Routing header described by cmsg.  An
     application should first call inet6_rthdr_segments() to obtain the number
     of segments in the Routing header.

     Upon an error the return value of the function is NULL.

   inet6_rthdr_getflags
     This function returns the flags value specified by index (which must have
     a value between 0 and the value returned by inet6_rthdr_segments()) in
     the Routing header described by cmsg.  For an IPv6 Type 0 Routing header
     the return value will be either IPV6_RTHDR_LOOSE or IPV6_RTHDR_STRICT.

     Upon an error the return value of the function is -1.

     Note: Addresses are indexed starting at 1, and flags starting at 0, to
     maintain consistency with the terminology and figures in RFC2460.

DIAGNOSTICS
     inet6_rthdr_space() returns 0 on errors.

     inet6_rthdr_add(), inet6_rthdr_lasthop() and inet6_rthdr_reverse() return
     0 on success, and returns -1 on error.
     inet6_rthdr_init() and inet6_rthdr_getaddr() return NULL on error.

     inet6_rthdr_segments() and inet6_rthdr_getflags() return -1 on error.

EXAMPLES
     RFC2292 gives comprehensive examples in chapter 8.

     Specification, RFC2460, December 1998.

HISTORY
     The implementation first appeared in KAME advanced networking kit.

STANDARDS
     The functions are documented in ``Advanced Sockets API for IPv6''
     (RFC2292).

BUGS
     The text was shamelessly copied from RFC2292.

     inet6_rthdr_reverse() is not implemented yet.

BSD                            December 10, 1999                           BSD
```

inet_net

```
INET_NET(3)              BSD Library Functions Manual              INET_NET(3)

NAME
     inet_net_ntop, inet_net_pton -- Internet network number manipulation rou-
     tines

SYNOPSIS
     #include <sys/socket.h>
     #include <netinet/in.h>
     #include <arpa/inet.h>

     char *
     inet_net_ntop(int af, const void *src, int bits, char *dst, size_t size);

     int
     inet_net_pton(int af, const char *src, void *dst, size_t size);

DESCRIPTION
     The inet_net_ntop() function converts an Internet network number from
     network format (usually a struct in_addr or some other binary form, in
     network byte order) to CIDR presentation format (suitable for external
     display purposes).  bits is the number of bits in src that are the net-
     work number.  It returns NULL if a system error occurs (in which case,
     errno will have been set), or it returns a pointer to the destination
     string.

     The inet_net_pton() function converts a presentation format Internet net-
     work number (that is, printable form as held in a character string) to
     network format (usually a struct in_addr or some other internal binary
     representation, in network byte order).  It returns the number of bits
     (either computed based on the class, or specified with /CIDR), or -1 if a
     failure occurred (in which case errno will have been set.  It will be set
     to ENOENT if the Internet network number was not valid).

     The only value for af currently supported is AF_INET.  size is the size
     of the result buffer dst.
```

```
NETWORK NUMBERS (IP VERSION 4)
     Internet network numbers may be specified in one of the following forms:

           a.b.c.d/bits
           a.b.c.d
           a.b.c
           a.b
           a

     When four parts are specified, each is interpreted as a byte of data and
     assigned, from left to right, to the four bytes of an Internet network
     number.  Note that when an Internet network number is viewed as a 32-bit
     integer quantity on a system that uses little-endian byte order (such as
     the Intel 386, 486, and Pentium processors) the bytes referred to above
     appear as ``d.c.b.a''.  That is, little-endian bytes are ordered from
     right to left.

     When a three part number is specified, the last part is interpreted as a
     16-bit quantity and placed in the rightmost two bytes of the Internet
     network number.  This makes the three part number format convenient for
     specifying Class B network numbers as ``128.net.host''.

     When a two part number is supplied, the last part is interpreted as a
     24-bit quantity and placed in the rightmost three bytes of the Internet
     network number.  This makes the two part number format convenient for
     specifying Class A network numbers as ``net.host''.

     When only one part is given, the value is stored directly in the Internet
     network number without any byte rearrangement.

     All numbers supplied as ``parts'' in a `.' notation may be decimal,
     octal, or hexadecimal, as specified in the C language (i.e., a leading 0x
     or 0X implies hexadecimal; otherwise, a leading 0 implies octal; other-
     wise, the number is interpreted as decimal).

SEE ALSO
     byteorder(3), inet(3), networks(5)

HISTORY
     The inet_net_ntop and inet_net_pton functions first appeared in BIND
     4.9.4.

BSD                             June 18, 1997                            BSD
```

ipx

```
IPX(3)                   BSD Library Functions Manual                   IPX(3)

NAME
     ipx_addr, ipx_ntoa -- IPX address conversion routines

SYNOPSIS
     #include <sys/types.h>
     #include <netipx/ipx.h>

     struct ipx_addr
     ipx_addr(const char *cp);

     char *
     ipx_ntoa(struct ipx_addr ipx);

DESCRIPTION
     The routine ipx_addr() interprets character strings representing IPX
     addresses, returning binary information suitable for use in system calls.
     The routine ipx_ntoa() takes IPX addresses and returns ASCII strings rep-
     resenting the address in a notation in common use:

           <network number>.<host number>.<port number>

     Trailing zero fields are suppressed, and each number is printed in hexa-
     decimal, in a format suitable for input to ipx_addr().  Any fields lack-
     ing super-decimal digits will have a trailing `H' appended.

     An effort has been made to ensure that ipx_addr() be compatible with most
     formats in common use.  It will first separate an address into 1 to 3
     fields using a single delimiter chosen from period (`.'), colon (`:'), or
     pound-sign (`#').  Each field is then examined for byte separators (colon
     or period).  If there are byte separators, each subfield separated is
     taken to be a small hexadecimal number, and the entirety is taken as a
     network-byte-ordered quantity to be zero extended in the high-network-
     order bytes.  Next, the field is inspected for hyphens, in which case the
     field is assumed to be a number in decimal notation with hyphens separat-
     ing the millenia.  Next, the field is assumed to be a number: It is
     interpreted as hexadecimal if there is a leading `0x' (as in C), a trail-
     ing `H' (as in Mesa), or there are any super-decimal digits present.  It
     is interpreted as octal is there is a leading `0' and there are no super-
     octal digits.  Otherwise, it is converted as a decimal number.

RETURN VALUES
     None.  (See BUGS.)

SEE ALSO
     ns(4), hosts(5), networks(5)

HISTORY
     The precursor ns_addr() and ns_ntoa() functions appeared in 4.3BSD.

BUGS
     The string returned by ipx_ntoa() resides in a static memory area.  The
     function ipx_addr() should diagnose improperly formed input, and there
     should be an unambiguous way to recognize this.

BSD                             June 4, 1993                             BSD
```

iso_addr

```
ISO_ADDR(3)              BSD Library Functions Manual              ISO_ADDR(3)

NAME
     iso_addr, iso_ntoa -- network address conversion routines for Open System
     Interconnection

SYNOPSIS
     #include <sys/types.h>
     #include <netiso/iso.h>

     struct iso_addr *
     iso_addr(char *cp);

     char *
     iso_ntoa(struct iso_addr *isoa);

DESCRIPTION
     The routine iso_addr() interprets character strings representing OSI
     addresses, returning binary information suitable for use in system calls.
     The routine iso_ntoa() takes OSI addresses and returns ASCII strings rep-
     resenting NSAPs (network service access points) in a notation inverse to
     that accepted by iso_addr().

     Unfortunately, no universal standard exists for representing OSI network
     addresses.
     The format employed by iso_addr() is a sequence of hexadecimal ``digits''
     (optionally separated by periods), of the form:

           <hex digits>.<hex digits>.<hex digits>

     Each pair of hexadecimal digits represents a byte with the leading digit
     indicating the higher-ordered bits.  A period following an even number of
     bytes has no effect (but may be used to increase legibility).  A period
     following an odd number of bytes has the effect of causing the byte of
     address being translated to have its higher order bits filled with zeros.

RETURN VALUES
     iso_ntoa() always returns a null terminated string.  iso_addr() always
     returns a pointer to a struct iso_addr.  (See BUGS.)

SEE ALSO
     iso(4)

HISTORY
     The iso_addr() and iso_ntoa() functions appeared in 4.3BSD-Reno.

BUGS
     The returned values reside in a static memory area.

     The function iso_addr() should diagnose improperly formed input, and
     there should be an unambiguous way to recognize this.

BSD                             June 4, 1993                             BSD
```

link_addr

```
LINK_ADDR(3)             BSD Library Functions Manual             LINK_ADDR(3)

NAME
     link_addr, link_ntoa -- elementary address specification routines for
     link level access

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>
     #include <net/if_dl.h>

     void
     link_addr(const char *addr, struct sockaddr_dl *sdl);

     char *
     link_ntoa(const struct sockaddr_dl *sdl);

DESCRIPTION
     The link_addr() function interprets character strings representing link-
     level addresses, returning binary information suitable for use in system
     calls.  link_ntoa() takes a link-level address and returns an ASCII
     string representing some of the information present, including the link
     level address itself, and the interface name or number, if present.  This
     facility is experimental and is still subject to change.

     For link_addr(), the string addr may contain an optional network inter-
     face identifier of the form ``name unit-number'', suitable for the first
     argument to ifconfig(8), followed in all cases by a colon and an inter-
     face address in the form of groups of hexadecimal digits separated by
     periods.  Each group represents a byte of address; address bytes are
     filled left to right from low order bytes through high order bytes.

     Thus le0:8.0.9.13.d.30 represents an Ethernet address to be transmitted
     on the first Lance Ethernet interface.
```

```
RETURN VALUES
     link_ntoa() always returns a null-terminated string.  link_addr() has no
     return value.  (See BUGS.)

SEE ALSO
     iso(4), ifconfig(8)

HISTORY
     The link_addr() and link_ntoa() functions appeared in 4.3BSD-Reno.

BUGS
     The returned values for link_ntoa reside in a static memory area.

     The function link_addr() should diagnose improperly formed input, and
     there should be an unambiguous way to recognize this.

     If the sdl_len field of the link socket address sdl is 0, link_ntoa()
     will not insert a colon before the interface address bytes.  If this
     translated address is given to link_addr() without inserting an initial
     colon, the latter will not interpret it correctly.

BSD                              July 28, 1993                             BSD
```

net_addrcmp

```
NET_ADDRCMP(3)           BSD Library Functions Manual           NET_ADDRCMP(3)

NAME
     net_addrcmp -- compare socket address structures

SYNOPSIS
     #include <netdb.h>

     int
     net_addrcmp(struct sockaddr *sa1, struct sockaddr *sa2);

DESCRIPTION
     The net_addrcmp() function compares two socket address structures, sa1
     and sa2.

RETURN VALUES
     If sa1 and sa2 are for the same address, net_addrcmp() returns 0.

     The sa_len fields are compared first.  If they do not match,
     net_addrcmp() returns -1 or 1 if sa1->sa_len is less than or greater than
     sa2->sa_len, respectively.

     Next, the sa_family members are compared.  If they do not match,
     net_addrcmp() returns -1 or 1 if sa1->sa_family is less than or greater
     than sa2->sa_family, respectively.

     Lastly, if each socket address structure's sa_len and sa_family fields
     match, the protocol-specific data (the sa_data field) is compared.  If
     there's a match, both sa1 and sa2 must refer to the same address, and 0
     is returned; otherwise, a value >0 or <0 is returned.

HISTORY
     A net_addrcmp() function was added in OpenBSD 2.5.

BSD                              July 3, 1999                              BSD
```

ns

```
NS(3)                    BSD Library Functions Manual                    NS(3)
```

```
NAME
     ns_addr, ns_ntoa -- Xerox NS(tm) address conversion routines

SYNOPSIS
     #include <sys/types.h>
     #include <netns/ns.h>

     struct ns_addr
     ns_addr(char *cp);

     char *
     ns_ntoa(struct ns_addr ns);

DESCRIPTION
     The routine ns_addr() interprets character strings representing XNS
     addresses, returning binary information suitable for use in system calls.
     The routine ns_ntoa() takes XNS addresses and returns ASCII strings rep-
     resenting the address in a notation in common use in the Xerox Develop-
     ment Environment:

           <network number>.<host number>.<port number>

     Trailing zero fields are suppressed, and each number is printed in hexa-
     decimal, in a format suitable for input to ns_addr().  Any fields lacking
     super-decimal digits will have a trailing `H' appended.

     Unfortunately, no universal standard exists for representing XNS
     addresses.  An effort has been made to ensure that ns_addr() be compati-
     ble with most formats in common use.  It will first separate an address
     into 1 to 3 fields using a single delimiter chosen from period (`.'),
     colon (`:'), or pound-sign `#'.  Each field is then examined for byte
     separators (colon or period).  If there are byte separators, each sub-
     field separated is taken to be a small hexadecimal number, and the
     entirety is taken as a network-byte-ordered quantity to be zero extended
     in the high-network-order bytes.  Next, the field is inspected for
     hyphens, in which case the field is assumed to be a number in decimal
     notation with hyphens separating the millenia.  Next, the field is
     assumed to be a number: It is interpreted as hexadecimal if there is a
     leading `0x' (as in C), a trailing `H' (as in Mesa), or there are any
     super-decimal digits present.  It is interpreted as octal is there is a
     leading `0' and there are no super-octal digits.  Otherwise, it is con-
     verted as a decimal number.

     hosts(5), networks(5)

HISTORY
     The ns_addr() and ns_toa() functions appeared in 4.3BSD.

BUGS
     The string returned by ns_ntoa() resides in a static memory area.  The
     function ns_addr() should diagnose improperly formed input, and there
     should be an unambiguous way to recognize this.

BSD                             June 4, 1993                             BSD

RESOLVER(3)              BSD Library Functions Manual              RESOLVER(3)

NAME
     res_query, res_search, res_mkquery, res_send, res_init, dn_comp,
     dn_expand -- resolver routines

SYNOPSIS
     #include <sys/types.h>
     #include <netinet/in.h>
     #include <arpa/nameser.h>
     #include <resolv.h>

     int
     res_query(char *dname, int class, int type, u_char *answer, int anslen);

     int
     res_search(char *dname, int class, int type, u_char *answer, int anslen);

     int
     res_mkquery(int op, char *dname, int class, int type, char *data,
         int datalen, struct rrec *newrr, char *buf, int buflen);

     int
     res_send(char *msg, int msglen, char *answer, int anslen);

     int
     res_init(void);

     int
     dn_comp(char *exp_dn, char *comp_dn, int length, char **dnptrs,
         char **lastdnptr);

     int
     dn_expand(u_char *msg, u_char *eomorig, u_char *comp_dn, u_char *exp_dn,
         int length);

DESCRIPTION
     These routines are used for making, sending, and interpreting query and
     reply messages with Internet domain name servers.

     Global configuration and state information that is used by the resolver
     routines is kept in the structure _res.  Most of the values have reason-
     able defaults and can be ignored.  Options stored in _res.options are
     defined in <resolv.h> and are as follows.  Options are stored as a simple
     bit mask containing the bitwise OR of the options enabled.

     RES_INIT       True if the initial name server address and default domain
                    name are initialized (i.e., res_init() has been called).

     RES_DEBUG      Print debugging messages.

     RES_AAONLY     Accept authoritative answers only.  With this option,
                    res_send() should continue until it finds an authoritative
                    answer or finds an error.  Currently this is not imple-
                    mented.

     RES_USEVC      Use TCP connections for queries instead of UDP datagrams.

     RES_STAYOPEN   Used with RES_USEVC to keep the TCP connection open
                    between queries.  This is useful only in programs that
                    regularly do many queries.  UDP should be the normal mode
                    used.

     RES_IGNTC      Unused currently (ignore truncation errors, i.e., don't
                    retry with TCP).

     RES_RECURSE    Set the recursion-desired bit in queries.  This is the
                    default.  (res_send() does not do iterative queries and
                    expects the name server to handle recursion.)

     RES_DEFNAMES   If set, res_search() will append the default domain name
```

```
                    to single-component names (those that do not contain a
                    dot).  This option is enabled by default.

     RES_DNSRCH     If this option is set, res_search() will search for host
                    names in the current domain and in parent domains; see
                    hostname(7).  This is used by the standard host lookup
                    routine gethostbyname(3).  This option is enabled by
                    default.

     RES_USE_INET6  Enables support for IPv6-only applications.  This causes
                    IPv4 addresses to be returned as an IPv4 mapped address.
                    For example, 10.1.1.1 will be returned as ::ffff:10.1.1.1.
                    The option is not meaningful on OpenBSD.

     The res_init() routine reads the configuration file (if any; see
     resolv.conf(5)) to get the default domain name, search list, and the
     Internet address of the local name server(s).  If no server is config-
     ured, the host running the resolver is tried.  The current domain name is
     defined by the hostname if not specified in the configuration file; it
     can be overridden by the environment variable LOCALDOMAIN.  This environ-
     ment variable may contain several blank-separated tokens if you wish to
     override the search list on a per-process basis.  This is similar to the
     search command in the configuration file.  Another environment variable
     RES_OPTIONS can be set to override certain internal resolver options
     which are otherwise set by changing fields in the _res structure or are
     inherited from the configuration file's options command.  The syntax of
     the RES_OPTIONS environment variable is explained in resolv.conf(5).
     Initialization normally occurs on the first call to one of the following
     routines.

     The res_query() function provides an interface to the server query mecha-
     nism.  It constructs a query, sends it to the local server, awaits a
     response, and makes preliminary checks on the reply.  The query requests
     information of the specified type and class for the specified fully qual-
     ified domain name dname.  The reply message is left in the answer buffer
     with length anslen supplied by the caller.

     The res_search() routine makes a query and awaits a response like
     res_query(), but in addition, it implements the default and search rules
     controlled by the RES_DEFNAMES and RES_DNSRCH options.  It returns the
     first successful reply.

     The remaining routines are lower-level routines used by res_query().  The
     res_mkquery() function constructs a standard query message and places it
     in buf.  It returns the size of the query, or -1 if the query is larger
     than buflen.  The query type op is usually QUERY, but can be any of the
     query types defined in <arpa/nameser.h>.  The domain name for the query
     is given by dname.  newrr is currently unused but is intended for making
     update messages.

     The res_send() routine sends a pre-formatted query and returns an answer.
     It will call res_init() if RES_INIT is not set, send the query to the
     local name server, and handle timeouts and retries.  The length of the
     reply message is returned, or -1 if there were errors.

     The dn_comp() function compresses the domain name exp_dn and stores it in
     comp_dn.  The size of the compressed name is returned or -1 if there were
     errors.  The size of the array pointed to by comp_dn is given by length.
     The compression uses an array of pointers dnptrs to previously compressed
     names in the current message.  The first pointer points to the beginning
     of the message and the list ends with NULL.  The limit to the array is
     specified by lastdnptr.  A side effect of dn_comp() is to update the list
     of pointers for labels inserted into the message as the name is com-
     pressed.  If dnptr is NULL, names are not compressed.  If lastdnptr is
     NULL, the list of labels is not updated.

     The dn_expand() entry expands the compressed domain name comp_dn to a
     full domain name The compressed name is contained in a query or reply
     message; msg is a pointer to the beginning of the message.  The uncom-
     pressed name is placed in the buffer indicated by exp_dn which is of size
     length.  The size of compressed name is returned or -1 if there was an
     error.

HISTORY
     The res_query function appeared in 4.3BSD.

BSD                              June 4, 1993                              BSD
```

accept

```
ACCEPT(2)                   BSD System Calls Manual                  ACCEPT(2)

NAME
     accept -- accept a connection on a socket

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     accept(int s, struct sockaddr *addr, socklen_t *addrlen);

DESCRIPTION
     The argument s is a socket that has been created with socket(2), bound to
     an address with bind(2), and is listening for connections after a
     listen(2).  The accept() argument extracts the first connection request
     on the queue of pending connections, creates a new socket with the same
     properties of s, and allocates a new file descriptor for the socket.  If
     no pending connections are present on the queue, and the socket is not
     marked as non-blocking, accept() blocks the caller until a connection is
     present.  If the socket is marked non-blocking and no pending connections
     are present on the queue, accept() returns an error as described below.
     The accepted socket may not be used to accept more connections.  The
     original socket s remains open.

     The argument addr is a result parameter that is filled in with the
     address of the connecting entity as known to the communications layer.
     The exact format of the addr parameter is determined by the domain in
     which the communication is occurring.  The addrlen is a value-result
     parameter; it should initially contain the amount of space pointed to by
     addr; on return it will contain the actual length (in bytes) of the
     address returned.  This call is used with connection-based socket types,
     currently with SOCK_STREAM.

     It is possible to select(2) or poll(2) a socket for the purposes of doing
     an accept() by selecting it for read.

     For certain protocols which require an explicit confirmation, such as ISO
     or DATAKIT, accept() can be thought of as merely dequeuing the next con-
     nection request and not implying confirmation.  Confirmation can be
     implied by a normal read or write on the new file descriptor, and rejec-
     tion can be implied by closing the new socket.
     One can obtain user connection request data without confirming the con-
     nection by issuing a recvmsg(2) call with an msg_iovlen of 0 and a non-
     zero msg_controllen, or by issuing a getsockopt(2) request.  Similarly,
     one can provide user connection rejection information by issuing a
     sendmsg(2) call with providing only the control information, or by call-
     ing setsockopt(2).

RETURN VALUES
     The call returns -1 on error.  If it succeeds, it returns a non-negative
     integer that is a descriptor for the accepted socket.

ERRORS
     The accept() will fail if:

     [EBADF]            The descriptor is invalid.

     [ENOTSOCK]         The descriptor references a file, not a socket.

     [EOPNOTSUPP]       The referenced socket is not of type SOCK_STREAM.

     [EINVAL]           The referenced socket is not listening for connections
                        (that is, listen(2) has not yet been called).

     [EFAULT]           The addr parameter is not in a writable part of the
                        user address space.

     [EWOULDBLOCK]      The socket is marked non-blocking and no connections
                        are present to be accepted.

     [EMFILE]           The per-process descriptor table is full.

     [ENFILE]           The system file table is full.

     [ECONNABORTED]     A connection has been aborted.

HISTORY
     The accept() function appeared in 4.2BSD.

BSD                            February 15, 1999                           BSD
```

bind

```
BIND(2)                     BSD System Calls Manual                    BIND(2)

NAME
     bind -- bind a name to a socket

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     bind(int s, const struct sockaddr *name, socklen_t namelen);

DESCRIPTION
     bind() assigns a name to an unnamed socket.  When a socket is created
     with socket(2) it exists in a name space (address family) but has no name
     assigned.  bind() requests that name be assigned to the socket.

NOTES
     Binding a name in the UNIX domain creates a socket in the file system
     that must be deleted by the caller when it is no longer needed (using
     unlink(2)).
     The rules used in name binding vary between communication domains.  Con-
     sult the manual entries in section 4 for detailed information.

RETURN VALUES
     If the bind is successful, a 0 value is returned.  A return value of -1
     indicates an error, which is further specified in the global errno.

ERRORS
     The bind() call will fail if:

     [EBADF]            S is not a valid descriptor.

     [ENOTSOCK]         S is not a socket.

     [EADDRNOTAVAIL]    The specified address is not available from the local
                        machine.

     [EADDRINUSE]       The specified address is already in use.

     [EINVAL]           The socket is already bound to an address.

     [EINVAL]           The family of the socket and that requested in
                        name->sa_family are not equivalent.

     [EACCES]           The requested address is protected, and the current
                        user has inadequate permission to access it.

     [EFAULT]           The name parameter is not in a valid part of the user
                        address space.

     The following errors are specific to binding names in the UNIX domain.

     [ENOTDIR]          A component of the path prefix is not a directory.

     [ENAMETOOLONG]     A component of a pathname exceeded {NAME_MAX} charac-
                        ters, or an entire path name exceeded {PATH_MAX} char-
                        acters.

     [ENOENT]           A prefix component of the path name does not exist.

     [ELOOP]            Too many symbolic links were encountered in translat-
                        ing the pathname.

     [EIO]              An I/O error occurred while making the directory entry
                        or allocating the inode.

     [EROFS]            The name would reside on a read-only file system.

     [EISDIR]           An empty pathname was specified.

SEE ALSO
     connect(2), getsockname(2), listen(2), socket(2)

HISTORY
     The bind() function call appeared in 4.2BSD.

BSD                             February 15, 1999                            BSD
```

connect

```
CONNECT(2)                   BSD System Calls Manual                  CONNECT(2)

NAME
     connect -- initiate a connection on a socket
```

```
SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     connect(int s, const struct sockaddr *name, socklen_t namelen);

DESCRIPTION
     The parameter s is a socket.  If it is of type SOCK_DGRAM, this call
     specifies the peer with which the socket is to be associated; this
     address is that to which datagrams are to be sent, and the only address
     from which datagrams are to be received.  If the socket is of type
     SOCK_STREAM, this call attempts to make a connection to another socket.
     The other socket is specified by name, which is an address in the commu-
     nications space of the socket.  Each communications space interprets the
     name parameter in its own way.  Generally, stream sockets may success-
     fully connect() only once; datagram sockets may use connect() multiple
     times to change their association.  Datagram sockets may dissolve the
     association by connecting to an invalid address, such as a null address.

RETURN VALUES
     If the connection or binding succeeds, 0 is returned.  Otherwise a -1 is
     returned, and a more specific error code is stored in errno.

ERRORS
     The connect() call fails if:

     [EBADF]            S is not a valid descriptor.

     [ENOTSOCK]         S is a descriptor for a file, not a socket.

     [EADDRNOTAVAIL]    The specified address is not available on this
                        machine.

     [EAFNOSUPPORT]     Addresses in the specified address family cannot be
                        used with this socket.

     [EISCONN]          The socket is already connected.

     [ETIMEDOUT]        Connection establishment timed out without establish-
                        ing a connection.

     [EINVAL]           A TCP connection with a local broadcast, the all-ones
                        or a multicast address as the peer was attempted.

     [ECONNREFUSED]     The attempt to connect was forcefully rejected.

     [EINTR]            A connect was interrupted before it succeeded by the
                        delivery of a signal.

     [ENETUNREACH]      The network isn't reachable from this host.

     [EADDRINUSE]       The address is already in use.

     [EFAULT]           The name parameter specifies an area outside the
                        process address space.

     [EINPROGRESS]      The socket is non-blocking and the connection cannot
                        be completed immediately.  It is possible to select(2)
                        or poll(2) for completion by selecting the socket for
                        writing, and also use getsockopt(2) with SO_ERROR to
                        check for error conditions.

     [EALREADY]         The socket is non-blocking and a previous connection
                        attempt has not yet been completed.

     The following errors are specific to connecting names in the UNIX domain.
     These errors may not apply in future versions of the UNIX IPC domain.

     [ENOTDIR]          A component of the path prefix is not a directory.

     [ENAMETOOLONG]     A component of a pathname exceeded {NAME_MAX} charac-
                        ters, or an entire path name exceeded {PATH_MAX} char-
                        acters.

     [ENOENT]           The named socket does not exist.

     [EACCES]           Search permission is denied for a component of the
                        path prefix.

     [EACCES]           Write access to the named socket is denied.

     [ELOOP]            Too many symbolic links were encountered in translat-
                        ing the pathname.

HISTORY
     The connect() function call appeared in 4.2BSD.

BSD                            February 15, 1999                           BSD
```

getpeername

```
GETPEERNAME(2)              BSD System Calls Manual             GETPEERNAME(2)

NAME
     getpeername -- get name of connected peer

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     getpeername(int s, struct sockaddr *name, socklen_t *namelen);

DESCRIPTION
     getpeername() returns the address information of the peer connected to
     socket s.  One common use occurs when a process inherits an open socket,
     such as TCP servers forked from inetd(8).  In this scenario,
     getpeername() is used to determine the connecting client's IP address.

     getpeername() takes three parameters:

     s Contains the file descriptor of the socket whose peer should be looked
     up.

     name Points to a sockaddr structure that will hold the address informa-
     tion for the connected peer.  Normal use requires one to use a structure
     specific to the protocol family in use, such as sockaddr_in (IPv4) or
     sockaddr_in6 (IPv6), cast to a (struct sockaddr *).

     For greater portability, especially with the newer protocol families, the
     new struct sockaddr_storage should be used.  sockaddr_storage is large
     enough to hold any of the other sockaddr_* variants.  On return, it can
     be cast to the correct sockaddr type, based the protocol family contained
     in its ss_family field.

     namelen Indicates the amount of space pointed to by name, in bytes.

     If address information for the local end of the socket is required, the
     getsockname(2) function should be used instead.
     If name does not point to enough space to hold the entire socket address,
     the result will be truncated to namelen bytes.

RETURN VALUES
     If the call succeeds, a 0 is returned and namelen is set to the actual
     size of the socket address returned in name.  Otherwise, errno is set and
     a value of -1 is returned.

ERRORS
     On failure, errno is set to one of the following:

     [EBADF]            The argument s is not a valid descriptor.

     [ENOTSOCK]         The argument s is a file, not a socket.

     [ENOTCONN]         The socket is not connected.

     [ENOBUFS]          Insufficient resources were available in the system to
                        perform the operation.

     [EFAULT]           The name parameter points to memory not in a valid
                        part of the process address space.

     accept(2), bind(2), getsockname(2), getpeereid(2), socket(2)

HISTORY
     The getpeername() function call appeared in 4.2BSD.

BSD                             July 17, 1999                            BSD
```

getsockname

```
GETSOCKNAME(2)             BSD System Calls Manual            GETSOCKNAME(2)

NAME
     getsockname -- get socket name

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     getsockname(int s, struct sockaddr *name, socklen_t *namelen);

DESCRIPTION
     getsockname() returns the locally bound address information for a speci-
     fied socket.

     Common uses of this function are as follows:

     +   When bind(2) is called with a port number of 0 (indicating the kernel
         should pick an ephemeral port) getsockname() is used to retrieve the
         kernel-assigned port number.

     +   When a process calls bind(2) on a wildcard IP address, getsockname()
         is used to retrieve the local IP address for the connection.

     +   When a function wishes to know the address family of a socket,
         getsockname() can be used.

     getsockname() takes three parameters:

     s, Contains the file desriptor for the socket to be looked up.
     name points to a sockaddr structure which will hold the resulting address
     information.  Normal use requires one to use a structure specific to the
     protocol family in use, such as sockaddr_in (IPv4) or sockaddr_in6
     (IPv6), cast to a (struct sockaddr *).

     For greater portability (such as newer protocol families) the new struc-
     ture sockaddr_storage exists.  sockaddr_storage is large enough to hold
     any of the other sockaddr_* variants.  On return, it should be cast to
     the correct sockaddr type, according to the current protocol family.

     namelen Indicates the amount of space pointed to by name, in bytes.  Upon
     return, namelen is set to the actual size of the returned address infor-
     mation.

     If the address of the destination socket for a given socket connection is
     needed, the getpeername(2) function should be used instead.

     If name does not point to enough space to hold the entire socket address,
     the result will be truncated to namelen bytes.

RETURN VALUES
     On success, getsockname() returns a 0, and namelen is set to the actual
     size of the socket address returned in name.  Otherwise, errno is set,
     and a value of -1 is returned.

ERRORS
     If getsockname() fails, errno is set to one of the following:

     [EBADF]            The argument s is not a valid descriptor.

     [ENOTSOCK]         The argument s is a file, not a socket.

     [ENOBUFS]          Insufficient resources were available in the system to
                        perform the operation.

     [EFAULT]           The name parameter points to memory not in a valid
                        part of the process address space.

SEE ALSO
     accept(2), bind(2), getpeername(2), getpeereid(2), socket(2)

BUGS
     Names bound to sockets in the UNIX domain are inaccessible; getsockname
     returns a zero length name.

HISTORY
     The getsockname() function call appeared in 4.2BSD.

BSD                             July 17, 1999                            BSD

getsockopt

```
GETSOCKOPT(2)               BSD System Calls Manual              GETSOCKOPT(2)

NAME
     getsockopt, setsockopt -- get and set options on sockets

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     getsockopt(int s, int level, int optname, void *optval,
         socklen_t *optlen);

     int
     setsockopt(int s, int level, int optname, const void *optval,
         socklen_t optlen);

DESCRIPTION
     getsockopt() and setsockopt() manipulate the options associated with a
     socket.  Options may exist at multiple protocol levels; they are always
     present at the uppermost ``socket'' level.

     When manipulating socket options the level at which the option resides
     and the name of the option must be specified.  To manipulate options at
     the socket level, level is specified as SOL_SOCKET.  To manipulate
     options at any other level the protocol number of the appropriate proto-
     col controlling the option is supplied.  For example, to indicate that an
     option is to be interpreted by the TCP protocol, level should be set to
     the protocol number of TCP; see getprotoent(3).

     The parameters optval and optlen are used to access option values for
     setsockopt().  For getsockopt() they identify a buffer in which the value
     for the requested option(s) are to be returned.  For getsockopt(), optlen
     is a value-result parameter, initially containing the size of the buffer
     pointed to by optval, and modified on return to indicate the actual size
     of the value returned.  If no option value is to be supplied or returned,
     optval may be NULL.

     optname and any specified options are passed uninterpreted to the appro-
     priate protocol module for interpretation.  The include file
     <sys/socket.h> contains definitions for socket level options, described
     below.  Options at other protocol levels vary in format and name; consult
     the appropriate entries in section 4 of the manual.

     Most socket-level options utilize an int parameter for optval.  For
     setsockopt(), the parameter should be non-zero to enable a boolean
     option, or zero if the option is to be disabled.  SO_LINGER uses a struct
     linger parameter, defined in <sys/socket.h>, which specifies the desired
     state of the option and the linger interval (see below).  SO_SNDTIMEO and
     SO_RCVTIMEO use a struct timeval parameter, defined in <sys/time.h>.

     The following options are recognized at the socket level.  Except as
     noted, each may be examined with getsockopt() and set with setsockopt().

           SO_DEBUG        enables recording of debugging information
           SO_REUSEADDR    enables local address reuse
           SO_REUSEPORT    enables duplicate address and port bindings
           SO_KEEPALIVE    enables keep connections alive
           SO_DONTROUTE    enables routing bypass for outgoing messages
           SO_LINGER       linger on close if data present
           SO_BROADCAST    enables permission to transmit broadcast messages
           SO_OOBINLINE    enables reception of out-of-band data in band
           SO_SNDBUF       set buffer size for output
           SO_RCVBUF       set buffer size for input
           SO_SNDLOWAT     set minimum count for output
           SO_RCVLOWAT     set minimum count for input
           SO_SNDTIMEO     set timeout value for output
           SO_RCVTIMEO     set timeout value for input
           SO_TYPE         get the type of the socket (get only)
           SO_ERROR        get and clear error on the socket (get only)

     SO_DEBUG enables debugging in the underlying protocol modules.
     SO_REUSEADDR indicates that the rules used in validating addresses sup-
     plied in a bind(2) call should allow reuse of local addresses.
     SO_REUSEPORT allows completely duplicate bindings by multiple processes
     if they all set SO_REUSEPORT before binding the port.  This option per-
     mits multiple instances of a program to each receive UDP/IP multicast or
     broadcast datagrams destined for the bound port.  SO_KEEPALIVE enables
     the periodic transmission of messages on a connected socket.  Should the
     connected party fail to respond to these messages, the connection is con-
     sidered broken and processes using the socket are notified via a SIGPIPE
     signal when attempting to send data.  SO_DONTROUTE indicates that outgo-
     ing messages should bypass the standard routing facilities.  Instead,
     messages are directed to the appropriate network interface according to
     the network portion of the destination address.

     SO_LINGER controls the action taken when unsent messages are queued on
     socket and a close(2) is performed.  If the socket promises reliable
     delivery of data and SO_LINGER is set, the system will block the process
     on the close(2) attempt until it is able to transmit the data or until it
     decides it is unable to deliver the information (a timeout period mea-
     sured in seconds, termed the linger interval, is specified in the
     setsockopt() call when SO_LINGER is requested).  If SO_LINGER is disabled
     and a close(2) is issued, the system will process the close in a manner
     that allows the process to continue as quickly as possible.

     The option SO_BROADCAST requests permission to send broadcast datagrams
     on the socket.  Broadcast was a privileged operation in earlier versions
     of the system.  With protocols that support out-of-band data, the
     SO_OOBINLINE option requests that out-of-band data be placed in the nor-
     mal data input queue as received; it will then be accessible with recv(2)
     or read(2) calls without the MSG_OOB flag.  Some protocols always behave
     as if this option is set.  SO_SNDBUF and SO_RCVBUF are options to adjust
     the normal buffer sizes allocated for output and input buffers, respec-
     tively.  The buffer size may be increased for high-volume connections, or
     may be decreased to limit the possible backlog of incoming data.  The
     system places an absolute limit on these values.

     SO_SNDLOWAT is an option to set the minimum count for output operations.
     Most output operations process all of the data supplied by the call,
     delivering data to the protocol for transmission and blocking as neces-
     sary for flow control.  Nonblocking output operations will process as
     much data as permitted subject to flow control without blocking, but will
     process no data if flow control does not allow the smaller of the low
     water mark value or the entire request to be processed.  A select(2) or
     poll(2) operation testing the ability to write to a socket will return
     true only if the low water mark amount could be processed.  The default
     value for SO_SNDLOWAT is set to a convenient size for network efficiency,
     often 1024.  SO_RCVLOWAT is an option to set the minimum count for input
     operations.  In general, receive calls will block until any (non-zero)
     amount of data is received, then return with the smaller of the amount
     available or the amount requested.  The default value for SO_RCVLOWAT is
     1.  If SO_RCVLOWAT is set to a larger value, blocking receive calls nor-
     mally wait until they have received the smaller of the low water mark
     value or the requested amount.  Receive calls may still return less than
     the low water mark if an error occurs, a signal is caught, or the type of
     data next in the receive queue is different than that returned.

     SO_SNDTIMEO is an option to set a timeout value for output operations.
     It accepts a struct timeval parameter with the number of seconds and
     microseconds used to limit waits for output operations to complete.  If a
     send operation has blocked for this much time, it returns with a partial
     count or with the error EWOULDBLOCK if no data was sent.  In the current
     implementation, this timer is restarted each time additional data are
     delivered to the protocol, implying that the limit applies to output por-
     tions ranging in size from the low water mark to the high water mark for
     output.  SO_RCVTIMEO is an option to set a timeout value for input opera-
     tions.  It accepts a struct timeval parameter with the number of seconds
     and microseconds used to limit waits for input operations to complete.
     In the current implementation, this timer is restarted each time addi-
     tional data are received by the protocol, and thus the limit is in effect
     an inactivity timer.  If a receive operation has been blocked for this
     much time without receiving additional data, it returns with a short
     count or with the error EWOULDBLOCK if no data were received.

     Finally, SO_TYPE and SO_ERROR are options used only with getsockopt().
     SO_TYPE returns the type of the socket, such as SOCK_STREAM; it is useful
     for servers that inherit sockets on startup.  SO_ERROR returns any pend-
     ing error on the socket and clears the error status.  It may be used to
     check for asynchronous errors on connected datagram sockets or for other
     asynchronous errors.

RETURN VALUES
     A 0 is returned if the call succeeds, -1 if it fails.

ERRORS
     The call succeeds unless:

     [EBADF]            The argument s is not a valid descriptor.

     [ENOTSOCK]         The argument s is a file, not a socket.

     [ENOPROTOOPT]      The option is unknown at the level indicated.

     [EFAULT]           The address pointed to by optval is not in a valid
                        part of the process address space.  For getsockopt(),
                        this error may also be returned if optlen is not in a
                        valid part of the process address space.

SEE ALSO
     connect(2), ioctl(2), poll(2), select(2), poll(2), socket(2),
     getprotoent(3), protocols(5)

BUGS
     Several of the socket options should be handled at lower levels of the
     system.

HISTORY
     The getsockopt() system call appeared in 4.2BSD.

BSD                             February 15, 1999                            BSD
```

ioctl

```
IOCTL(2)                   BSD System Calls Manual                   IOCTL(2)

NAME
     ioctl -- control device

SYNOPSIS
     #include <sys/ioctl.h>

     int
     ioctl(int d, unsigned long request, …);

DESCRIPTION
     The ioctl() function manipulates the underlying device parameters of spe-
     cial files.  In particular, many operating characteristics of character
     special files (e.g., terminals) may be controlled with ioctl() requests.

     The argument d must be an open file descriptor. The third argument is
     called arg and contains additional information needed by this device to
     perform the requested function.  arg is either an int or a pointer to a
     device-specific data structure, depending upon the given request.

     An ioctl request has encoded in it whether the argument is an ``in''
     parameter or ``out'' parameter, and the size of the third argument (arg)
     in bytes.  Macros and defines used in specifying an ioctl request are
     located in the file <sys/ioctl.h>.

RETURN VALUES
     If an error has occurred, a value of -1 is returned and errno is set to
     indicate the error.
```

```
ERRORS
     ioctl() will fail if:

     [EBADF]            d is not a valid descriptor.

     [ENOTTY]           d is not associated with a character special device.

     [ENOTTY]           The specified request does not apply to the kind of
                        object that the descriptor d references.

     [EINVAL]           request or arg is not valid.

     [EFAULT]           arg points outside the process's allocated address
                        space.

HISTORY
     An ioctl() function call appeared in Version 7 AT&T UNIX.

BSD                            December 11, 1993                           BSD
```

listen

```
LISTEN(2)                   BSD System Calls Manual                  LISTEN(2)

NAME
     listen -- listen for connections on a socket

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     listen(int s, int backlog);

DESCRIPTION
     To accept connections, a socket is first created with socket(2), a will-
     ingness to accept incoming connections and a queue limit for incoming
     connections are specified with listen(), and then the connections are
     accepted with accept(2).  The listen() call applies only to sockets of
     type SOCK_STREAM or SOCK_SEQPACKET.

     The backlog parameter defines the maximum length the queue of pending
     connections may grow to.  If a connection request arrives with the queue
     full the client may receive an error with an indication of ECONNREFUSED,
     or, if the underlying protocol supports retransmission, the request may
     be ignored so that retries may succeed.

RETURN VALUES
     A 0 return value indicates success; -1 indicates an error.

ERRORS
     listen() will fail if:

     [EBADF]            The argument s is not a valid descriptor.

     [ENOTSOCK]         The argument s is not a socket.

     [EOPNOTSUPP]       The socket is not of a type that supports the opera-
                        tion listen().

SEE ALSO
     accept(2), connect(2), socket(2)
```

```
HISTORY
     The listen() function call appeared in 4.2BSD.

BUGS
     The backlog is currently limited (silently) to 128.

BSD                            December 11, 1993                           BSD
```

poll

```
POLL(2)                    BSD System Calls Manual                   POLL(2)

NAME
     poll -- synchronous I/O multiplexing

SYNOPSIS
     #include <poll.h>

     int
     poll(struct pollfd *fds, int nfds, int timeout);

DESCRIPTION
     poll() provides a mechanism for reporting I/O conditions across a set of
     file descriptors.

     The arguments are as follows:

     fds      Points to an array of pollfd structures, which are defined as:

                    struct pollfd {
                            int fd;
                            short events;
                            short revents;
                    };

              The fd member is an open file descriptor.  The events and
              revents members are bitmasks of conditions to monitor and condi-
              tions found, respectively.

     nfds     The number of pollfd structures in the array.

     timeout  Maximum interval to wait for the poll to complete, in millisec-
              onds.  If this value is 0, then poll() will return immediately.
              If this value is INFTIM (-1), poll() will block indefinitely
              until a condition is found.

     The calling process sets the events bitmask and poll() sets the revents
     bitmask.  Each call to poll() resets the revents bitmask for accuracy.
     The condition flags in the bitmasks are defined as:

     POLLIN      Data is available on the file descriptor for reading.

     POLLNORM    Same as POLLIN.

     POLLPRI     Same as POLLIN.

     POLLOUT     Data can be written to the file descriptor without blocking.

     POLLERR     This flag is not used in this implementation and is provided
                 only for source code compatibility.

     POLLHUP     The file descriptor was valid before the polling process and
                 invalid after.  Presumably, this means that the file descrip-
                 tor was closed sometime during the poll.

     POLLNVAL    The corresponding file descriptor is invalid.
     POLLRDNORM  Same as POLLIN.

     POLLRDBAND  Same as POLLIN.

     POLLWRNORM  Same as POLLOUT.

     POLLWRBAND  Same as POLLOUT.

     POLLMSG     This flag is not used in this implementation and is provided
                 only for source code compatibility.

     All flags except POLLIN, POLLOUT, and their synonyms are for use only in
     the revents member of the pollfd structure.  An attempt to set any of
     these flags in the events member will generate an error condition.

     In addition to I/O multiplexing, poll() can be used to generate simple
     timeouts.  This functionality may be achieved by passing a null pointer
     for fds.

WARNINGS
     The POLLHUP flag is only a close approximation and may not always be
     accurate.

RETURN VALUES
     Upon error, poll() returns a -1 and sets the global variable errno to
     indicate the error.  If the timeout interval was reached before any
     events occurred, a 0 is returned.  Otherwise, poll() returns the number
     of file descriptors for which revents is non-zero.

ERRORS
     poll() will fail if:

     [EINVAL]   nfds was either a negative number or greater than the number
                of available file descriptors.

     [EINVAL]   An invalid flags was set in the events member of the pollfd
                structure.

     [EINVAL]   The timeout passed to poll() was too large.

     [EAGAIN]   Resource allocation failed inside of poll().  Subsequent calls
                to poll() may succeed.

     [EINTR]    poll() caught a signal during the polling process.

SEE ALSO
     poll(2), select(2), sysconf(3)

HISTORY
     A poll() system call appeared in AT&T System V UNIX.

BSD                            December 13, 1994                           BSD
```

select

```
SELECT(2)                   BSD System Calls Manual                  SELECT(2)

NAME
     select -- synchronous I/O multiplexing

SYNOPSIS
     #include <sys/types.h>
     #include <sys/time.h>
     #include <unistd.h>
     int
     select(int nfds, fd_set *readfds, fd_set *writefds, fd_set *exceptfds,
         struct timeval *timeout);

     FD_SET(fd, &fdset);

     FD_CLR(fd, &fdset);

     FD_ISSET(fd, &fdset);

     FD_ZERO(&fdset);

DESCRIPTION
     select() examines the I/O descriptor sets whose addresses are passed in
     readfds, writefds, and exceptfds to see if some of their descriptors are
     ready for reading, are ready for writing, or have an exceptional condi-
     tion pending, respectively.  The first nfds descriptors are checked in
     each set; i.e., the descriptors from 0 through nfds-1 in the descriptor
     sets are examined.  On return, select() replaces the given descriptor
     sets with subsets consisting of those descriptors that are ready for the
     requested operation.  select() returns the total number of ready descrip-
     tors in all the sets.

     The descriptor sets are stored as bit fields in arrays of integers.  The
     following macros are provided for manipulating such descriptor sets:
     FD_ZERO(&fdset) initializes a descriptor set fdset to the null set.
     FD_SET(fd, &fdset) includes a particular descriptor fd in fdset.
     FD_CLR(fd, &fdset) removes fd from fdset.  FD_ISSET(fd, &fdset) is non-
     zero if fd is a member of fdset, zero otherwise.  The behavior of these
     macros is undefined if a descriptor value is less than zero or greater
     than or equal to FD_SETSIZE, which is normally at least equal to the max-
     imum number of descriptors supported by the system.

     If timeout is a non-null pointer, it specifies a maximum interval to wait
     for the selection to complete.  If timeout is a null pointer, the select
     blocks indefinitely.  To effect a poll, the timeout argument should be
     non-null, pointing to a zero-valued timeval structure.  timeout is not
     changed by select(), and may be reused on subsequent calls; however, it
     is good style to re-initialize it before each invocation of select().

     Any of readfds, writefds, and exceptfds may be given as null pointers if
     no descriptors are of interest.

RETURN VALUES
     select() returns the number of ready descriptors that are contained in
     the descriptor sets, or -1 is an error occurred.  If the time limit
     expires, select() returns 0.  If select() returns with an error, includ-
     ing one due to an interrupted call, the descriptor sets will be unmodi-
     fied.

ERRORS
     An error return from select() indicates:

     [EFAULT]           One or more of readfds, writefds, or exceptfds points
                        outside the process's allocated address space.

     [EBADF]            One of the descriptor sets specified an invalid
                        descriptor.

     [EINTR]            A signal was delivered before the time limit expired
                        and before any of the selected events occurred.

     [EINVAL]           The specified time limit is invalid.  One of its com-
                        ponents is negative or too large.

     send(2), write(2), getdtablesize(3)

BUGS
     Although the provision of getdtablesize(3) was intended to allow user
     programs to be written independent of the kernel limit on the number of
     open files, the dimension of a sufficiently large bit field for select
     remains a problem.  The default bit size of fd_set is based on the symbol
     FD_SETSIZE (currently 256), but that is somewhat smaller than the current
     kernel limit to the number of open files.  However, in order to accommo-
     date programs which might potentially use a larger number of open files
     with select, it is possible to increase this size within a program by
     providing a larger definition of FD_SETSIZE before the inclusion of
     <sys/types.h>.  The kernel will cope, and the userland libraries provided
     with the system are also ready for large numbers of file descriptors.

     Alternatively, to be really safe, it is possible to allocate fd_set bit-
     arrays dynamically.  The idea is to permit a program to work properly
     even if it is execve(2)'d with 4000 file descriptors pre-allocated.  The
     following illustrates the technique which is used by userland libraries:

                   fd_set *fdsr;
                   int max = fd;

                   fdsr = (fd_set *)calloc(howmany(max+1, NFDBITS),
                       sizeof(fd_mask));
                   if (fdsr == NULL) {
                           …
                           return (-1);
                   }
                   FD_SET(fd, fdsr);
                   n = select(max+1, fdsr, NULL, NULL, &tv);
                   …
                   free(fdsr);

     Alternatively, it is possible to use the poll(2) interface.  poll(2) is
     more efficient when the size of select()'s fd_set bit-arrays are very
     large, and for fixed numbers of file descriptors one need not size and
     dynamically allocate a memory object.

     select() should probably have been designed to return the time remaining
     from the original timeout, if any, by modifying the time value in place.
     Even though some systems stupidly act in this different way, it is
     unlikely this semantic will ever be commonly implemented, as the change
     causes massive source code compatibility problems.  Furthermore, recent
     new standards have dictated the current behaviour.  In general, due to
     the existence of those brain-damaged non-conforming systems, it is unwise
     to assume that the timeout value will be unmodified by the select() call,
     and the caller should reinitialize it on each invocation.  Calculating
     the delta is easily done by calling gettimeofday(2) before and after the
     call to select(), and using timersub() (as described in getitimer(2)).

     Internally to the kernel, select() works poorly if multiple processes
     wait on the same file descriptor.  Given that, it is rather surprising to
     see that many daemons are written that way (i.e., httpd(8)).

HISTORY
     The select() function call appeared in 4.2BSD.

BSD                             March 25, 1994                             BSD
```

send

```
SEND(2)                     BSD System Calls Manual                    SEND(2)

NAME
     send, sendto, sendmsg -- send a message from a socket
```

```
SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     ssize_t
     send(int s, const void *msg, size_t len, int flags);

     ssize_t
     sendto(int s, const void *msg, size_t len, int flags,
         const struct sockaddr *to, socklen_t tolen);

     ssize_t
     sendmsg(int s, const struct msghdr *msg, int flags);

DESCRIPTION
     send(), sendto(), and sendmsg() are used to transmit a message to another
     socket.  send() may be used only when the socket is in a connected state,
     while sendto() and sendmsg() may be used at any time.

     The address of the target is given by to with tolen specifying its size.
     The length of the message is given by len.  If the message is too long to
     pass atomically through the underlying protocol, the error EMSGSIZE is
     returned, and the message is not transmitted.

     No indication of failure to deliver is implicit in a send().  Locally
     detected errors are indicated by a return value of -1.

     If no messages space is available at the socket to hold the message to be
     transmitted, then send() normally blocks, unless the socket has been
     placed in non-blocking I/O mode.  The select(2) or poll(2) system calls
     may be used to determine when it is possible to send more data.

     The flags parameter may include one or more of the following:

     #define MSG_OOB        0x1  /* process out-of-band data */
     #define MSG_DONTROUTE  0x4  /* bypass routing, use direct interface */

     The flag MSG_OOB is used to send ``out-of-band'' data on sockets that
     support this notion (e.g., SOCK_STREAM); the underlying protocol must
     also support ``out-of-band'' data.  MSG_DONTROUTE is usually used only by
     diagnostic or routing programs.

     See recv(2) for a description of the msghdr structure.

RETURN VALUES
     The call returns the number of characters sent, or -1 if an error
     occurred.

ERRORS
     send(), sendto(), and sendmsg() fail if:

     [EBADF]            An invalid descriptor was specified.

     [ENOTSOCK]         The argument s is not a socket.

     [EFAULT]           An invalid user space address was specified for a
                        parameter.

     [EMSGSIZE]         The socket requires that message be sent atomically,
                        and the size of the message to be sent made this
                        impossible.

     [EAGAIN]           The socket is marked non-blocking and the requested
                        operation would block.

     [ENOBUFS]          The system was unable to allocate an internal buffer.
```

```
                         The operation may succeed when buffers become avail-
                         able.

     [ENOBUFS]           The output queue for a network interface was full.
                         This generally indicates that the interface has
                         stopped sending, but may be caused by transient con-
                         gestion.

     [EACCES]            The SO_BROADCAST option is not set on the socket, and
                         a broadcast address was given as the destination.

     [EHOSTUNREACH]      The destination address specified an unreachable host.

     [EINVAL]            The flags parameter is invalid.

     [EHOSTDOWN]         The destination address specified a host that is down.

     [ENETDOWN]          The destination address specified a network that is
                         down.

     [ECONNREFUSED]      The destination host rejected the message (or a previ-
                         ous one).  This error can only be returned by con-
                         nected sockets.

     [ENOPROTOOPT]       There was a problem sending the message.  This error
                         can only be returned by connected sockets.

     [EDESTADDRREQ]      The socket is not connected, and no destination
                         address was specified.

     [EISCONN]           The socket is already connected, and a destination
                         address was specified.

     In addition, send() and sendto() may return the following error:

     [EINVAL]            len was larger than SSIZE_MAX.

     Also, sendmsg() may return the following errors:

     [EINVAL]            The sum of the iov_len values in the msg_iov array
                         overflowed an ssize_t.

     [EMSGSIZE]          The msg_iovlen member of msg was less than 0 or larger
                         than IOV_MAX.

     [EAFNOSUPPORT]      Addresses in the specified address family cannot be
                         used with this socket.

HISTORY
     The send() function call appeared in 4.2BSD.

BSD                              July 28, 1998                             BSD
```

shutdown

```
SHUTDOWN(2)                 BSD System Calls Manual                SHUTDOWN(2)

NAME
     shutdown -- shut down part of a full-duplex connection

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     shutdown(int s, int how);

DESCRIPTION
     The shutdown() call causes all or part of a full-duplex connection on the
     socket associated with s to be shut down.  If how is SHUT_RD, further
     receives will be disallowed.  If how is SHUT_WR, further sends will be
     disallowed.  If how is SHUT_RDWR, further sends and receives will be dis-
     allowed.

RETURN VALUES
     A 0 is returned if the call succeeds, -1 if it fails.

ERRORS
     The call succeeds unless:

     [EINVAL]           how is not SHUT_RD, SHUT_WR, or SHUT_RDWR.

     [EBADF]            s is not a valid descriptor.

     [ENOTSOCK]         s is a file, not a socket.

     [ENOTCONN]         The specified socket is not connected.

SEE ALSO
     connect(2), socket(2)

HISTORY
     The shutdown() function call appeared in 4.2BSD.  The how arguments used
     to be simply 0, 1, and 2, but now have named values as specified by
     X/Open Portability Guide Issue 4 (``XPG4'').

BSD                              June 4, 1993                              BSD
```

socket

```
SOCKET(2)                   BSD System Calls Manual                  SOCKET(2)

NAME
     socket -- create an endpoint for communication

SYNOPSIS
     #include <sys/types.h>
     #include <sys/socket.h>

     int
     socket(int domain, int type, int protocol);

DESCRIPTION
     socket() creates an endpoint for communication and returns a descriptor.

     The domain parameter specifies a communications domain within which com-
     munication will take place; this selects the protocol family which should
     be used.  These families are defined in the include file <sys/socket.h>.
     The currently understood formats are

           AF_UNIX          (UNIX internal protocols),
           AF_INET          (ARPA Internet protocols),
           AF_INET6         (ARPA IPv6 protocols),
           AF_ISO           (ISO protocols),
           AF_NS            (Xerox Network Systems protocols),
           AF_IPX           (Internetwork Packet Exchange), and
           AF_IMPLINK       (IMP host at IMP link layer).
     The socket has the indicated type, which specifies the semantics of com-
     munication.  Currently defined types are:

           SOCK_STREAM
           SOCK_DGRAM
           SOCK_RAW
           SOCK_SEQPACKET
           SOCK_RDM

     A SOCK_STREAM type provides sequenced, reliable, two-way connection based
     byte streams.  An out-of-band data transmission mechanism may be sup-
     ported.  A SOCK_DGRAM socket supports datagrams (connectionless, unreli-
     able messages of a fixed (typically small) maximum length).  A
     SOCK_SEQPACKET socket may provide a sequenced, reliable, two-way connec-
     tion-based data transmission path for datagrams of fixed maximum length;
     a consumer may be required to read an entire packet with each read system
     call.  This facility is protocol specific, and presently implemented only
     for PF_NS.  SOCK_RAW sockets provide access to internal network protocols
     and interfaces.  The types SOCK_RAW, which is available only to the supe-
     ruser, and SOCK_RDM, which is planned, but not yet implemented, are not
     described here.

     The protocol specifies a particular protocol to be used with the socket.
     Normally only a single protocol exists to support a particular socket
     type within a given protocol family.  However, it is possible that many
     protocols may exist, in which case a particular protocol must be speci-
     fied in this manner.  The protocol number to use is particular to the
     communication domain in which communication is to take place; see
     protocols(5).  A value of 0 for protocol will let the system select an
     appropriate protocol for the requested socket type.

     Sockets of type SOCK_STREAM are full-duplex byte streams, similar to
     pipes.  A stream socket must be in a connected state before any data may
     be sent or received on it.  A connection to another socket is created
     with a connect(2) call.  Once connected, data may be transferred using
     read(2) and write(2) calls or some variant of the send(2) and recv(2)
     calls.  When a session has been completed a close(2) may be performed.
     Out-of-band data may also be transmitted as described in send(2) and
     received as described in recv(2).

     The communications protocols used to implement a SOCK_STREAM ensure that
     data is not lost or duplicated.  If a piece of data for which the peer
     protocol has buffer space cannot be successfully transmitted within a
     reasonable length of time, then the connection is considered broken and
     calls will indicate an error with -1 returns and with ETIMEDOUT as the
     specific code in the global variable errno.  The protocols optionally
     keep sockets ``warm'' by forcing transmissions roughly every minute in
     the absence of other activity.  An error is then indicated if no response
     can be elicited on an otherwise idle connection for a extended period
     (e.g., 5 minutes).  A SIGPIPE signal is raised if a process sends on a
     broken stream; this causes naive processes, which do not handle the sig-
     nal, to exit.

     SOCK_SEQPACKET sockets employ the same system calls as SOCK_STREAM sock-
     ets.  The only difference is that read(2) calls will return only the
     amount of data requested, and any remaining in the arriving packet will
     be discarded.

     SOCK_DGRAM and SOCK_RAW sockets allow sending of datagrams to correspon-
     dents named in send(2) calls.  Datagrams are generally received with
     recvfrom(2), which returns the next datagram with its return address.

     An fcntl(2) call can be used to specify a process group to receive a
     SIGURG signal when the out-of-band data arrives.  It may also enable non-
     blocking I/O and asynchronous notification of I/O events via SIGIO.

     The operation of sockets is controlled by socket level options.  These
     options are defined in the file <sys/socket.h>.  setsockopt(2) and
     getsockopt(2) are used to set and get options, respectively.

RETURN VALUES
     A -1 is returned if an error occurs, otherwise the return value is a
     descriptor referencing the socket.

ERRORS
     The socket() call fails if:

     [EPROTONOSUPPORT]  The protocol type or the specified protocol is not
                        supported within this domain.

     [EMFILE]           The per-process descriptor table is full.

     [ENFILE]           The system file table is full.

     [EACCES]           Permission to create a socket of the specified type
                        and/or protocol is denied.

     [ENOBUFS]          Insufficient buffer space is available.  The socket
                        cannot be created until sufficient resources are
                        freed.

Part XLII. FreeBSD TCP/IP Stack port for eCos

TCP/IP Networking for eCos now provides a complete TCP/IP networking stack, based on a recent snapshot of the FreeBSD code, released by the KAME project. The networking support is fully featured and well tested within the eCos environment.

Table of Contents

Chapter 150. Networking Stack Features

Since this networking package is based on BSD code, it is very complete and robust. The eCos implementation includes support for the following protocols:

- IPv4
- UDP
- TCP
- ICMP
- raw packet interface
- Multi-cast addressing
- IPv6 (including UDP, ICP, ICMP)

These additional features are also present in the package, but are not supported:

- Berkeley Packet Filter
- Uni-cast support
- Multi-cast routing

Chapter 151. Freebsd TCP/IP stack port

This document describes how to get started with the Freebsd TCP/IP network stack.

Targets

A number of ethernet devices may be supported. The default configuration supports two instances of the interface by default, and you will need to write your own driver instantiation code, and supplemental startup and initialization code, if you should add additional ones.

The target for your board will normally be supplied with an ethernet driver, in which case including the network stack and generic ethernet driver package to your build will automatically enable usage of the ethernet device driver. If your target is not supplied with an ethernet driver, you will need to use loopback (see the section called “Loopback tests”).

Building the Network Stack

Using the *Build->Packages* dialog, add the packages “Networking”, “Freebsd TCP/IP Stack” and “Common Ethernet Support” to your configuration. Their package names are CYGPKG_NET, CYGPKG_NET_FREEBSD_STACK and CYGPKG_NET_ETH_DRIVERS respectively.

A short-cut way to do this is by using the “net” *template* if it is available for your platform.

The platform-specific ethernet device driver for your platform will be added as part of the target selection (in the *Build->Templates* “Hardware” item), along with the PCI I/O subsystem (if relevent) and the appropriate serial device driver.

For example, the PowerPC MBX target selection adds the package PKG_NET_QUICC_ETH_DRIVERS, and the Cirrus Logic EDB7xxx target selection adds the package CYGPKG_NET_EDB7XXX_ETH_DRIVERS. After this, eCos and its tests can be built exactly as usual.

Note

By default, most of the network tests are not built. This is because some of them require manual intervention, i.e. they are to be run “by hand”, and are not suitable for automated testing. To build the full set of network tests, set the configuration option CYGPKG_NET_BUILD_HW_TESTS “Build hardware networking tests (demo programs)” within “Networking support build options”.

Chapter 152. APIs

Standard networking

The APIs for the standard networking calls such as `socket()`, `recv()` and so on, are in header files relative to the top-level include directory, within the standard subdirectories as conventionally found in `/usr/include`. For example:

```
install/include/arpa/tftp.h
install/include/netinet/tcpip.h
install/include/sys/socket.h
install/include/sys/socketvar.h
install/include/sys/sockio.h
```

`network.h` at the top level defines various extensions, for example the API `init_all_network_interfaces(void)` described above. We advise including `network.h` whether you use these features or not.

In general, using the networking code may require definition of two symbols: _KERNEL and __ECOS. _KERNEL is not normally required; __ECOS is normally required. So add this to your compile lines for files which use the network stack:

```
        -D__ECOS
```

To expand a little, it,s like this because this is a port of a standard distribution external to eCos. One goal is to perturb the sources as little as possible, so that upgrading and maintenance from the external distribution is simplified. The __ECOS symbol marks out the eCos additions in making the port. The _KERNEL symbol is traditional UNIX practice: it distinguishes a compilation which is to be linked into the kernel from one which is part of an application. eCos applications are fully linked, so this distinction does not apply. _KERNEL can however be used to control the visibility of the internals of the stack, so depending on what features your application uses, it may or may not be necessary.

The include file `network.h` undefines _KERNEL unconditionally, to provide an application-like compilation environment. If you were writing code which, for example, enumerates the stack,s internal structures, that is a kernel-like compilation environment, so you would need to define _KERNEL (in addition to __ECOS) and avoid including `network.h`.

Part XLIII. eCos PPP User Guide

This package provides support for PPP (Point-to-Point Protocol) in the eCos FreeBSD TCP/IP networking stack.

Table of Contents

Chapter 153. Features

The eCos PPP implementation provides the following features:

- PPP line protocol including VJ compression.
- LCP, IPCP and CCP control protocols.
- PAP and CHAP authentication.
- CHAT subset connection scripting.
- Modem control line support.

Chapter 154. Using PPP

Before going into detail, let's look at a simple example of how the eCos PPP package is used. Consider the following example:

```
static void ppp_up(void)
{
    cyg_ppp_options_t options;
    cyg_ppp_handle_t ppp_handle;

    // Bring up the TCP/IP network
    init_all_network_interfaces();

    // Initialize the options
    cyg_ppp_options_init( &options );

    // Start up PPP
    ppp_handle = cyg_ppp_up( "/dev/ser0", &options );

    // Wait for it to get running
    if( cyg_ppp_wait_up( ppp_handle ) == 0 )
    {
        // Make use of PPP
        use_ppp();

        // Bring PPP link down
        cyg_ppp_down( ppp_handle );

        // Wait for connection to go down.
        cyg_ppp_wait_down( ppp_handle );
    }
}
```

This is a simple example of how to bring up a simple PPP connection to another computer over a directly connected serial line. The other end is assumed to already be running PPP on the line and waiting for a connection.

The first thing this code does is to call `init_all_network_interfaces()` to bring up the TCP/IP stack and initialize any other network interfaces. It then calls `cyg_ppp_options_init()` to initialize the PPP options structure to the defaults. As it happens, the default options are exactly what we want for this example, so we don't need to make any further changes. We go straight on to bring the PPP interface up by calling `cyg_ppp_up()`. The arguments to this function give the name of the serial device to use, in this case `"/dev/ser0"`, and a pointer to the options.

When `cyg_ppp_up()` returns, it passes back a handle to the PPP connection which is to be used in other calls. The PPP link will not necessarily have been fully initialized at this time. There is a certain amount of negotiation that goes on between the ends of a PPP link before it is ready to pass packets. An application can wait until the link is ready by calling `cyg_ppp_wait_up()`, which returns zero if the link is up and running, or `-1` if it has gone down or failed to come up.

After a successful return from `cyg_ppp_wait_up()`, the application may make use of the PPP connection. This is represented here by the call to `use_ppp()` but it may, of course, be accessed by any thread. While the connection is up the application may use the standard socket calls to make or accept network connections and transfer data in the normal way.

Once the application has finished with the PPP link, it can bring it down by calling `cyg_ppp_down()`. As with bringing the connection up, this call is asynchronous, it simply informs the PPP subsystem to start bringing the link down. The application can wait for the link to go down fully by calling `cyg_ppp_wait_down()`.

That example showed how to use PPP to connect to a local peer. PPP is more often used to connect via a modem to a remote server, such as an ISP. The following example shows how this works:

```
static char *isp_script[] =
{
    "ABORT"             ,       "BUSY"                                  ,
    "ABORT"             ,       "NO CARRIER"                            ,
    "ABORT"             ,       "ERROR"                                 ,
    ""                  ,       "ATZ"                                   ,
    "OK"                ,       "AT S7=45 S0=0 L1 V1 X4 &C1 E1 Q0"      ,
    "OK"                ,       "ATD" CYGPKG_PPP_DEFAULT_DIALUP_NUMBER  ,
    "ogin:--ogin:"      ,       CYGPKG_PPP_AUTH_DEFAULT_USER            ,
    "assword:"          ,       CYGPKG_PPP_AUTH_DEFAULT_PASSWD          ,
    "otocol:"           ,       "ppp"                                   ,
    "HELLO"             ,       "\\c"                                   ,
    0
};

static void ppp_up(void)
{
    cyg_ppp_options_t options;
    cyg_ppp_handle_t ppp_handle;

    // Bring up the TCP/IP network
    init_all_network_interfaces();

    // Initialize the options
    cyg_ppp_options_init( &options );

    options.script = isp_script;
    options.modem  = 1;

    // Start up PPP
    ppp_handle = cyg_ppp_up( "/dev/ser0", &options );

    // Wait for it to get running
    if( cyg_ppp_wait_up( ppp_handle ) == 0 )
    {
        // Make use of PPP
        use_ppp();

        // Bring PPP link down
        cyg_ppp_down( ppp_handle );

        // Wait for connection to go down.
        cyg_ppp_wait_down( ppp_handle );
    }
}
```

The majority of this code is exactly the same as the previous example. The main difference is in the setting of a couple of options before calling `cyg_ppp_up()`. The *`script`* option is set to point to a CHAT script to manage the setup of the connection. The *`modem`* option is set to cause the PPP system to make use of the modem control lines.

During the PPP bring-up a call will be made to `cyg_ppp_chat()` to run the CHAT script (see Chapter 157, *CHAT Scripts*). In the example this script sets up various modem options and then dials a number supplied as part of the PPP package configuration (see Chapter 156, *Installing and Configuring PPP*). When the connection has been established, the script log on to the server, using a name and password also supplied by the configuration, and then starts PPP on the remote end. If this script succeeds the PPP connection will be brought up and will then function as expected.

The *`modem`* option causes the PPP system to make use of the modem control lines. In particular it waits for `Carrier Detect` to be asserted, and will bring the link down if it is lost. See cyg_ppp_options_init() for more details.

Chapter 155. PPP Interface

Name

cyg_ppp_options_init — Initialize PPP link options

Synopsis

#include <cyg/ppp/ppp.h>

`cyg_int32 **cyg_ppp_options_init**(*options);`

Description

This function initializes the PPP options, pointed to by the *options* parameter, to the default state. Once the defaults have been initialized, application code may adjust them by assigning new values to the the fields of the cyg_ppp_options_t structure.

This function returns zero if the options were initialized successfully. It returns -1 if the *options* argument is NULL, or the options could not be initialized.

The option fields, their functions and default values are as follows:

debug

If set to 1 this enables the reporting of debug messages from the PPP system. These will be generated using `diag_printf()` and will appear on the standard debug channel. Note that `diag_printf()` disables interrupts during output: this may cause the PPP link device to overrun and miss characters. It is quite possible for this option to cause errors and even make the PPP link fail completely. Consequently, this option should be used with care.

Default value: 0

kdebugflag

This five bit field enables low level debugging messages from the PPP device layer in the TCP/IP stack. As with the *debug* option, this may result in missed characters and cause errors. The bits of the field have the following meanings:

Bit	BSD Name	Description
0x01	SC_DEBUG	Enable debug messages
0x02	SC_LOG_INPKT	Log contents of good packets received
0x04	SC_LOG_OUTPKT	Log contents of packets sent
0x08	SC_LOG_RAWIN	Log all characters received
0x10	SC_LOG_FLUSH	Log all characters flushed

Default value: 0

default_route

If set to 1 this option causes the PPP subsystem to install a default route in the TCP/IP stack's routing tables using the peer as the gateway. This entry will be removed when the PPP link is broken. If there is already an existing working network connection, such as an ethernet device, then there may already be a default route established. If this is the case, then this option will have no effect.

Default value: 1

modem

If this option is set to 1, then the modem lines will be used during the connection. Specifically, the PPP subsystem will wait until the `carrier detect` signal is asserted before bringing up the PPP link, and will take the PPP link down if this signal is de-asserted.

Default value: 0

flowctl

This option is used to specify the mechanism used to control data flow across the serial line. It can take one of the following values:

`CYG_PPP_FLOWCTL_DEFAULT`

The flow control mechanism is not changed and is left at whatever value was set before bringing PPP up. This allows a non-standard flow control mechanism to be used, or for it to be chosen and set by some other means.

`CYG_PPP_FLOWCTL_NONE`

Flow control is turned off. It is not recommended that this option be used unless the baud rate is set low or the two communicating machines are particularly fast.

`CYG_PPP_FLOWCTL_HARDWARE`

Use hardware flow control via the RTS/CTS lines. This is the most effective flow control mechanism and should always be used if available. Availability of this mechanism depends on whether the serial device hardware has the ability to control these lines, whether they have been connected to the socket pins and whether the device driver has the necessary support.

`CYG_PPP_FLOWCTL_SOFTWARE`

Use software flow control by embedding XON/XOFF characters in the data stream. This is somewhat less effective that hardware flow control since it is subject to the propagation time of the serial cable and the latency of the communicating devices. Since it does not rely on any hardware support, this flow control mechanism is always available.

Default value: CYG_PPP_FLOWCTL_HARDWARE

refuse_pap

If this option is set to 1, then the PPP subsystem will not agree to authenticate itself to the peer with PAP. When dialling in to a remote server it is normal to authenticate the client. There are three ways this can be done, using a straightforward login mechanism via the CHAT script, with the Password Authentication Protocol (PAP), or with the Challenge Handshake Authentication Protocol (CHAP). For PAP to work the *`user`* and *`passwd`* options must be set to the expected values. If they are not, then this option should be set to force CHAP authentication.

Default value: 0

refuse_chap

If this option is set to 1, then the PPP subsystem will not agree to authenticate itself to the peer with CHAP. CHAP authentication will only work if the *`passwd`* option has been set to the required CHAP secret for the destination server. Otherwise this option should be disabled.

If both *`refuse_pap`* and *`refuse_chap`* are set, then either no authentication will be carried out, or it is the responsibility of the **chat** script to do it. If the peer does not require any authentication, then the setting of these options is irrelevant.

Default value: 0

baud

This option is set to the baud rate at which the serial connection should be run. The default value is the rate at which modems conventionally operate. This field is an instance of the cyg_serial_baud_rate_t enum defined in the `serialio.h` header and may only take one of the baud rate constants defined in there.

Default value: `CYGNUM_SERIAL_BAUD_115200` idle_time_limit

This is the number of seconds that the PPP connection may be idle before it is shut down automatically.

Default value: 60

maxconnect

This causes the connection to terminate when it has been up for this number of seconds. The default value of zero means that the connection will stay up indefinitely, until either end explicitly brings it down, or the link is lost.

Default value: 0

our_address

This is the IP address, in network byte order, to be attached to the local end of the PPP connection. The default value of `INADDR_ANY` causes the local address to be obtained from the peer.

Default value: `INADDR_ANY`

his_address

This is the IP address, in network byte order, to be attached to the remote end of the PPP connection. The default value of `INADDR_ANY` causes the remote address to be obtained from the peer.

Default value: `INADDR_ANY`

accept_local

This allows the behaviour described above for `our_address` to be modified. Normally, if `our_address` is set, then the PPPD will insist that this address be used. However, if this option is also set, the PPPD will accept a value supplied by the peer.

Default value: 0

accept_remote

This allows the behaviour described above for `his_address` to be modified. Normally, if `his_address` is set, then the PPPD will insist that this address be used. However, if this option is also set, the PPPD will accept a value supplied by the peer.

Default value: 0

script

This is a pointer to a CHAT script suitable for passing to `cyg_ppp_chat()`. See Chapter 157, *CHAT Scripts* for details of the format and contents of this script.

Default value: `NULL`

user

This array contains the user name to be used for PAP authentication. This field is not used for CHAP authentication. By default the value of this option is set from the `CYGPKG_PPP_AUTH_DEFAULT_USER` configuration option.

Default value: `CYGPKG_PPP_AUTH_DEFAULT_USER`

passwd

This array contains the password to be used for PAP authentication, or the secret to be used during CHAP authentication. By default the value of this option is set from the `CYGPKG_PPP_AUTH_DEFAULT_PASSWD` configuration option.

Default value: `CYGPKG_PPP_AUTH_DEFAULT_PASSWD`

Name

cyg_ppp_up — Bring PPP connection up

Synopsis

#include <cyg/ppp/ppp.h>

`cyg_ppp_handle_t` **`cyg_ppp_up`**`(`*`*devnam`*`, `*`*options`*`);`

Description

This function starts up a PPP connection. The *`devnam`* argument is the name of the device to be used for the connection, typically `"/dev/ser0"` or `"/dev/ser1"`. The *`options`* argument should point to an initialized cyg_ppp_options_t object.

The return value will either be zero, indicating a failure, or a cyg_ppp_handle_t object that may be used as an argument to other PPP functions.

Note

Although the PPP API is designed to permit several simultaneous connections to co-exist, at present only one PPP connection is actually implemented. Any attempt to create a second connection while there is already one open will fail.

Name

cyg_ppp_down — Bring PPP connection down

Synopsis

#include <cyg/ppp/ppp.h>

`cyg_int32 **cyg_ppp_down**(*handle*);`

Description

This function brings the PPP connection down. The *`handle`* argument is the result of a successful call to `cyg_ppp_up()`. This function only signals to the PPP subsystem that the link should be brought down. The link will be terminated asynchronously. If the application needs to wait for the link to terminate, then it should call `cyg_ppp_wait_down()` after calling `cyg_ppp_down()`.

The function returns zero if it was able to start the termination of the PPP connection successfully. It will return -1 if the connection is not running, or if it could not otherwise start the termination.

Name

cyg_ppp_wait_up — Wait for PPP connection to come up

Synopsis

#include <cyg/ppp/ppp.h>

```
cyg_int32 cyg_ppp_wait_up(handle);
```

Description

This function waits until the PPP connection is running and then returns. This is needed because the actual bring up of the connection happens mostly after the call to `cyg_ppp_up()` returns, and may take some time to complete, especially if dialling a remote server.

The result of this call will be zero when the connection is running, or -1 if the connection failed to start for some reason. If the connection is already running when this call is made it will return immediately with a zero result. If the connection is not in the process of coming up, or has failed, or has terminated, then a result of -1 will be returned immediately. Thus this function may also be used to test that the connection is still running at any point.

Name

cyg_ppp_wait_down — Wait for PPP connection to terminate

Synopsis

#include <cyg/ppp/ppp.h>

```
void cyg_ppp_wait_down(handle);
```

Description

This function waits for the PPP connection to terminate. The link may be terminated with a call to `cyg_ppp_down()`, by the remote end, or by the telephone line being dropped or lost.

This function has no return value. If the PPP connection is not running, or has terminated, it will return. Applications should use `cyg_ppp_wait_up()` to test the link state.

Name

cyg_ppp_chat — Execute chat script

Synopsis

#include <cyg/ppp/ppp.h>

```
cyg_int32 cyg_ppp_chat(*devname, *script[]);
```

Description

This function implements a subset of the automated conversational scripting as defined by the **chat** program. The first argument is the name of the serial device to be used, typically `"/dev/ser0"` or `"/dev/ser1"`. The *`script`* argument is a pointer to a zero terminated array of strings that comprise the chat script. See Chapter 154, *Using PPP* for an example script, and Chapter 157, *CHAT Scripts* for full detail of the script used.

The return value of this function will be zero if the chat script fails for any reason, such as an ABORT or a timeout. If the end of the script is reached, then the return value will be non-zero.

Under normal use this function is called from the PPP subsystem if the cyg_ppp_options_t *`script`* field is set to a non-`NULL` value. This function should only be used directly if the application needs to undertake special processing between running the chat script, and bringing up the PPP connections.

Chapter 156. Installing and Configuring PPP

Including PPP in a Configuration

PPP is contained entirely within a single eCos package. So to include PPP in a configuration all you need to do is add that package.

In the GUI configuration tool use the **Build->Packages** menu item, find the "PPP Support" package in the left-hand pane and use the **Add** button to add it to the list of packages in use in the right-hand pane.

In the command-line tool **ecosconfig**, you can use the following command during the configuration phase to add the PPP package:

```
$ ecosconfig add ppp
```

In addition to the PPP package you will also need to have the `"Network"` package and the `"Serial Device Drivers"` package in the configuration. The dependencies and requirements of the networking package are such that it is strongly recommended that you start with the `net` template.

See the eCos User Guide for full details on how to configure and build eCos.

Configuring PPP

The PPP package contains a number of configuration options that may be changed to affect its behaviour.

CYGNUM_PPP_PPPD_THREAD_PRIORITY

> The PPP system contains two threads, One is used for receiving data from the link and processing control packets. The other is used to transmit data asynchronously to the link when it cannot be completed synchronously. The receive thread runs at the priority given here, and the transmit thread runs at the next lower priority. The exact priority needed here depends on the importance of the PPP subsystem relative to the rest of the system. The default is to put it in the middle of the priority range to provide reasonable response without impacting genuine high priority threads.
>
> Default value: `CYGNUM_KERNEL_SCHED_PRIORITIES/2`

CYGPKG_PPP_DEBUG_WARN_ONLY

> The runtime `debug` option enables logging of high level debug messages. Too many of these can interfere with the PPP device and may result in missed messages. This is because these messages are emitted via the diag_printf() mechanism, which disables interrupts while it prints. By default, therefore, we only report errors and warnings, and not all events. Setting this option to zero will enable the logging of all events.
>
> Default value: `1`

CYGPKG_PPP_AUTH_DEFAULT_USER

> This option gives the default value for the user name used to initialize the *`user`* field in the PPP options.
>
> Default value: `"eCos"`

CYGPKG_PPP_AUTH_DEFAULT_PASSWD

> This option gives the default value for the password used to initialize the *`passwd`* field in the PPP options.

Default value: `"secret"`

CYGPKG_PPP_DEFAULT_DIALUP_NUMBER

This option provides a default dialup number for use in **chat** scripts. This value is not used anywhere in the PPP package, but is provided to complete the information needed, alongside the user name and password, for accessing a typical dialup server.

Default value: `"5551234"`

CYGPKG_PPP_PAP

This component enables the inclusion of PAP authentication support.

Default value: 1

CYGPKG_PPP_CHAP

This component enables the inclusion of CHAT authentication support.

Default value: 1

CYGPKG_PPP_COMPRESSION

This component provides control over PPP compression features. WARNING: at present there are problems with this option, and and in any case the compression code needs to allocate large amounts of memory. Hence this option is currently disabled and should remain so.

Default value: 0

PPP_BSDCOMP

This option enables inclusion of BSD compression into the PPP protocol.

Default value: 0

PPP_DEFLATE

This option enables inclusion of ZLIB compression into the PPP protocol.

Default value: 0

CYGPKG_PPP_CHAT

This component enables the inclusion of a simple scripting system to bring up PPP connections. It implements a subset of the **chat** scripting language.

Default value: 1

CYGNUM_PPP_CHAT_ABORTS_MAX

This option defines the maximum number of `ABORT` strings that the CHAT system will store.

Default value: 10

CYGNUM_PPP_CHAT_ABORTS_SIZE

This option defines the maximum size of each `ABORT` strings that the **chat** system will store.

Default value: 20

CYGNUM_PPP_CHAT_STRING_LENGTH

This option defines the maximum size of any expect or reply strings that the **chat** system will be given.

Default value: 256

CYGPKG_PPP_TEST_DEVICE

This option defines the serial device to be used for PPP test programs.

Default value: `"/dev/ser0"`

CYGPKG_PPP_TESTS_AUTOMATE

This option enables automated testing features in certain test programs. These programs will interact with a test server at the remote end of the serial link to run a variety of tests in different conditions. Without this option most tests default to running a single test instance and are suitable for being run by hand for debugging purposes.

Default value: 0

CYGDAT_PPP_TEST_BAUD_RATES

This option supplies a list of baud rates at which certain tests will run if the `CYGPKG_PPP_TESTS_AUTOMATE` option is set.

Default value: `"CYGNUM_SERIAL_BAUD_19200, CYGNUM_SERIAL_BAUD_38400, CYGNUM_SERIAL_BAUD_57600, CYGNUM_SERIAL_BAUD_115200"`

Chapter 157. CHAT Scripts

The automated conversational scripting supported by the eCos PPP package is a subset of the scripting language provided by the **chat** command found on most UNIX and Linux systems.

Unlike the **chat** command, the eCos `cyg_ppp_chat()` function takes as a parameter a zero-terminated array of pointers to strings. In most programs this will be defined by means of an initializer for a static array, although there is nothing to stop the application constructing it at runtime. A simple script would be defined like this:

```
static char *chat_script[] =
{
    "ABORT"        ,  "BUSY"        ,
    "ABORT"        ,  "NO CARRIER"  ,
    ""             ,  "ATD5551234"  ,
    "ogin:--ogin:" ,  "ppp"         ,
    "ssword:"      ,  "hithere"     ,
    0
};
```

The following sections have been abstracted from the public domain documentation for the **chat** command.

Chat Script

A script consists of one or more "expect-send" pairs of strings, separated by spaces, with an optional "subexpect- subsend" string pair, separated by a dash as in the following example:

```
    "ogin:--ogin:"     ,  "ppp"       ,
    "ssword:"          ,   "hello2u2" ,
    0
```

This script fragment indicates that the `cyg_ppp_chat()` function should expect the string "ogin:". If it fails to receive a login prompt within the time interval allotted, it is to send a carriage return to the remote and then expect the string "ogin:" again. If the first "ogin:" is received then the carriage return is not generated.

Once it received the login prompt the `cyg_ppp_chat()` function will send the string "ppp" and then expect the prompt "ssword:". When it receives the prompt for the password, it will send the password "hello2u2".

A carriage return is normally sent following the reply string. It is not expected in the "expect" string unless it is specifically requested by using the "\r" character sequence.

The expect sequence should contain only what is needed to identify the string. It should not contain variable information. It is generally not acceptable to look for time strings, network identification strings, or other variable pieces of data as an expect string.

To help correct for characters which may be corrupted during the initial sequence, look for the string "ogin:" rather than "login:". It is possible that the leading "l" character may be received in error and you may never find the string even though it was sent by the system. For this reason, scripts look for "ogin:" rather than "login:" and "ssword:" rather than "password:".

A very simple script might look like this:

```
    "ogin:"    , "ppp"       ,
    "ssword:"  , " hello2u2" ,
    0
```

In other words, expect "….ogin:", send "ppp", expect "…ssword:", send "hello2u2".

In actual practice, simple scripts are rare. At the very least, you should include sub-expect sequences should the original string not be received. For example, consider the following script:

```
    "ogin:--ogin:"  , "ppp"     ,
    "ssword:"       , "hello2u2",
    0
```

This would be a better script than the simple one used earlier. This would look for the same "login:" prompt, however, if one was not received, a single return sequence is sent and then it will look for "login:" again. Should line noise obscure the first login prompt then sending the empty line will usually generate a login prompt again.

ABORT Strings

Many modems will report the status of the call as a string. These strings may be CONNECTED or NO CARRIER or BUSY. It is often desirable to terminate the script should the modem fail to connect to the remote. The difficulty is that a script would not know exactly which modem string it may receive. On one attempt, it may receive BUSY while the next time it may receive NO CARRIER.

These "abort" strings may be specified in the script using the ABORT sequence. It is written in the script as in the following example:

```
    "ABORT"    , "BUSY"    ,
    "ABORT"    , "NO CARRIER"  ,
    ""         , "ATZ"         ,
    "OK"       , "ATDT5551212" ,
    "CONNECT"  , …
```

This sequence will expect nothing; and then send the string ATZ. The expected response to this is the string OK. When it receives OK, it sends the string ATDT5551212 to dial the telephone. The expected string is CONNECT. If the string CONNECT is received the remainder of the script is executed. However, should the modem find a busy telephone, it will send the string BUSY. This will cause the string to match the abort character sequence. The script will then fail because it found a match to the abort string. If it received the string NO CARRIER, it will abort for the same reason. Either string may be received. Either string will terminate the chat script.

TIMEOUT

The initial timeout value is 45 seconds. To change the timeout value for the next expect string, the following example may be used:

```
    ""               , "ATZ"          ,
    "OK"             , "ATDT5551212" ,
    "CONNECT"        , "\\c"          ,
    "TIMEOUT"        , "10"           ,
    "ogin:--ogin:"   , "ppp"          ,
    "TIMEOUT"        , "5"            ,
    "assword:"       , "hello2u2"     ,
    0
```

This will change the timeout to 10 seconds when it expects the login: prompt. The timeout is then changed to 5 seconds when it looks for the password prompt.

The timeout, once changed, remains in effect until it is changed again.

Sending EOT

The special reply string of EOT indicates that the chat program should send an EOT character to the remote. This is normally the End-of-file character sequence. A return character is not sent following the EOT. The EOT sequence may be embedded into the send string using the sequence "\x04" (i.e. a Control-D character).

Escape Sequences

Most standard **chat** escape sequences can be replaced with standard C string escapes such as '\r', '\n', '\t' etc. Additional escape sequences may be embedded in the expect or reply strings by introducing them with *two* backslashes.

\\c Suppresses the newline at the end of the reply string. This is the only method to send a string without a trailing return character. It must be at the end of the send string. For example, the sequence "hello\\c" will simply send the characters h, e, l, l, o. (not valid in expect strings.)

Chapter 158. PPP Enabled Device Drivers

For PPP to function fully over a serial device, its driver must implement certain features. At present not all eCos serial drivers implement these features. A driver indicates that it supports a certain feature by including an `"implements"` line in its CDL for the following interfaces:

`CYGINT_IO_SERIAL_FLOW_CONTROL_HW`

> This interface indicates that the driver implements hardware flow control using the RTS and CTS lines. When data is being transferred over high speed data lines, it is essential that flow control be used to prevent buffer overrun.
>
> The PPP subsystem functions best with hardware flow control. If this is not available, then it can be configured to use software flow control. Since software flow control is implemented by the device independent part of the serial device infrastructure, it is available for all serial devices. However, this will have an effect on the performance and reliability of the PPP link.

`CYGINT_IO_SERIAL_LINE_STATUS_HW`

> This interface indicates that the driver implements a callback interface for indicating the status of various RS232 control lines. Of particular interest here is the ability to detect changes in the Carrier Detect (CD) line. Not all drivers that implement this interface can indicate CD status.
>
> This functionality is only needed if it is important that the link be dropped immediately a telephone connection fails. Without it, a connection will only be dropped after it times out. This may be acceptable in many situations.

At the time of writing, the serial device drivers for the following platforms implement some or all of the required functionality:

- All drivers that use the generic 16x5x driver implement all functions:
  - ARM CerfPDA
  - ARM IQ80321
  - ARM PID
  - ARM IOP310
  - i386 PC
  - MIPS Atlas
  - MIPS Ref4955
  - SH3 SE77x9
- The following drivers implement flow control but either do not support line status callbacks, or do not report CD changes:
  - SH4 SCIF
  - A&M AdderI
  - A&M AdderII
- All other drivers can support software flow control only.

Chapter 159. Testing

Test Programs

There are a number of test programs supplied with the PPP subsystem. By default all of these tests use the device configured by `CYGPKG_PPP_TEST_DEVICE` as the PPP link device.

`ppp_up`

This test just brings up the PPP link on `CYGPKG_PPP_TEST_DEVICE` and waits until the remote end brings it back down. No modem lines are used and the program expects a PPP connection to be waiting on the other end of the line. Typically the remote end will test the link using **ping** or access the HTTP system monitor if it is present.

If `CYGPKG_PPP_TESTS_AUTOMATE` is set, then this test attempts to bring PPP up at each of the baud rates specified in `CYGDAT_PPP_TEST_BAUD_RATES`. If it is not set then it will just bring the connection up at 115200 baud.

`ppp_updown`

This test brings the PPP link up on `CYGPKG_PPP_TEST_DEVICE` and attempts to **ping** the remote end of the link. Once the pings have finished, the link is then brought down.

If `CYGPKG_PPP_TESTS_AUTOMATE` is set, then this test attempts to bring PPP up at each of the baud rates specified in `CYGDAT_PPP_TEST_BAUD_RATES`. If it is not set then it will just bring the connection up at 115200 baud.

`chat`

This test does not bring the PPP link up but simply executes a chat script. It expects a server at the remote end of the link to supply the correct responses.

This program expects the **test_server.sh** script to be running on the remote end and attempts several different tests, expecting a variety of different responses for each.

`ppp_auth`

This test attempts to bring up the PPP link under a variety of different authentication conditions. This includes checking that both PAP and CHAP authentication work, and that the connection is rejected when the incorrect authentication protcol or secrets are used.

This test expects the **test_server.sh** script to be running on the remote end. For this test to work the `/etc/ppp/pap-secrets` file on the remote end should contain the following two lines:

```
eCos       *          secret       *
eCosPAP    *          secretPAP    *
```

The `/etc/ppp/chap-secrets` file should contain:

```
eCos       *          secret       *
eCosCHAP   *          secretCHAP   *
```

`isp`

This test expects the serial test device to be connected to a Hayes compatible modem. The test dials the telephone number given in `CYGPKG_PPP_DEFAULT_DIALUP_NUMBER` and attempts to log on to an ISP using the user name and password supplied in `CYGPKG_PPP_AUTH_DEFAULT_USER` and `CYGPKG_PPP_AUTH_DEFAULT_PASSWD`. Once the PPP connection has been made, the program then attempts to ping a number of well known addresses.

Since this test is designed to interact with an ISP, it does not run within the automated testing system.

`tcp_echo`

This is a version of the standard network **tcp_echo** test that brings up the PPP connection before waiting for the **tcp_sink** and **tcp_source** programs to connect. It is expected that at least one of these programs will connect via the PPP link. However, if another network interface is present, such as an ethernet device, then one may connect via that interface.

While this test is supported by the **test_server.sh** script, it runs for such a long time that it should not normally be used during automated testing.

`nc_test_slave`

This is a version of the standard network **nc_test_slave** test that brings up the PPP connection before waiting for the **nc_test_master** program to connect. It is expected that the master will connect via the PPP link.

While this test is supported by the **test_server.sh** script, it runs for such a long time that it should not normally be used during automated testing.

Test Script

The PPP package additionally contains a shell script (**test_server.sh**) that may be used to operate the remote end of a PPP test link.

The script may be invoked with the following arguments:

`--dev=<devname>`

This mandatory option gives the name of the device to be used for the PPP link. Typically `"/dev/ttyS0"` or `"/dev/ttyS1"`.

`--myip=<ipaddress>`

This mandatory option gives the IP address to be attached to this end of the PPP link.

`--hisip=<ipaddress>`

This mandatory option gives the IP address to be attached to the remote (test target) end of the PPP link.

`--baud=<baud_rate>`

This option gives the baud rate at which the PPP link is to be run. If absent then the link will run at the value set for `--redboot-baud`.

`--redboot`

If this option is present then the script will look for a `"RedBoot>"` prompt between test runs. This is necessary if the serial device being used for testing is also used by RedBoot.

`--redboot-baud=<baud_rate>`

This option gives the baud rate at which the search for the RedBoot prompt will be made. If absent then the link will run at 38400 baud.

`--debug`

If this option is present, then the script will print out some additional debug messages while it runs.

This script operates as follows: If the `--redboot` option is set it sets the device baud rate to the RedBoot baud rate and waits until a `"RedBoot>"` prompt is encountered. It then sets the baud rate to the value given by the `--baud` option and reads lines from the device until a recognizable test announce string is read. It then executes an appropriate set of commands to satisfy the test. This usually means bringing up the PPP link by running **pppd** and maybe executing various commands. It then either terminates the link itself, or waits for the target to terminate it. It then goes back to looking for another test announce string. If a string of the form `"BAUD:XXX"` is received then the baud rate is changed depending on the `XXX` value. If a `"FINISH"` string is received it returns to waiting for a `"RedBoot>"` prompt. The script repeats this process until it is terminated with a signal.

Part XLIV. lwIP - the lightweight IP stack for eCosPro

Table of Contents

Chapter 160. lwIP overview

Introduction

lwIP, short for lightweight IP, is an implementation of a standard Internet Protocol v4 and v6 networking protocol stack designed to operate in a resource-constrained environment. It was created in 2001 by Adam Dunkels of the Swedish Institute of Computer Science for his Master's thesis. The core lwIP code was released publically under an open licence.

The lwIP stack supports the IP, TCP, UDP, ICMP, IGMP, ARP, DHCP, AutoIP, DNS, SNMP, SLIP and PPP protocols, and there is a selection of APIs which applications can use to interact with it. As well as being designed from the outset to have a low memory footprint, it also gains many of its lightweight properties from being highly configurable. This makes it an excellent choice for integration into eCos.

This documentation describes lwIP and properties specific to its port to eCosPro. The usage, configuration and tuning of lwIP will also be discussed. Many of the concepts discussed here will require some understanding of the inherent underlying properties of the TCP, UDP and IP protocols. This documentation cannot substitute for an introduction to TCP/IP stacks and protocols generally, and it is recommended that where needed the reader seeks out a good reference book, such as:

- *TCP/IP Illustrated, Volume 1: The Protocols*, W. Richard Stevens, published by Addison-Wesley Professional, ISBN-10: 0-201-63346-9, ISBN-13: 978-0-201-63346-7.
- *Internetworking with TCP/IP: volume 1*, Douglas E. Comer, published by Prentice-Hall, ISBN-10: 0-131-87671-6, ISBN-13: 978-0-131-87671-2.

or one of the many online guides:

- Network Sorcery RFC Sourcebook
- Wikipedia

lwIP sources and ports

lwIP is portable and by no means specific to eCos. It has an active development community and undergoes continuous development of its core code, focussed around its project page on the Savannah development site run by the Free Software Foundation.

In order to provide a robust, feature-rich, and commercially supportable solution for eCosPro, the eCos support has been overhauled by eCosCentric® to work with the latest lwIP releases.

This documentation corresponds solely to the eCosPro port of lwIP, and the usage, configuration system and operation differs in many regards from that in other code bases.

Warning

As detailed in the section called “Port status” the current eCosPro lwIP is using a much newer lwIP source base with substantial changes from previous eCosPro lwIP offerings. As such some CDL compatibility issues will arise if attempts are made to use old `.ecc` configuration files.

Either a fresh configuration can be created, and options re-selected as desired, or prior to switching to the newer source world, whilst still configured to use the older `ECOS_REPOSITORY` the eCos configtool can be used to export (`File->Export`) the configuration to a `.ecm` (minimal configuration) file. Then after switching to the new `ECOS_REPOSITORY` source tree the eCos configtool can be used to import (`File->Import`) the created `.ecm` file.

External documentation

A limited amount of publically available documentation is available for the lwIP project. Some of it has been incorporated into this manual. The following lists useful documentation known about at the time of writing:

- Adam Dunkel's Master's Thesis - the original description of lwIP design and operation, but now somewhat outdated.
- Report by Adam Dunkel into the design and implementation of lwIP, including a sequential API reference, and example code. Largely still applicable to current lwIP, albeit incomplete. A copy of the PDF version may be found in the `doc/` subdirectory of the lwIP package in the eCosPro source repository (`packages/net/lwip_tcpip/`*`VERSION`*`/doc/dunkels-lwip.pdf` relative to the base of the eCosPro installation).
- The lwIP Wiki site provides a good introduction to many lwIP features, and provides links to related documentation.
- Text description of the lwIP raw API. A copy of the version at time of writing may be found in the `doc/` subdirectory of the lwIP package in the eCosPro source repository (`packages/net/lwip_tcpip/`*`VERSION`*`/doc/rawapi.txt` relative to the base of the eCosPro installation).
- Text description of the sys_arch porting abstraction layer. A copy of the version at time of writing may be found in the `doc/` subdirectory of the lwIP package in the eCosPro source repository (`packages/net/lwip_tcpip/`*`VERSION`*`/doc/sys_arch.txt` relative to the base of the eCosPro installation).

Licensing

The lwIP core code is distributed under a 3 clause BSD-style license. Confirmation has been received from Adam Dunkels that the existing public lwIP documentation is also covered by this license.

The original public eCos port included elements distributed under the eCos license.

As a result of the changes made by eCosCentric, portions of the eCos port of lwIP in eCosPro are covered by the eCosPro License.

Chapter 161. Basic concepts

Structure

lwIP has been incorporated into eCos as a single package (`CYGPKG_NET_LWIP`) which contains all the core lwIP code and the bulk of the eCos port. The remaining elements that constitute the eCos port can be found in the generic Ethernet driver package (`CYGPKG_IO_ETH_DRIVERS`) and so is only relevant when using an Ethernet-based network card rather than SLIP or PPP. Support for SLIP and PPPoS (PPP-over-Serial) is layered over the standard eCos serial driver API.

The port to eCos has been constructed using the sys_arch porting abstraction within lwIP, and this allows the eCos port to be cleanly separated from the core lwIP code, although it still remains in the lwIP eCos package.

Application Programming Interfaces (APIs)

There are three different APIs which may be used by applications to interface with the stack: the raw API, the sequential API, or the BSD sockets compatibility API. Each one in turn builds on the functionality provided by the previous API. This allows users the flexibility of choosing a fairly bare implementation to squeeze the maximum out of the available resources; or to use a more powerful API to simplify application coding and reduce time-to-market. Note that despite the presence of the BSD sockets compatibility API, the lwIP stack implementation is not in any way related to the other BSD-derived TCP/IP stacks present in eCos.

The raw API provides an event-based interface with callbacks directly into the application in order to handle incoming/outgoing data and events. There is no inter-thread protection and can only operate with a single thread of execution.

The sequential API is a more traditional style of network interface API which provides functions that may be called synchronously to perform network operations, and where those operations can be considered complete (or will complete asynchronously with no further application interaction) when those functions return to the application.

When using the sequential API (or the BSD sockets API which is layered on top of it), lwIP maintains its own internal thread for network data processing and event management. This is usually referred to as lwIP's TCP/IP thread (even though that is a slight misnomer). This thread uses mailboxes to communicate with application threads, and semaphores to provide mutual exclusion protection.

The BSD sockets compatibility API included in lwIP provides a subset of the Berkeley sockets interface introduced in the BSD 4.2 operating system. The Berkeley sockets interface, recently standardised by ISO/IEC in POSIX 2003.1, will be familiar to those who have developed network applications on Linux, POSIX, UNIX or to a limited extent Windows with Winsock.

As the BSD sockets API provided as part of lwIP is only a subset of the full sockets, it should be considered only as an aid to development or for when porting existing code. It should not be considered as a drop-in replacement for applications written for a complete BSD network stack implementation which supports a wealth of features that do not exist in, and in many cases would be inappropriate for, a low footprint implementation such as lwIP.

Protocol implementations

lwIP implements a variety of protocols. Support for each protocol can be individually included in or excluded from the configuration, subject to dependency constraints. The protocol implementations are mostly compartmentalised into separate source modules. Support exists for TCP, UDP, UDP-Lite, IP (IPv4 and IPv6), ICMP, ICMP6, ARP when using Ethernet, IGMP, DHCP, AutoIP and Stateless AutoConfiguration, DNS, MLD, ND, SNMP, SNTP, TFTP, SLIP and PPP.

In most cases functionality has been intentionally restricted to avoid "bloat" (unnecessary features increasing resource use), or in some cases completely omitted. This is covered in slightly more detail in the section called “Limitations”.

Packet data buffers

lwIP does not only possess features allowing it by itself to maintain a small footprint, but also has design aspects which allow it to work with the application to reduce footprint. One important case of this is lwIP packet data buffers.

Packet data buffers in lwIP are termed *pbufs*. Pbufs can be chained together in fairly arbitrary ways to create a *pbuf chain*. The idea is that the application can pass the stack a pbuf of data to transmit, and the stack can prepend and possibly append other pbufs to encapsulate the data in protocol headers/footers without having to copy the data elsewhere, thus saving resources. In some cases, depending on precisely how the pbuf was allocated, the stack may even be able to fit protocol headers inside the pbuf passed to it. It also means that the application can itself provide data allocated in differing ways and from different locations, but assembled together as a pbuf chain. This will ensure that the data is treated as if it were all allocated contiguously. When using the sequential API, the underlying pbufs are wrapped in a *netbuf* construct in order to provide a simpler API to manipulate data in buffers; but the underlying functionality remains based on pbufs.

When a pbuf is created, it must be one of a variety of types:

PBUF_RAM This is a conventional buffer, which points to data allocated from a pool in RAM managed by lwIP. On creation the buffer size must be given.

PBUF_ROM This is a buffer pointing to immutable read-only data. This allows fixed literal data to be stored in ROM/Flash rather than using up precious RAM. Note that data pointed at by a PBUF_ROM pbuf does not literally have to point at read-only memory. All it means is that the data must not change, even if control has returned to the application. The pbuf data may still be being referenced as part of a packet waiting in a queue to be transmitted, or more often, waiting in a queue in case retransmission is necessary.

> ⚠ **Caution**
>
> Not all architectures will allow ethernet transfers direct from ROM, so the underlying hardware device driver may need to perform copying of data as required.

PBUF_REF This is a buffer pointing to mutable data, passed in by reference. This means data provided by the application allocated from its own resources, and which could change in the future. This differs from PBUF_RAM packets in that the data is allocated by the application, and not from lwIP's PBUF_RAM buffer memory pool. As the application could change the data after control is returned to it, if lwIP finds it must enqueue the pbuf, it will internally copy the data to a new PBUF_RAM. The benefits of this type of packet occur when the packet does not need to be enqueued, and so no PBUF_RAM pbuf needs to be allocated.

PBUF_POOL The buffer is allocated as a chain of fixed size pbufs from a fixed size pool.

Configurability

lwIP was designed from the outset to have a low resource footprint. One of the techniques it uses to achieve this goal is its high level of configurability.

lwIP allows both coarse- and fine-grained control of functionality. Large sections of potentially unused functionality can be selected to be removed by the user, including entire protocol stacks. Such examples of removable coarse-grained functionality include UDP, TCP, SLIP, PPP stacks, ethernet/ARP support, IP fragmentation and/or reassembly, or the sequential API.

It has a somewhat modular and layered design to assist with this. It is intentionally only somewhat modular: other TCP/IP stacks have strictly enforced interfaces and abstractions between protocol layers. These abstractions are frequently cumbersome and can result in unnecessary resource implications. lwIP deliberately violates some of these protocol interface layering abstractions where doing so could improve resource utilization. An example is reserving an estimated appropriate amount of space for protocol headers when constructing packets, where the choice of protocol dictates the amount of space.

Where lwIP really stands out is in its fine-grained control over the various pools of resources. Most resources are compartmentalised into fixed size memory pools to allow sizes to be constrained deterministically. The application designer will know, or can choose, the maximum number of network connections which are to be supported depending on application requirements. They also know the level of data throughput required for transmission or reception and can control the levels of the necessary resources appropriately, such as numbers of buffers (separately for incoming or outgoing packet data) and their sizes, numbers of protocol control blocks, TCP window sizes and more.
