The ST STM32Fxxxx series of Cortex-M microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting most of the on-chip peripherals. These include device drivers for the on-chip flash, serial, I²C, SPI, MMC/SD, Ethernet, CAN, USB OTG HS and FS, ADC, RTC/wallclock and watchdog devices. In addition it provides common functionality and definitions that STM32 based platform ports may require, as well as definitions useful to application developers.

This documentation covers the STM32 functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the STM32 variant HAL provides. The areas that are specific to platform HALs and not the STM32 variant HAL include:

- memory map and related configuration and setup
- Clock parameters
- GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED/LCD control

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

On-chip memory

The ST STM32 parts include on-chip SRAM, and on-chip FLASH. The RAM can vary in size from as little as 4KiB to 128KiB. The FLASH can be up to 1024KiB in size depending on model. There is also support in some models for external SRAM and Flash, which eCos may use where available.

Typically, an eCos platform HAL port will expect a GDB stub ROM monitor or RedBoot image to be programmed into the STM32 on-chip ROM memory for development, and the board would boot this image from reset. The stub ROM/RedBoot provides GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels. The JTAG interface may also be used for development if a suitable JTAG device is available. If RedBoot is present it may also be used to manage the on-chip and external flash memory. For production purposes, applications are programmed into external or on-chip FLASH and will be self-booting.

On-Chip FLASH

The package `CYGPKG_DEVS_FLASH_STM32` ("STM32 Flash memory support") provides a driver for the on-chip flash. This driver conforms to the Version 2 flash driver API, and is automatically enabled if the generic "Flash device drivers" (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant which has been selected in the eCos configuration.

Cache Handling

The STM32 does not contain any caches, however, the variant HAL supplies the `cyg/hal/hal_cache.h` header to satisfy generic code. This header describes zero sized caches and provides null macros for the required functions.

Serial I/O

The STM32 variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices, and where appropriate for the target platform, DMA can be used to reduce the CPU load. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_CORTEXM_STM32` which provides all support for the STM32 on-chip serial devices. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor or RedBoot for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it *cannot* also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

Depending on the STM32Fx series processor configured, the HAL defines CDL interfaces from `CYGINT_HAL_STM32_UART0` up to `CYGINT_HAL_STM32_UART7` for each of the available UARTs. For `F1` series devices the range is 0..4. For `F2` and `F4[01]` family members the range is 0..5 (4 USARTs and 2 UARTs). For `F4[23]` and `F7` devices the range is 0..7 (4 USARTs and 4 UARTs). The platform HAL CDL should contain an **implements** directive for each such UART that is available for use on the board. This will enable use of the UART for diagnostic and application use.

Caution

eCos uses a numbering scheme for UARTs which starts at 0, whereas STM32 documentation uses a numbering scheme which starts at 1. Be sure to check which numbering scheme is relevant when interpreting UART numbers in CDL options or eCos interfaces (eCos numbering) or hardware-specific definitions (ST numbering).

The STM32 USARTs provide TX and RX data lines plus hardware flow control using RTS/CTS for those UARTs that have them connected.

The `CYGPKG_IO_SERIAL_CORTEXM_STM32` package provides a number of CDL options that allow the size and location of buffers to be configured. These settings, in conjunction with platform specific manifests for DMA stream/channel configuration, are used to control how data is buffered by the STM32 UART driver. For the options listed below, the relevant UART controller is specified by replacing *`x`* with the logical eCos interface number.

`CYGNUM_IO_SERIAL_CORTEXM_STM32_SERIALx_BUFSIZE`

> This option specifies the size of both the input and output buffers for the common serial I/O driver layer, which sits above the low-level STM32 specific driver. When using high baud rates, to avoid overrun, the buffer size may need to be increased to cope with the application serial handler thread switching latency. If the device should only be used in polled mode then this option can be disabled by setting the value to `0`. Typically the device driver will run in interrupt or DMA mode (as configured by the platform), such that it will perform some buffering of both incoming and outgoing data.

`CYGIMP_IO_SERIAL_CORTEXM_STM32_SERIALx_BUFSRAM`

> By default the common serial I/O buffers of the size specified by the `CYGNUM_IO_SERIAL_CORTEXM_STM32_SERIALx_BUFSIZE` option are held in the main application data memory as defined by the active `CYG_HAL_STARTUP` configuration. For the majority of standard serial uses this will be sufficient, and this option can remain disabled. However, this option can be enabled to force the buffers to be placed into on-chip SRAM, which may be required when using very high communication rates with applications that use off-chip data memory. This option is ignored if the `CYG_HAL_STARTUP` configuration already selects the on-chip SRAM for application data.

`CYGNUM_IO_SERIAL_CORTEXM_STM32_SERIALx_RXBUFSIZE`

> This option controls the size of the low-level UART driver RX buffer.
>
> When interrupt transfers are being used then this option specifies the size of the RX buffer used to provide FIFO-alike operation to minimise the possibility for dropped characters when waiting for the UART DSR to be processed. A minimal buffer size is enforced since if the processor is using off-chip RAM then it may be too slow to handle higher baud rates.
>
> For DMA enabled RX this buffer is used to reduce the overall STM32 serial driver ISR and DSR system overhead. For DMA an interrupt will only be generated when 50% of the buffer size has been received, or when the receiver has been idle for some time. This reduces overall system load at the expense of making the driver slightly less “responsive” for non-continuous transfers. The DMA suport actually splits the buffer into two equal sized buffers and uses the hardware double-buffer support to automatically switch between buffers.

Serial overrun mitigation

Ideally it is prudent for UART connections to use hardware flow control where possible, since it provides a mechanism for both ends of a connection to throttle the data flow to avoid buffer overrun. This is especially true when using very high baud rates, since many characters could be received within the ISR, DSR and scheduling latencies of a running application.

If H/W flow control is *not* available then, especially when using higher baud rates, it is critical that the application developer understands the serial transfer requirements, and that the STM32 UART driver processing method and configured buffering is tuned to avoid (or at least minimise the possibility of) overrun. When H/W flow control is not being used then it may not be possible to avoid overrun completely, since the remote end can always transmit more data than the receiver has buffer space for. The possibility of overrun can be mitigated by ensuring a suitable software “throttling” handshake mechanism between the transmitted and receiver, or by ensuring that the receiver has sufficient buffer space at both the low-level driver reception layer (`CYGNUM_IO_SERIAL_CORTEXM_STM32_SERIALx_RXBUFSIZE`) and the higher-level common serial/application layer (`CYGNUM_IO_SERIAL_CORTEXM_STM32_SERIALx_BUFSIZE`) to cope with the worst-case scheduling latency of the application.

Caution

When DMA usage is configured by the specific STM32 platform support (implemented by provision of a suitably named manifest describing the stream/channel configuration), the UART DSR *MUST* have copied data out of the RX buffer into the common serial buffers BEFORE the second DMA buffer has been filled. For example, at 10.5MHz over 1000 8N1 characters can be received in 1-millisecond. The buffer depth should be tuned accordingly to cope with the worst-case UART driver DSR latency to ensure that the automatic hardware switch on DMA buffer fill does not cause data which has not yet been copied to the higher serial layer to be overwritten.

Further, when using DMA, the RX IDLE support is used to force data to be passed to the common serial layer in a timely fashion. This avoids the eCos receiver application having to wait for a complete DMA buffer fill for pending data, which is useful for “character” based serial protocols. The downside is that due to the IDLE implementation having to disable the DMA stream temporarily, if the remote end transmits multiple characters shortly after IDLE is detected by the STM32 receiver then the DMA ISR latency may affect whether RX overrun occurs before the handler can re-enable the DMA stream. The CYGNUM_IO_SERIAL_CORTEXM_STM32_SERIAL*x*_RXINTR_PRI configuration option can be tuned to ensure that the DMA interrupt priority is sufficiently high to minimise the possibility of overrun.

I²C

Note

The I/O controller found on newer STM32 designs (e.g. F7, H7 or L4 families) only supports divided transactions with repeated START conditions. The hardware is not capable of splitting a transaction without generating a START.

So all transaction calls between the cyg_i2c_transaction_begin() and cyg_i2c_transaction_end() calls should use true for the send_start parameter.

Interrupts

The STM32 HAL relies on the architectural HAL to provide support for the interrupts directly routed to the NVIC. The cyg/hal/var_intr.h header defines the vector mapping for these.

In addition support is present for interrupts EXTI5 to EXTI15 that share NVIC vectors. These are decoded by a springboard ISR routine that decodes the interrupt from the EXTI_PR register and calls hal_deliver_interrupt in the architectural HAL to deliver it to the real ISR. Variant specific macros are also defined to permit the masking and configuration of these interrupts.

GPIO

The variant HAL provides support for packaging the configuration of a GPIO line into a single 32-bit descriptor that can then be used with macros to configure the pin and set and read its value. Details are supplied later.

MMC/SD

The variant HAL provides support for MultiMediaCard (MMC) and Secure Digital (SD) media cards via the CDL component CYGPKG_HAL_STM32_MMCSD ("On-chip MMC/SD driver"). This makes use of the STM32 SDIO on-chip interface. NOTE: No support is yet in place for Secure Digital Input Output (I/O) cards.

If enabled this driver allows use of MultiMedia Cards (MMC cards) and Secure Digital (SD) flash storage cards within eCos, exported as block devices. This makes them suitable for use as the underlying devices for filesystems such as FAT.

This driver provides the necessary support for the generic MMC bus layer within the CYGPKG_DEVS_DISK_MMC package to export a disk block device. The disk block device is only available if the generic disk I/O layer found in the package CYGPKG_IO_DISK is included in the configuration.

The block device may then be used as the device layer for a filesystem such as FAT. Example devices are "/dev/mmcsd0/1" to refer to the first partition on the card, or "/dev/mmcsd0/0" to address the whole device including potentially the partition table at the start.

If the driver is enabled, the following options are available to configure it:

`CYGIMP_HAL_STM32_SDIO_INTMODE`

> This indicates that the driver should operate in interrupt-driven mode if possible. This is enabled by default if the eCos kernel is enabled. Note though that if the driver finds that global interrupts are off when running, then it will fall back to polled mode even if this option is enabled. This allows for use of the MMC/SD driver in an initialisation context.

`CYGNUM_HAL_STM32_SDIO_POWERSAVE`

> This option enables the power-saving feature that will disable the SD clock when the device is idle. This feature can normally be safely enabled on all STM32 platforms.

USB OTG Controllers

The STM32 series supports two different USB OTG controller implementations: OTG1 FS and OTG2 HS. If a specific STM32 microcontroller contains both controllers then configuration support is provided to enable you to select specific operation modes for each.

If only `CYGPKG_IO_USB_HOST` host support is enabled then both controllers will operate in host mode. Similarly, if only `CYGPKG_IO_USB_TARGET` is enabled then both controllers will operate in peripheral mode.

If both options are enabled then the controllers will default to host mode. To force a specific controller into peripheral mode then `CYGHWR_DEVS_USB_STM32_OTG_FS` or `CYGHWR_DEVS_USB_STM32_OTG_HS` should be set to `"TARGET"`.

If only one controller is in target mode, then `CYGHWR_IO_USB_TARGET_PCDI_DEFAULT`, and thus `CYGHWR_IO_USB_TARGET_PCDI`, will be set to that controller. If both controllers are in target mode then the FS controller will be used as the default. If you want to select the other controller then this will need to be set explicitly.

Note

The STM32 HS OTG2 controller support is currently limited to use in FS speed mode only. In addition, dynamically changing controller mode between host and target is not supported at this time.

RTC/Wallclock

eCos includes RTC (known in eCos as a wallclock) device drivers for the on-chip RTC in the STM32 family. For the F1 processor family this is located in the package `CYGPKG_DEVS_WALLCLOCK_STM32` ("STM32 RTC wallclock support"), and for the F2, F4, F7, L4 and H7 processor families this is located in the package `CYGPKG_DEVS_WALLCLOCK_STM32F2` ("STM32F2 RTC wallclock support").

On the F1 processor family, the wallclock driver can be configured with three different clock sources using the CDL configuration option `CYGHWR_DEVS_WALLCLOCK_STM32_RTC_SOURCE` ("RTC clock source"): `LSE` for the low-speed 32.768KHz external clock, `LSI` for the low-speed internal clock, or `HSE_128` for the high-speed external clock with a fixed divider of 128. The decision of which source to use depends on the desired clock stability and hardware configuration, and power requirements. Consult the STM32 documentation for more details.

The F2, F4, F7, L4 and H7 processor families are similar, except that the `LSI` clock is at 32KHz clock, and the CDL option name is `CYGHWR_DEVS_WALLCLOCK_STM32F2_RTC_SOURCE`.

Profiling Support

The STM32 HAL contains support for **gprof**-base profiling using a sampling timer. The default timer used is Timer 6, which is one of the basic timers, leaving the more complex timers for application code. The timer used is selected by a set of `#define`s in src/stm32_misc.c which can be changed to refer to a different timer if required. This timer is only enabled when the gprof profiling package (CYGPKG_PROFILE_GPROF) is included and enabled in the eCos configuration, otherwise it remains available for application use.

Clock Control

The platform HAL must provide the input clock frequency (CYGARC_HAL_CORTEXM_STM32_INPUT_CLOCK) in its CDL file. This is then combined with the following options defined in this package to define the default system clocks:

CYGHWR_HAL_CORTEXM_STM32_CLOCK_PLL_SOURCE

> This defines the source of the input to the PLL that generates the main system clock. There are two possible sources: the HSE selects the high speed external oscillator, and the HSI selects the high speed internal oscillator. This option defaults to the HSE.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_NEED_HSE

> This indicates whether the HSE clock should be started at all. If the system clock is running solely from the HSI clock, there may be no need for an HSE clock, and no crystal connected to it. In that scenario, this option can be disabled. This is usually set by the platform HAL.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_PLL_PREDIV

> This option specifies how much the clock from the input source defined by CYGHWR_HAL_CORTEXM_STM32_CLOCK_PLL_SOURCE is divided down by, before being used as an input for the PLL. On non-connectivity parts, you can only divide by 2 or 1. On other F1 parts, if using HSI as the clock source, then that is automatically divided by 2. If using HSE as the clock source, then this value corresponds to the PREDIV1 field of register RCC_CFGR2. On F2 and F4 parts, this value corresponds to the PLLM field of RCC_PLLCFGR.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_PLL_MUL

> This defines the factor by which the PLL will multiply the selected input clock, after being divided by CYGHWR_HAL_CORTEXM_STM32_CLOCK_PLL_PREDIV. It ranges from 2 to 16 on F1 parts, and 2 to 432 on F2 and F4 parts, and defaults to 9, which is intended to give a 72MHz system clock on those boards with an 8MHz input. On the F1 it corresponds to the PLLMUL field of RCC_CFGR. On the F2/F4 it corresponds to the PLLN field of RCC_PLLCFGR.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_SYSCLK_DIV

> This setting is only applicable to the F2 and F4 family of processors. This defines the divider applied to the PLL output for use as the SYSCLK. It can only have values 2, 4, 6 or 8 and defaults to 4. This setting corresponds to the PLLP field of RCC_PLLCFGR.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_HCLK_DIV

> This defines the divider applied to the prescaler for all peripheral clocks. The HCLK fed to the AHB bus and other peripherals is taken directly from this output. Other peripheral clocks are derived by dividing it further. This can take values between 1 and 512 in powers of 2, the default value is 1.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_PCLK1_DIV

> This defines the prescaler divider for the peripheral clock passed to peripherals on the APB1 bus. It can take values between 1 and 16 in powers of 2, the default value is 2.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_PCLK2_DIV

> This defines the prescaler divider for the peripheral clock passed to peripherals on the APB2 bus. It can take values between 1 and 16 in powers of 2, the default value is 1.

CYGHWR_HAL_CORTEXM_STM32_CLOCK_PLLQ_DIV

> This setting only applies to the F2 and F4 family of processors. It defines the divider used to divide down the PLL output clock (VCO clock) for use by the USB OTG FS, SDIO and RNG peripherals. USB OTG FS requires a 48MHz clock and other peripherals require a clock no greater than 48MHz. The allowable values range from 4 to 15 and the default is 10.

The actual values of these clocks, in Hz, is stored in global variables `hal_stm32_sysclk`, `hal_stm32_hclk`, `hal_stm32_pclk1`, `hal_stm32_pclk2` and for the F2/F4/F7 processor families only, `hal_stm32_qclk`. The clock supplied to the SysTick timer, HCLK/8, is also assigned to `hal_cortexm_systick_clock`. These variables are used, rather than configuration options, in anticipation of future support for power management by varying the system clock rate.

Note that when changing or configuring any of these clock settings, you should consult the relevant processor datasheet as there may be both upper and lower constraints on the frequencies of some clock signals, including intermediate clocks. There are also some clocks where, while there is no strict constraint, clock stability is improved if values are chosen wisely. Finally, be aware that increasing clock speeds using this package may have an effect on platform specific properties, such as memory timings which may have to be adjusted accordingly.

`CYGHWR_HAL_STM32_GPIO_OUT`` (`*`pin`*`, `*`val`*`);`

`CYGHWR_HAL_STM32_GPIO_IN`` (`*`pin`*`, `*`val`*`);`

Description

The STM32 HAL provides a number of macros to support the encoding of GPIO pin identity and configuration into a single 32 bit descriptor. This is useful to drivers and other packages that need to configure and use different lines for different devices.

A descriptor is created with one of the 5 variants depending on how the pin is to be used: `CYGHWR_HAL_STM32_PIN_IN` defines the pin as an input whose value can be accessed by the user using the macro `CYGHWR_HAL_STM32_GPIO_IN` (see later) `CYGHWR_HAL_STM32_PIN_OUT` defines the pin as an output where the user can set the pin output value with the macro `CYGHWR_HAL_STM32_GPIO_OUT` (see later); `CYGHWR_HAL_STM32_PIN_ALTFN_OUT` and `CYGHWR_HAL_STM32_PIN_ALTFN_IN` are used to define a pin that will be controlled by an on-chip peripheral; or `CYGHWR_HAL_STM32_PIN_ANALOG` which means it can be used as an input to the ADC peripheral or an output from the DAC peripheral.

The distinction between the `CYGHWR_HAL_STM32_PIN_ALTFN_OUT` and `CYGHWR_HAL_STM32_PIN_ALTFN_IN` is purely whether a speed parameter is required, since both macros define a pin that will be controlled by an on-chip peripheral. This distinction is required to provide simpler F1 family support for its different alternative I/O mapping implementation.

The 5 variants take a subset of arguments from the following list:

`port`
: This identifies the GPIO port to which the pin is attached. Ports are identified by letters from A to I.

`bit`
: This gives the bit or pin number within the port. These are numbered from 0 to 15.

`af`
: For the `ALTFN` macros this parameter indicates which on-chip peripheral is used to control the pin. Consult ST's documentation for the specific processor model to determine which peripheral number is used to select the peripheral for the required pin mapping.

  This field is not-relevant to, and hence ignored by, the F1 family of devices where the alternative AFIO configuration mechanism is used.

`ppod`
: If this is an output pin (either GPIO output or driven by a peripheral), this setting indicates whether it should be driven in push-pull mode (`PUSHPULL`) or open-drain mode (`OPENDRAIN`). If the pin is not an output pin, this value is unused, but for clarity can be given the setting `NA`.

pupd

If this is an input pin, or an output pin configured in open-drain mode (whether controlled by GPIO or a peripheral), this setting can be used to indicate whether a weak pull-up resistor (PULLUP) is used, or a weak pull-down resistor (PULLDOWN) is used. If neither are to be used, then a value of NONE can be given. For F1 family devices the value FLOATING can be used to identify a floating input, which is synonomous with NONE for F2/F4 family devices.

speed

This setting indicates the output speed for GPIO outputs. At time of writing, the speeds for F1 parts can be 2MHz, 10MHz or 50MHz and for F2/F4 parts can be 2MHz, 25MHz, 50Mhz, 100MHz with 30pF capacitance or 80MHz with 15pF capacitance. It is possible to indicate the desired speed by passing in the generic values LOW, MED, FAST, or HIGH.

For F1 family devices these are synonymous with using values of 2MHZ, 25MHZ, 50MHz or 50MHz respectively (FAST and HIGH being synonyms due to the 50MHz limit on F1 family devices).

For F2/F4 family devices these are synonymous with using values of 2MHZ, 25MHZ, or 50MHz respectively, with no corresponding value for HIGH due to its variable nature.

In order to make these definitions more future-proof and abstract, it is therefore strongly recommended to use this form of setting instead: AT_LEAST(*mhz*) to indicate the next speed rating above the supplied speed (in MHz); and analogously, AT_MOST(*mhz*) to indicate that the supplied speed in MHz must not be exceeded.

For non-GPIO output pins, a value of NA can be given.

The following examples show how these macros may be used:

```
// Define port A pin 10 as being controlled by a peripheral which, for
// this pin on F2/F4 devices, is alternate function 7 (and for this
// pin that means USART1), without any pull-ups/pull-downs.
#define CYGHWR_HAL_STM32_UART1_RX               CYGHWR_HAL_STM32_ALTFN_IN( A, 10, 7, NA, NONE )

// Define port B pin 10 as a push-pull output under the control of the
// peripheral which, for this pin on F2/F4 devices, is alternate
// function 7 (and for this pin that means USART3), with an output
// speed of 50MHz or greater.
#define CYGHWR_HAL_STM32_UART3_TX               CYGHWR_HAL_STM32_ALTFN_OUT( B, 10, 7, PUSHPULL, NONE, AT_LEAST(50) )

// Define port A pin 12 as a push-pull output under GPIO control, with no
// pull-ups/pull-downs, with an output speed of 50MHz or greater.
#define CYGHWR_HAL_STM32_UART1_RTS              CYGHWR_HAL_STM32_OUT( A, 12, PUSHPULL, NONE, AT_LEAST(50) )
```

Additionally, the macro CYGHWR_HAL_STM32_GPIO_NONE may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used. This can be useful when defining pin configurations for a series of instances of a peripheral (e.g. UART ports), but where not all instances support all the same pins (e.g. hardware flow control lines).

The remaining macros all take a suitably constructed GPIO pin descriptor as an argument. CYGHWR_HAL_STM32_GPIO_SET configures the pin according to the descriptor and must be called before any other macros. CYGHWR_HAL_STM32_GPIO_OUT sets the output to the value of the least significant bit of the *val* argument. The *val* argument of CYGHWR_HAL_STM32_GPIO_IN should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

Further helper macros are available, and it is recommended to consult the header file <cyg/hal/var_io_pins.h> (also present in the include subdirectory of the STM32 variant HAL package within the eCos source repository), for the complete list if needed. Ensure you only inspect the relevant sections of this low-level header file when investigating specific F1 and F2/F4 processor family variants.

EXTI wrapper

If a platform implements CYGINT_HAL_STM32_GPIO_EXTI_VECTOR then support for a simple EXTI interrupt handler wrapper is provided. This is used to “hide” the eCos interrupt implementation when supporting callback handlers for interrupt enabled

GPIO pins. For almost all STM32 platforms and eCos applications this wrapper functionality is *NOT* required, and the `CYGIMP_HAL_STM32_GPIO_EXTI_VECTOR` option should not be enabled.

The interface is exported via manifests that are only defined when the relevant functionality is available. The *`pin`* argument is a standard eCos GPIO pin descriptor as described above.

The `CYGHWR_HAL_VAR_GPIO_IRQ_INIT()` referenced code should be called at a suitable initialisation point either by the platform or the eCos application, prior to enabling a specific source.

When enabling a callback for a GPIO EXTI source the *`trigger`* parameter encodes whether the handler is called for rising (`CYGHWR_HAL_VAR_IRQ_EDGE_RISE`), falling (`CYGHWR_HAL_VAR_IRQ_EDGE_FALL`), or either (`CYGHWR_HAL_VAR_IRQ_EDGE_BOTH`), edge events. When the configured event occurs the referenced *`handler`* function is called with the supplied *`arg`* parameter.

An example use of this functionality is when building eCos WICED applications against an unmodified WICED-SDK source-tree,

The `HAL_VAR_EXTI_EVENT_CONFIGURE()` code allows for control of EXTI events. The *`vector`* is the corresponding EXTI interrupt identifier. The *`up`* parameter encodes whether the event is triggered from a rising signal (`1`) or falling signal (`0`). The *`enable`* parameter defines whether the event is being enabled (`1`) or disabled (`0`).

EXTI wrapper API

#include <cyg/hal/hal_io.h>

`void` **`CYGHWR_HAL_VAR_GPIO_IRQ_INIT`**`();`

`cyg_bool enabled =` **`CYGHWR_HAL_VAR_GPIO_IRQ_ENABLE`**`(`*`pin`*`,` *`trigger`*`,` *`handler`*`,` *`arg`*`);`

`void` **`CYGHWR_HAL_VAR_GPIO_IRQ_DISABLE`**`(`*`pin`*`);`

`void` **`HAL_VAR_EXTI_EVENT_CONFIGURE`**`(`*`vector`*`,` *`up`*`,` *`enable`*`);`

Name

Peripheral clock control — Details

Synopsis

#include <cyg/hal/hal_io.h>

cyg_uint32 clkdesc = **CYGHWR_HAL_STM32_CLOCK**(*clk*);

CYGHWR_HAL_STM32_CLOCK_ENABLE (*clkdesc*);

CYGHWR_HAL_STM32_CLOCK_DISABLE (*clkdesc*);

Description

The HAL provides macros which may be used to enable or disable peripheral clocks. Effectively this indicates whether the peripheral is powered on (enabled) or powered down (disabled) and so may be used to ensure unused peripherals are turned off, to save power.

It is important to remember that before a peripheral can be used, it must be enabled. It is safe to re-enable a peripheral that is already enabled, although usually a device driver will only do so once in its initialisation. eCos will automatically initialise some peripheral blocks where it needs to use the associated peripherals (such as memory controllers and some (but usually not all) GPIO banks), and in eCos-supplied device drivers which are included in the eCos configuration. However this should not be relied on - it is always safest to enable the peripheral clocks anyway just in case. Finally, remember that each GPIO bank must be enabled separately.

The `CYGHWR_HAL_STM32_CLOCK` macro can be used to create a descriptor used to specify the clock. This takes the following parameter:

clk
: This parameter selects the specific clock. Definitions for each clock can be found in the file `<cyg/hal/var_io.h>` which can also be found as the file `include/var_io.h` within the STM32 processor variant HAL package in the eCos source repository, ensuring you are looking at the correct section for the relevant processor family.

Once a descriptor has been created, it may be used as the parameter to the `CYGHWR_HAL_STM32_CLOCK_ENABLE` or `CYGHWR_HAL_STM32_CLOCK_DISABLE` macros in order to enable or disable the peripheral clock.

The following example shows how these macros may be used:

```
#define CYGHWR_HAL_STM32_ETH_MAC_CLOCK          CYGHWR_HAL_STM32_CLOCK( ETHMAC )

int init_eth(...)
{
      CYGHWR_HAL_STM32_CLOCK_ENABLE(CYGHWR_HAL_STM32_ETH_MAC_CLOCK);
      ... /* Rest of initialisation */
}

void stop_eth(...)
{
     ... /* Free up resources */
     CYGHWR_HAL_STM32_CLOCK_DISABLE(CYGHWR_HAL_STM32_ETH_MAC_CLOCK);
}
```

DMA Support — Details

Synopsis

#include <cyg/hal/var_dma.h>

`pin = CYGHWR_HAL_STM32_DMA(ctlr, stream, chan, mode);`

`pin = CYGHWR_HAL_STM32_DMA(dmareq_id, dmamux_channel, mode);`

`hal_stm32_dma_init (hal_stm32_dma_stream *stream, int priority);`

`hal_stm32_dma_delete (hal_stm32_dma_stream *stream);`

`hal_stm32_dma_disable (hal_stm32_dma_stream *stream);`

`hal_stm32_dma_configure (hal_stm32_dma_stream *stream, int tfr_size, cyg_bool no_minc, cyg_bool polled);`

`hal_stm32_dma_configure_circular (hal_stm32_dma_stream *stream, cyg_bool enable);`

`hal_stm32_dma_configure_doublebuffer (hal_stm32_dma_stream *stream, cyg_bool enable, void *memory1);`

`hal_stm32_dma_configure_flow (hal_stm32_dma_stream *stream, cyg_bool enable);`

`hal_stm32_dma_start (hal_stm32_dma_stream *stream, void *memory, CYG_ADDRESS peripheral, cyg_uint32 size);`

`hal_stm32_dma_stop (hal_stm32_dma_stream *stream);`

`hal_stm32_dma_poll (hal_stm32_dma_stream *stream);`

Description

The HAL provides support for access to the DMA controllers. This support is not intended to expose the full functionality of these devices and is mainly limited to supporting peripheral DMA, currently ADC, SPI, I²C and MMC/SD.

The user is referred to the ST documentation for a full description of the DMA devices, and to the sources of the ADC, I²C, SPI and MMC/SD drivers for examples of the use of this API. This documentation only gives a brief description of the functions available.

A DMA stream is defined by a controller number (0 or 1), a stream number (0 to 8), a channel number (0 to 7) and a mode defining transfer direction. The macro `CYGHWR_HAL_STM32_DMA()` combines these into a 32-bit descriptor that may be stored with a device driver and used to initialize the stream.

NOTE: the DMA terminology has changed between F1 and F2/F4 versions of the STM32 family. In F1 devices each DMA controller has a number of channels, each of which can be driven by a subset of the on-chip devices; there is no way to select which device drives the channel, and care must be taken to allocate channels so that devices don't trigger the wrong channel. In F2/F4 devices each DMA controller has a number of streams; each stream can explicitly select one of a number of driving devices by means of a channel selection field in a control register. F1 channels and F2/F4 streams are essentially the same thing, and the problems of false triggering in F1 devices is solved in F2/F4 by adding the explicit channel selection. To make things more complicated, F1 channels are numbered from one while F2/F4 streams are numbered from zero. HAL support for DMA largely follows the F2/F4 terminology, but the original channel numbering for the F1 is preserved when defining channels.

The following examples show how definitions should be made:

```
    // F1 definition: controller 1, channel 6, memory-to-peripheral
    #define CYGHWR_HAL_STM32_I2C1_DMA_TX            CYGHWR_HAL_STM32_DMA( 1, 6, 0, M2P )

    // F2/F4 definition: controller 2, stream 0, channel 3, peripheral-to-memory
    #define CYGHWR_HAL_STM32_SPI1_DMA_RX            CYGHWR_HAL_STM32_DMA( 2, 0, 3, P2M )
```

The special manifest `CYGHWR_HAL_STM32_DMA_NONE` can be used when the code does not require DMA support for a specific stream. For example:

```
    // I2C2 RX should NOT use DMA
    #define CYGHWR_HAL_STM32_I2C2_DMA_RX            CYGHWR_HAL_STM32_DMA_NONE
```

Note

Not all device drivers support the ability of using `CYGHWR_HAL_STM32_DMA_NONE` to disable DMA use for specific stream mappings. For example, the STM32 I²C driver does allow for individual streams to be configured for interrupt-driven or DMA transfers as required.

Some later variants such as the L4+ or H7 implement a DMA multipexor which routes peripheral DMA requests to DMA controller channels. This means that the way in which DMA channels are associated with peripherals is somewhat different and DMA descriptors have a different format. Instead of selecting a DMA controller and channel, a DMAMUX channel is selected which automatically selects the DMA controller and channel. The following examples show how these descriptors are initialized:

```

// L4+
// I2C1 RX uses DMAMUX channel 0, which maps to DMAC 1, channel 0, peripheral-to-memory
#define CYGHWR_HAL_STM32_I2C1_DMA_RX     CYGHWR_HAL_STM32_DMA(CYGHWR_HAL_STM32_DMAMUX_I2C1_RX,0,P2M)

// H7
// SPI5 TX uses DMAMUX channel 10, which maps to DMAC 2, channel 3, memory-to-peripheral
#define CYGHWR_HAL_STM32_SPI5_DMA_TX    CYGHWR_HAL_STM32_DMA(SPI5_TX,10,M2P)

```

Before use a DMA stream must be initialized. This is done by calling `hal_stm32_dma_init()`. The first argument to this is a hal_stm32_dma_stream structure in which the *`desc`* field should have been initialized to a DMA descriptor; the *`callback`* field set to a callback function; and the *`data`* field set to any user defined data. The *`priority`* argument defines both the interrupt level assigned to the stream interrupt, and the DMA channel arbitration priority level (defined by the top two bits). This function initializes the hardware and the stream structure and needs only to be called once during driver initialization.

By default a stream is initialized to perform 8 bit transfers under interrupt control and to advance the memory address pointer. If a different configuration is required, then the driver should call `hal_stm32_dma_configure()` which will allow these options to be varied. The *`tfr_size`* argument defines the transfer size and may be 8, 16 or 32 bits. The *`no_minc`* argument disables memory increments if true. The *`polled`* argument configures the stream for polled mode if true, otherwise it will be interrupt driven. This function may either be called once to set up the stream permanently, or on a transfer-by-transfer basis, or not at all if the defaults are what is required.

If the driver needs circular mode DMA processing then it can call the function `hal_stm32_dma_configure_circular()` with *`enable`* set to true. This allows circular buffers and continuous data flows (e.g. ADC scan mode as used by the STM32F ADC driver). Calling the function with *`enable`* set to false will disable circular mode.

If a F2/F4 driver wants to use the continuous double-buffer support then it can call the `hal_stm32_dma_configure_doublebuffer()` with *`enable`* set to true. This configures the DMA to automatically switch between buffers at the end of a transfer. The *`memory1`* is the second buffer to be used in conjunction with the buffer passed as the *`memory`* parameter to the `hal_stm32_dma_start()` function.

Note

The second buffer *must* be at least the same *`size`* as the (first) buffer subsequently passed to the `hal_stm32_dma_start()` function.

Calling the function with *enable* set to false will disable the double buffer mode, with the passed *memory1* parameter being ignored.

Warning

The DMA controller hardware when using double buffer mode will automatically switch buffers on a buffer fill event.

When using double buffer mode the developer should ensure that the buffer size used is large enough to cope with the processing code associated with a completed transaction being able to complete to avoid overrun. The size of the buffers will depend on the DMA transfer rate for the peripheral being used and the application DSR latency, plus the actual callback buffer processing code time.

If a F2/F4 driver needs to use peripheral controlled DMA flow then it can call the function `hal_stm32_dma_configure_flow()` with *enable* set to true. This configures the DMA to allow the peripheral to control the flow of DMA transfers, instead of the DMA controller (e.g. the STM32 SDIO device signals the end of data transfers). Calling the function with *enable* set to false will disable the peripheral flow control mode.

A transfer is defined and started by calling `hal_stm32_dma_start()`. The *memory* argument defines the memory address to/from which the transfer will be made. The *peripheral* argument is the address of the data register of the peripheral involved. The *size* argument defines the number of data items to be transferred, or in the case of peripheral flow control configurations the number of items expected, as defined by *tfr_size*. Once this call completes, the channel is operational and will transfer data once the peripheral starts triggering transfers.

If the stream is configured for interrupt control then when a transfer completes an interrupt is raised. This will disable the stream and cause the callback in the stream structure to be called from DSR mode. The prototype of the callback is as follows:

```
    typedef void hal_stm32_dma_callback( hal_stm32_dma_stream *stream, cyg_uint32 count, CYG_ADDRWORD data );
```

The *stream* argument is the stream structure initialized by the user. The *count* argument is a count of the number of data items that remain to be transferred, and will be zero for a successful transfer. The *data* argument is a copy of the *data* field from the stream structure.

The configuration option `CYGIMP_HAL_STM32_DMA_CALLBACK_ISR` can be used to enable the optional support for an ISR level callback when the DMA TransferComplete (TC) interrupt is triggered. This support is not normally required, but some STM32 family variants may require some collusion between the DMA system and the peripheral H/W controller to ensure correct operation. As such it is not expected that the developer should ever need to manually enable `CYGIMP_HAL_STM32_DMA_CALLBACK_ISR` since it will be automatically enabled if any of the configured packages require the functionality. The callback is executed within the ISR of the DMA TC processing and so should not block.

```
    typedef void hal_stm32_dma_callback_isr( hal_stm32_dma_stream *stream, CYG_ADDRWORD data );
```

As with the normal DSR callback the *stream* argument is the stream structure initialized by the user and the *data* argument is a copy of the *data* field from the stream structure.

If the stream is configured for polled mode, then the driver must call `hal_stm32_dma_poll()` frequently. When the transfer has completed the callback function will be called from within the poll routine. The driver needs to detect this and terminate the polling loop.

Most drivers will initialize a DMA stream and keep it enabled throughout the system lifetime. However, if it is necessary to share a stream, or otherwise disable use of a stream, the driver may call `hal_stm32_dma_delete()` to return a stream to unused state. It will be necessary to call `hal_stm32_dma_init()` before it can be used again.

Alternatively for circular mode configured streams the `hal_stm32_dma_disable()` can be used to disable the stream DMA without clearing the state. The function `hal_stm32_dma_start()` can then be used to re-enable the DMA stream with the previous configured state.

The `hal_stm32_dma_stop()` function allows a stream to be disabled *without* clearing the transfer state. The normal callback handler is subsequently called with a non-zero *count* indicating a partial transfer.

Note

The `hal_stm32_dma_stop()` function will return immediately, however the stream may remain active until any active “item” transfer has completed (*not* the full *`size`* amount). When appropriate the stream will be disabled by the DMA controller and the relevant callback handler function called asynchronously.

Name

Test Programs — Details

Test Programs

The STM32 variant HAL contains some test programs which allow various aspects of the microcontroller or the architecture to be tested.

Timers Test

The `timers` test checks the functionality of the microcontroller timers and in particular the interrupt priority and nesting mechanisms. The test programs all the available timers to interrupt at a variety of different rates and records various parameters. The timers are programmed to interrupt at higher rates for lower numbered timers, and higher rate timers are given higher priority. The test outputs a sequence of tables of the following format:

```
ISRs max_nesting 6 max_nesting_seen 7
 T      Ticks         0         1         2         3         4         5         6         7         8

       count:         0     33722         0         0         0         0         0         0         0
 3:  preempt:     99002       354        95         7        55        31        23        18        15
       count:         0     16401         0         0         0         0         0         0         0
 4:  preempt:     79892       331        83        39         3        23        21        12        13
       count:         0     12006         0         0         0         0         0         0         0
 5:  preempt:     60628       184        65        33        27         0         9        13         6
       count:         0      8258         0         0         0         0         0         0         0
 6:  preempt:     49798       180        53        22        21        15         0        12         6
       count:         0      6215         0         0         0         0         0         0         0
 7:  preempt:     53583       158        48        25        18        11        16         0         5
       count:         0      5968         0         0         0         0         0         0         0
 8:  preempt:     50937       140        46        22        18         6         9         8         0
       count:         0      5118         0         0         0         0         0         0         0
```

The first line shows the depth of ISR nesting seen since the last report, plus the maximum seen throughout the run.

The first table contains a row for each timer. The *Ticks* column shows the total number of ISRs called for this timer. The *0* column shows how many ISR calls interrupted thread state. The remaining columns show how many ISR calls preempted the ISR for the given timer. For example, the ISR for timer 1 preempted the ISR for timer 6 60741 times.

The second table contains two rows for each timer. The *preempt:* row shows how many times the ISR preempted the DSR for the given timer. The zero column correspond to thread state as before. For example the ISR for timer 2 preempted the DSR for timer 4 75 times. The *count:* row shows the range of `count` values passed to the DSR and indicate the number of DSR calls not matched exactly to ISR calls. The ISR calls the DSR every 10 ticks, so the total counts should be one tenth of the ISR Ticks value.

Chapter 297. STM3210C-EVAL Platform HAL

Name

CYGPKG_HAL_CORTEXM_STM32_STM3210C_EVAL — eCos Support for the STM3210C-EVAL Board

Description

The STM3210C-EVAL board contains a STM32F107VCT microcontroller. It has connectors for one UART, I²C, MicroSD, USB, CAN, JTAG and various other devices.

For typical eCos development, a GDB stub image is programmed into internal FLASH and the CPU boots directly into that. It is then possible to download and debug stand-alone and eCos applications via the gdb debugger using USART1. Alternatively test programs may be downloaded and debugged via a JTAG debugger attached to the JTAG socket. Available RAM is limited to 64KB, so development for larger applications may also consist of programming them to flash and using JTAG to debug them from there.

This documentation describes platform-specific elements of the STM3210C-EVAL board support within eCos. The STM32 variant HAL documentation covers various topics including HAL support common to STM32 variants, and on-chip device support. This document complements the STM32 documentation.

Supported Hardware

The STM32 has two on-chip memory regions. A RAM region of 64KiB is present at 0x20000000. A FLASH region is present at 0x08000000 and is aliased to 0x0000000 during normal execution.

The STM32 variant HAL includes support for the five on-chip serial devices which are documented in the variant HAL. USART1 is connected to an external connector on the board marked "CN6". The UART does not have any RTS/CTS lines, but the CTS and DSR pins are connected to bootloader reset and select lines. Care must therefore be taken when connecting this board to a host to ensure that these lines are not pulled in the wrong direction. A three wire cable is recommended.

The STM32 variant HAL also includes support for the I²C bus. A single I²C device is instantiated as part of the platform port, which is for the M24C64 serial EEPROM connected via I²C. It is exported to `<cyg/io/i2c.h>` with the name `hal_stm32_i2c_eeprom` in the normal way.

Device drivers are provided for the STM32 on-chip ADC interfaces, SPI interface and Ethernet MAC. Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

Also, while the board is fitted with a CAN interface, this is not presently supported by the HAL port; nor is the microSD card (or SDIO interface) at the present time. The STM32F1 processor and the STM3210C-EVAL board provide an extremely wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.3.2, **arm-eabi-gdb** version 6.8, and **binutils** version 2.18.

Name

Setup — Preparing the STM3210C-EVAL Board for eCos Development

Overview

In a typical development environment, the STM3210C-EVAL board boots from internal flash into the GDB Stubrom. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**.

Stubrom Installation

For serial communications, the Stubrom runs with 8 bits, no parity, and 1 stop bit at 38400 baud. This rate can be changed in the platform HAL configuration. Under normal circumstances, the Stubrom runs in-place from the internal Flash.

Programming The Stubrom

To program the Stubrom into the internal flash either a JTAG debugger that understands the STM32 flash may be used, such as a Ronetix PEEDI or an Abatron BDI3000, or the ST **Flash Loader Demonstrator** may be used. Configuration files for the PEEDI and BDI3000 are supplied in the STM3210C-EVAL HAL package, and brief instructions for downloading the Stubrom are given in there. If no JTAG debugger is available, then the Stubrom must be downloading using the **Flash Loader Demonstrator** which can be downloaded from the page for the STM32F101ZE CPU, in the *Design Support->Demo SW* section of ST's website at http://www.st.com/internet/mcu/product/164506.jsp

The documentation for this may be found at http://www.st.com/internet/com/TECHNICAL_RESOURCES/TECHNICAL_LITERATURE/USER_MANUAL/CD00171488.pdf

The following are brief instructions for downloading the Stubrom using the **Flash Loader Demonstrator**.

1. Download the **Flash Loader Demonstrator** from the ST website and install it on a PC running Windows that has an available serial port.

2. Copy the file `stubrom.bin` from the `loaders/stm3210c_eval/gdbstub/ROM` sub-directory within your eCosPro installation to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the USART1 serial port and a serial port on the Windows machine.

4. Move the *BOOT0/SW2* switch to the 1 position, ensure the *BOOT1/SW1* switch remains in the 0 position, and press the reset button.

5. Start the **Flash Loader Demonstrator** and in the first screen select the COM port connected to the board under *Port Name*. Ensure that the baud rate is also set at *115200*, with *Even* parity and *Echo* disabled. Press *Next*. If you are succesfully connected to the board, you should see the message *Target is readable. Please press "Next" to proceed* . Press *Next* and you will be prompted to select a target. Select *STM32_Connectivity-line_256K*, then *Next* to go to the Operation choice page. If any of these steps fail, follow the direction given by the loader to recover.

6. On the operation choice page select *"Download to device"* and under *"Download from file"* either type the location of the `stubrom.bin` file, or browse to it. Ensure that the *"@"* field is set to *8000000*, the *"Global Erase"* radio button is selected and that all other options are clear except *"Verify after download"*.

7. Press *"Next"* and the loader should download and verify the binary file. The download or verify may fail if the flash has been previously locked, in which case you should select the *"Enable/Disable Flash protection"* radio button, *"Disable"* and *"Write Protection"* drop-down items, press *"Next"* and retry the download. Upon successful download press *"Close"* to exit the loader.

8. Move the *BOOT0/SW2* switch back to the 0 position and press the reset button.

The behaviour of the **Flash Loader Demonstrator** documented here is that of version 2.2.0. The actual behaviour of newer or older versions may vary slightly.

Whatever mechanism is used to program the Stubrom, something similar to the following output should be seen on USART1 when the reset button is pressed:

```
+$T050f:e2230008;0d:f0ff0020;#b5
```

Rebuilding the Stubrom

Should it prove necessary to rebuild a Stubrom binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of the Stubrom are:

```
$ mkdir stubrom_stm3210c_rom
$ cd stubrom_stm3210c_rom
$ ecosconfig new stm3210c stubs
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm3210c_eval/VERSION/misc/stubs_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `stubrom.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The STM3210C-EVAL board platform HAL package is loaded automatically when eCos is configured for an `stm3210c_eval` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM3210C-EVAL board platform HAL package supports three separate startup types:

RAM

> This is the startup type which is normally used during application development. The board has GDB stubs programmed into internal Flash at location 0x08000000 and uses internal RAM at location 0x20000000. arm-eabi-gdb is then used to load a RAM startup application into memory from 0x20001000 and debug it. It is assumed that the hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain services from the stubs, including diagnostic output.

ROM

> This startup type can be used for finished applications which will be programmed into internal ROM at location 0x08000000. Data and BSS will be put into internal RAM starting from 0x20000400. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

JTAG

> This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000400 and entered at that address. eCos startup code will perform all necessary hardware initialization.

Monitors and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the Stubrom.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port 0 will be claimed for HAL diagnostics.

UART Serial Driver

The STM3210C-EVAL board uses the STM32's internal UART serial support. As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_CORTEXM_STM32` package which contains all the code necessary to support interrupt-driven operation with greater functionality. All five UARTs can be supported by this driver, although only USART1 is actually routed to an external connector. Note that it is not recommended to enable this driver on the port used for HAL diagnostic I/O. This driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Ethernet Driver

The STM3210C-EVAL board is fitted with an Ethernet port connected via a DP83848 PHY to the STM32's on-chip Ethernet MAC. This is supported in eCosPro with a driver for the lwIP networking stack, contained in the package `CYGPKG_DEVS_ETH_CORTEXM_STM32`. At the present time it only supports the lwIP networking stack, and cannot be used for either the BSD networking stack, nor RedBoot.

The driver will be inactive (not built and greyed out in the eCos Configuration Tool) unless the platform HAL option "STM32 Ethernet Support" (`CYGPKG_HAL_CORTEXM_STM32_STM3210C_EVAL_ETH0`) is enabled. This option in turn is only active if the "Common Ethernet support" (`CYGPKG_IO_ETH_DRIVERS`) package is included in your configuration. As the STM32 ethernet driver is an lwIP-only driver, it is most appropriate to choose the `lwip_eth` template as a starting point when choosing an eCos configuration, which will cause the necessary packages to be automatically included.

The STM32 ethernet driver defines a further configuration option "Use MCO as PHY clock" (`CYGHWR_DEVS_ETH_CORTEXM_STM32_PHY_CLK_MCO`) which indicates whether the MCO1 clock signal is used as the 25MHz clock for the Ethernet PHY. With this option disabled, the on-board 25MHz crystal oscillator located at X1 can be used instead, although in that case the board jumper JP4 must be changed. You may wish to make this change if you wish to use the MCO1 clock output for another purpose. Consult the STM32 clock and ethernet documentation for more details.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. But the platform I²C support can also be configured separately at `CYGPKG_HAL_CORTEXM_STM32_STM3210C_EVAL_I2C`. This ensures that the M24C64 serial EEPROM is instantiated and becomes available for applications from `<cyg/io/i2c.h>`, and also ensures the STM32's I²C bus 1 is enabled for it. This option also allows the m24c64.c test is built. In order to allow writes to the serial EEPROM, you must ensure that the STM3210C-EVAL jumper JP17 is fitted. The m24c64.c test will not pass otherwise.

SPI Driver

An SPI bus driver is available for the STM32 in the package "ST STM32 SPI driver" (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

The only SPI device instantiated by default is for an external Aardvark SPI test board, connected to SPI bus 3 with the SD card attached to chip select 0 on PA4 and the Aardvark AT25080 to chip select 1 on PD2 (CN8 pin 24). To disable the Aardvark device support, the platform HAL contains an option "SPI devices" (`CYGPKG_HAL_CORTEXM_STM32_STM3210C_EVAL_SPI`) which can be disabled. No other SPI devices are instantiated.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM3210C-EVAL platform HAL enables the support for the devices ADC1, ADC2 and ADC3 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including the Stubrom.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M3 core of the STM32 only supports two such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.stm32.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the clocks, GPIO lines, SRAM and flash memory controller.

The `peedi.stm32c.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.stm32c.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode can be selected in two ways. Either with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi.stm32c.cfg` file. Or by using the **reset run** command. Either approach conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Although using **reset run** will not be persistent across reboots of the PEEDI itself.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
stm3210c> memory load tftp://192.168.7.9/test.bin bin 0x02000000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x20000400
loading at 0x20000400

Successfully loaded 23KB (24560 bytes) in 0.1s
stm3210c> go
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

Abatron BDI3000 notes

On the Abatron BDI3000, the `bdi3000.stm32.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the clocks, GPIO lines, SRAM and flash memory controller.

The `bdi3000.stm32.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **boot** command on the BDI3000 command line interface.

On the BDI3000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI3000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI3000 is powered up, the target will always run the initialization section of the `bdi3000.stm32.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
STM3210C> load 0x20000400 test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
STM3210C> go 0x20000400
```

Consult the BDI3000 documentation for information on other formats and loading mechanisms.

Configuration of JTAG applications

JTAG applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required, and a memory layout selected which will take advantage of the extra RAM space available. All necessary settings are made automatically if the JTAG startup type is selected.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM3210C-EVAL board hardware, and should be read in conjunction with that specification. The STM3210C-EVAL platform HAL package complements the ARM architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM and JTAG startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm3210c_eval_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM

> This is located at address 0x20000000 of the memory space, and is 64KiB in size. The eCos VSR table occupies the bottom 512 bytes. The virtual vector table starts at 0x00000200 and extends to 0x00000300. The top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH

> This is located at address 0x08000000 of the memory space and will be mapped to 0x00000000 at reset. This region is 512KiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals

> These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table	This defines the location of the VSR table. This is set to 0x20000000 for all startup types, and space for 128 entries is reserved.
hal_virtual_vector_table	This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20000200. To permit expansion and possible addition of other tables, the linker scripts then allocate further sections from 0x20000400.
hal_interrupt_stack	This defines the location of the interrupt stack. For all startups, this is allocated to the top of internal SRAM, 0x20010000.

hal_startup_stack

This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Name

Test Programs — Details

Test Programs

The STM3210C platform HAL contains some test programs which allow various aspects of the board to be tested.

ADC test

This program tests the ADC driver for the STM32. The only device connected to the ADC on the board is the potentiometer connected to ADC1 logical channel 14. Therefore this test primarily tests that. However, in addition it also report the values of the temperature sensor and Vrefint inputs that are sourced on-chip. The option `CYGBLD_HAL_CORTEXM_STM3210C_EVAL_TEST_ADC` must be enabled to run this test since it needs human interaction.

M24C64 I²C serial EEPROM test

This program tests I²C access to the on-board M24C64 serial EEPROM. This test is only built if the CDL configuration option `CYGPKG_HAL_CORTEXM_STM32_STM3210C_EVAL_I2C` is enabled. The STM3210C-EVAL board prevents writes to the EEPROM unless jumper JP17 is closed. Therefore to allow this test to pass, ensure JP17 is fitted with a jumper.

Chapter 298. STM3210E-EVAL Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM3210E_EVAL` — eCos Support for the STM3210E-EVAL Board

Description

The STM3210E-EVAL board consists of a STM32F103Z microcontroller, 1MiB of external SRAM, 16MiB NOR flash and 64MiB NAND flash. It has connectors for two UARTs, I²C, MicroSD, USB, CAN, JTAG and various other devices. Early versions of the board contain STM32F103ZET6 MCUs and later boards from RevD-03 onwards are populated with the STM32F103ZGT6. The former has 512KiB of internal flash and the latter 1MiB.

For typical eCos development, RedBoot or a GDB stub image is programmed into internal FLASH and the CPU boots directly into that. It is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART0. Alternatively test programs may be downloaded and debugged via a JTAG debugger attached to the JTAG socket.

This documentation describes platform-specific elements of the STM3210E-EVAL board support within eCos. The STM32 variant HAL documentation covers various topics including HAL support common to STM32 variants, and on-chip device support. This document complements the STM32 documentation.

We have found that some revisions of the STM3210E-EVAL board and its attached LCD are unreliable unless the LCD is removed. If the board suffers from lockups or other reliability issues then we recommend disconnecting the LCD to determine if that is the cause.

Supported Hardware

The STM32 has two on-chip memory regions. A RAM region of 64KiB is present at 0x20000000. A FLASH region is present at 0x08000000 and is aliased to 0x0000000 during normal execution. On-board memory consists of 1MiB of SRAM mapped to 0x68000000 and 16MiB of NOR FLASH mapped to 0x64000000.

The STM32 variant HAL includes support for the five on-chip serial devices which are documented in the variant HAL. UART0 and UART1 are connected to external connectors on the board marked "CN12" and "CN8" respectively. Only UART1 on CN8 is equipped with RTS/CTS lines.

Device drivers are provided for the STM32 on-chip ADC interfaces, I²C interface, and SPI interface. Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

Due to a silicon errata with the STM32F103Zx device the I2C1 bus cannot be used if FSMC is enabled. Therefore the I²C test example for the on-board STLM75 Temperature sensor explicitly disables FSMC prior to accessing I2C1.

Also, while the board is fitted with a CAN interface, this is not presently supported by the HAL port. The STM32F1 processor and the STM3210E-EVAL board provide an extremely wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.3.2, **arm-eabi-gdb** version 6.8, and **binutils** version 2.18.

Name

Setup — Preparing the STM3210E-EVAL Board for eCos Development

Overview

In a typical development environment, the STM3210E-EVAL board boots from internal flash into either the GDB stubrom or RedBoot. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**.

RedBoot Installation

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from internal FLASH	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running from external RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
JTAG	RedBoot running from external RAM, loaded via JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed using the RedBoot **baud** command.

Under normal circumstances, RedBoot runs in-place from the internal Flash. The RAM version is provided to allow for updating the resident RedBoot image in Flash. The JTAG version is only used if loading RedBoot into RAM via a JTAG debugger. It is similar to the RAM version, but loads at a lower address within RAM, and so can be used to load eCos applications, as if it is the normal resident boot monitor. The ELF format image of this JTAG version of RedBoot can also be loaded and executed from GDB using a JTAG device, to allow it to be debugged.

Programming RedBoot

To program RedBoot into the internal flash either a JTAG debugger that understands the STM32 flash may be used, such as a Ronetix PEEDI or an Abatron BDI3000, or the ST **Flash Loader Demonstrator** may be used. Configuration files for the PEEDI and BDI3000 are supplied in the STM3210E-EVAL HAL package, and brief instructions for downloading RedBoot are given in there. If no JTAG debugger is available, then RedBoot must be downloading using the **Flash Loader Demonstrator** which can be downloaded from the page for the STM32F101ZE CPU, in the *Design Support->Demo SW* section of ST's website at http://www.st.com/internet/mcu/product/164506.jsp

The documentation for this may be found at http://www.st.com/internet/com/TECHNICAL_RESOURCES/TECHNICAL_LITERATURE/USER_MANUAL/CD00171488.pdf

The following are brief instructions for downloading RedBoot using the **Flash Loader Demonstrator**.

1. Download the **Flash Loader Demonstrator** from the ST website and install it on a PC running Windows that has an available serial port.

2. Copy the file `redboot_ROM.bin` from the `loaders/stm3210e_eval` sub-directory within your eCosPro installation to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the USART1 serial port and a serial port on the Windows machine.

4. Move the *BOOT0/SW2* switch to the 1 position, ensure the *BOOT1/SW2* switch remains in the 0 position, and press the reset button.

5. Start the **Flash Loader Demonstrator** and in the first screen select the COM port connected to the board under *Port Name*. Ensure that the baud rate is also set at *115200*, with *Even* parity and *Echo* disabled. Press *Next*. If you are succesfully connected to the board, you should see the message *Target is readable. Please press "Next" to proceed* . It should also note the size of the internal flash memory. Press *Next* and you will be prompted to select a target. Depending on the CPU model on your STM3210E-EVAL board and the size of its internal flash, either select the *STM32_High-density_512K* or *STM32_XL-density_1024K*, then *Next* to go to the Operation choice page. If any of these steps fail, follow the direction given by the loader to recover.

6. On the operation choice page select *"Download to device"* and under *"Download from file"* either type the location of the `redboot_ROM.bin` file, or browse to it. Ensure that the *"@"* field is set to *8000000*, the *"Global Erase"* radio button is selected and that all other options are clear except *"Verify after download"*.

7. Press *"Next"* and the loader should download and verify the binary file. The download or verify may fail if the flash has been previously locked, in which case you should select the *"Enable/Disable Flash protection"* radio button, *"Disable"* and *"Write Protection"* drop-down items, press *Next* and retry the download. Upon successful download press *"Close"* to exit the loader.

8. Move the *BOOT0/SW2* switch back to the 0 position and press the reset button.

The behaviour of the **Flash Loader Demonstrator** documented here is that of version 2.5. The actual behaviour of newer or older versions may vary slightly.

Whatever mechanism is used to program RedBoot, something similar to the following output should be seen on USART1 when the reset button is pressed:

```
RedBoot(tm) bootstrap and debug environment [ROM]
eCosCentric certified release, version v3_1_25 - built 15:36:19, May  8 2012

RAM: 0x68000000-0x68100000 [0x680036d0-0x680dd000 available]
     0x20000000-0x2000f000 [0x20000000-0x2000f000 available]
FLASH: 0x08000000-0x0807ffff, 256 x 0x800 blocks
FLASH: 0x64000000-0x64ffffff, 128 x 0x20000 blocks
RedBoot>
```

Initializing RedBoot Flash Configuration

While RedBoot is loaded into the on-chip flash, it manages the external flash for the storage of application programs and configuration data. The flash needs to be initialized with the following commands.

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x64fe0000-0x64ffffff: .
... Program from 0x680e0000-0x68100000 to 0x64fe0000: .
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Console baud rate: 115200
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x64fe0000-0x64ffffff: .
... Program from 0x680e0000-0x68100000 to 0x64fe0000: .
```

```
RedBoot>
```

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot are:

```
$ mkdir redboot_stm3210e_rom
$ cd redboot_stm3210e_rom
$ ecosconfig new stm3210e redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm3210e_eval/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

The other versions of RedBoot - RAM or JTAG - may be similarly built by choosing the appropriate alternative .ecm file.

Name

Configuration — Platform-specific Configuration Options

Overview

The STM3210E-EVAL board platform HAL package is loaded automatically when eCos is configured for an `stm3210e_eval` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM3210E-EVAL board platform HAL package supports five separate startup types:

RAM

> This is the startup type which is normally used during application development. The board has RedBoot programmed into internal Flash at location 0x08000000 and uses external RAM at location 0x68000000. arm-eabi-gdb is then used to load a RAM startup application into memory from 0x68008000 and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

ROM

> This startup type can be used for finished applications which will be programmed into internal ROM at location 0x08000000. Data and BSS will be put into external RAM starting from 0x68000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

ROMINT

> This startup type can be used for finished applications which will be programmed into internal ROM at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x20000400. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

JTAG

> This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x68000000 and entered at that address. eCos startup code will perform all necessary hardware initialization.

SRAM

> This is a variation of the JTAG type that only uses internal memory. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000400 and entered at that address. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for

a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port 0 will be claimed for HAL diagnostics.

UART Serial Driver

The STM3210E-EVAL board uses the STM32's internal UART serial support. As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_CORTEXM_STM32` package which contains all the code necessary to support interrupt-driven operation with greater functionality. All five UARTs can be supported by this driver, although only UARTs 0 and 1 are actually routed to external connectors. Note that it is not recommended to enable this driver on the port used for HAL diagnostic I/O. This driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

SPI Driver

An SPI bus driver is available for the STM32 in the package "ST STM32 SPI driver" (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

The only SPI device present on the board is the M25PXX device connected to SPI bus 1 using PB2 as the chip-select. To enable support for this device the platform HAL "External SPI M25PXX flash support" (`CYGHWR_HAL_CORTEXM_STM32_FLASH_M25PXX`) option should be enabled.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 processor variant HAL provides an I²C driver. The STM3210E-EVAL platform HAL enables the support for bus 1 with the on-board STLM75 temperature sensor instantiated by default. It is exported to `<cyg/io/i2c.h>` with the name `hal_stm32_i2c_temperature` in the normal way.

Consult the generic I²C driver API documentation in the eCosPro Reference Manual for further details on I²C support in eCosPro, along with the configuration options in the STM32 on-chip I²C driver.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM3210E-EVAL platform HAL enables the support for the devices ADC1, ADC2 and ADC3 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Onboard NAND

The HAL port includes a low-level driver to access the on-board NAND flash memory chip. To enable the driver, ensure that the `CYGPKG_DEVS_NAND_ST_NANDXXXX3A` and `CYGPKG_IO_NAND` packages are present in your eCos configuration. The driver is capable of operating with the NAND_RB jumper (JP7) in either position.

`CYGHWR_HAL_CORTEXM_STM3210E_EVAL_RB_ON_INT2`

Jumper 7 on the board - labelled NAND_RB - controls the wiring of the NAND chip's Ready/Busy line. You must set this option correspondingly. If the jumper is in position 1-2, this option must be 0; in position 2-3, this option must be 1. This setting changes the behaviour of the driver when waiting for slow NAND operations to complete. In position 1-2, the memory controller halts accesses until the chip is ready; in 2-3, memory access is unimpeded but the CPU polls for the chip to signal ready before attempting to read from it. The latter case may yield an efficiency boost in multi-threaded applications.

Partitioning the NAND chip

The NAND chip must be partitioned before it can become available to applications.

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_DEVS_NAND_STM3210E_EVAL_PARTITION_MANUAL_CONFIG`); if you choose to use this, the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script sets up a single partition (number 0) encompassing the entire device.

It is possible to configure the partitions in some other way, should it be appropriate for your setup. To do so you will have to add appropriate code to `stm3210e_eval_nand.c`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including RedBoot.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M3 core of the STM32 only supports two such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.stm32e.cfg` file, supplied in the platform HAL package's misc directory, should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the clocks, GPIO lines, SRAM and flash memory controller.

The `peedi.stm32e.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.stm32e.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi.stm32e.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
stm32> memory load tftp://192.168.7.9/test.bin bin 0x68000000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x68000000
loading at 0x68000000
loading at 0x68004000

Successfully loaded 28KB (29064 bytes) in 0.1s
stm32> go 0x68000000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

Abatron BDI3000 notes

On the Abatron BDI3000, the `bdi3000.stm32e.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the clocks, GPIO lines, SRAM and flash memory controller.

The `bdi3000.stm32e.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **boot** command on the BDI3000 command line interface.

On the BDI3000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI3000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI3000 is powered up, the target will always run the initialization section of the `bdi3000.stm32e.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
STM32> load 0x68000000 test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
STM32> go 0x68000000
```

Consult the BDI3000 documentation for information on other formats and loading mechanisms.

Configuration of JTAG applications

JTAG applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Both of these settings are made automatically if the JTAG startup type is selected.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM3210E-EVAL board hardware, and should be read in conjunction with that specification. The STM3210E-EVAL platform HAL package complements the ARM architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM and JTAG startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm3210e_eval_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External RAM

> This is located at address 0x68000000 of the memory space, and is 1MiB long. For ROM applications, all of RAM is available for use. For RAM startup applications, RAM below 0x68008000 is reserved for RedBoot and the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack, the remainder is available for the application.

External FLASH

> This is located at address 0x64000000 of the memory space and is 4MiB in size. Since RedBoot is normally programmed into the internal flash this memory is entirely available for application use and may be managed by the FIS flash file system.

Internal RAM

> This is located at address 0x20000000 of the memory space, and is 64KiB in size. The eCos VSR table occupies the bottom 512 bytes. The virtual vector table starts at 0x00000100 and extends to 0x00000200. For ROM and JTAG startups, the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH

> This is located at address 0x08000000 of the memory space and will be mapped to 0x00000000 at reset. This region is 512KiB in size. ROM applications are by default configured to run from this memory. This memory is not managed by RedBoot's FIS system, but it can be written using the **fis write** command and erased using the **fis erase** command.

On-Chip Peripherals

> These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table

This defines the location of the VSR table. This is set to 0x20000000 for all startup types, and space for 128 entries is reserved.

hal_virtual_vector_table

This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20000100. To permit expansion and possible addition of other tables, the linker scripts then allocate further sections from 0x20000400.

hal_interrupt_stack

This defines the location of the interrupt stack. For ROM and JTAG startups, this is allocated to the top of internal SRAM, 0x20010000. For RAM startups, it is allocated to the top of external SRAM, 0x68100000.

hal_startup_stack

This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Name

Test Programs — Details

Test Programs

The STM3210E platform HAL contains some test programs which allow various aspects of the board to be tested.

ADC Test

This program tests the ADC driver for the STM32. The only device connected to the ADC on the board is the potentiometer connected to ADC1 logical channel 14. Therefore this test primarily tests that. However, in addition it also report the values of the temperature sensor and Vrefint inputs that are sourced on-chip. The option `CYGBLD_HAL_CORTEXM_STM3210E_EVAL_TEST_ADC` must be enabled to run this test since it needs human interaction.

SPI flash test

This program tests the MPC25Pxx serial flash connected to SPI bus 1. It erases, programs and reads a number of sectors in the flash, and should therefore not be run if the flash contains data that should be retained. The `CYGPKG_IO_FLASH` package must be present and `CYGHWR_HAL_CORTEXM_STM32_FLASH_M25PXX` enabled to allow this test to be built.

I²C Test

This program tests the I²C driver for the STM32. The only device connected to I²C on the board is the STLM75 temperature sensor on I2C1. The option `CYGBLD_HAL_CORTEXM_STM3210E_EVAL_TEST_STLM75` must be enabled to run this test.

NAND ECC walk test

This program is an adapted version of the `sweccwalk` test in the NAND Flash library which tests the hardware ECC support provided by the on-chip FSMC. It does not affect any data currently stored on the on-board NAND flash chip.

Chapter 299. STM32X0G-EVAL Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32X0G_EVAL` — eCos Support for the STM3220G-EVAL, STM3240G-EVAL and STM3241G-EVAL Boards

Description

There are currently three variants of ST's STM32 "G" evaluation board, the STM3220G-EVAL. STM3240G-EVAL and STM3241G-EVAL. This documentation uses "STM32X0G-EVAL" to refer generically to these boards. The boards have "STM32 20-21-45-46 G-EVAL" silk screened on the PCB, with the specific board model only identifiable by the CPU markings.

The STM3220G-EVAL board has a STM32F207IG microcontroller that incorporates 1MiB of internal flash and 128KiB of internal SRAM.

The STM3240G-EVAL board has a STM32F407IG microcontroller that incorporates 1MiB of internal flash and 192KiB of internal SRAM.

The STM3241G-EVAL board has a STM32F417IG microcontroller that incorporates 1MiB of internal flash and 192KiB of internal SRAM.

The boards have an additional 2MiB of external SRAM, and connectors for UART, Ethernet, MicroSD, USB, CAN, JTAG and various other devices.

For typical eCos development, RedBoot or a GDB stub image is programmed into internal FLASH and the CPU boots directly into that. It is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART4. Alternatively test programs may be downloaded and debugged via a JTAG debugger attached to the JTAG socket.

This documentation describes platform-specific elements of the STM32X0G-EVAL board support within eCos. The STM32 variant HAL documentation covers various topics including HAL support common to STM32 variants, and on-chip device support. This document complements the STM32 documentation.

Supported Hardware

The STM32F207IG has two on-chip memory regions, with the STM32F407IG and STM32F417IG having three on-chip memory regions. The F2 and F4 devices have a RAM region of 128KiB present at 0x20000000 and a 1MiB FLASH region present at 0x08000000 which is aliased to 0x00000000 during normal execution. The STM32F407IG and STM32F417IG devices have another RAM region of 64KiB present at 0x10000000. For all platform variants on-board memory consists of 2MiB of SRAM mapped to 0x64000000.

The STM32 variant HAL includes support for the six on-chip serial devices which are documented in the variant HAL. UART4 is connected to the external connector on the board marked "CN16". There is no connection for hardware flow control (RTS/CTS) lines.

The STM32 variant HAL also includes support for the I²C bus. A single I²C device is instantiated as part of the platform port, which is for the M24C64 serial EEPROM connected via I²C. It is exported to `<cyg/io/i2c.h>` with the name `hal_stm32_i2c_eeprom` in the normal way.

Device drivers are provided for the STM32 on-chip Ethernet MAC, ADC interfaces, I²C interface, SPI interface and SDIO interface. Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

The STM32 variant HAL support for the SDIO interface is currently limited to supporting MMC/SD cards. Due to the GPIO availability on the platform by default only 1-bit MMC/SD data accesses are enabled, since 4-bit data access would clash with the UART4 debug channel. If 4-bit mode is required then the platform configuration would need to be changed to avoid the use of UART3/UART4. For 4-bit mode the use of on-chip SRAM for the transfer buffers is recommended to avoid RX overrun and TX underrun errors due to the slow external RAM access speed.

A driver is available for the BXCAN devices present on the chip. Note that BXCAN1 is incompatible with the use of off-chip SRAM. Under normal circumstances ensure jumpers JP3 and JP10 are not fitted so that neither CAN device is enabled, or fitted to enable CAN2 only. Also that JP1 and JP2 are set with pins 2-3 connected to allow SRAM use. These are the factory-supplied defaults for these jumpers.

Also, while the board is fitted with OneNAND Flash, this is not presently supported by the HAL port. The STM32F2 processor and the STM32X0G-EVAL board provide an extremely wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.4.5, **arm-eabi-gdb** version 7.2, and **binutils** version 2.20.1.

Name

Setup — Preparing the STM32X0G-EVAL Board for eCos Development

Overview

In a typical development environment, the STM32X0G-EVAL board boots from internal flash into either the GDB stubrom or RedBoot. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE.

RedBoot Installation

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from internal FLASH	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running from external RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
JTAG	RedBoot running from external RAM, loaded via JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.elf`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed using the RedBoot **baud** command, or in the eCos configuration used for building RedBoot.

Under normal circumstances, RedBoot runs in-place from the internal Flash. The RAM version is provided to allow for updating the resident RedBoot image in Flash. The JTAG version is only used if loading RedBoot into RAM via a JTAG debugger. It is similar to the RAM version, but loads at a lower address within RAM. The ELF format image of this JTAG version of RedBoot can also be loaded and executed from GDB using a JTAG device, to allow it to be debugged.

Programming RedBoot with ST Flash Loader Demonstrator

To program RedBoot into the internal flash either a JTAG debugger that understands the STM32 flash may be used, such as a Ronetix PEEDI , or the ST **Flash Loader Demonstrator** may be used. Configuration files for the PEEDI have been supplied in the STM32X0G-EVAL HAL package. If no JTAG debugger is available, then RedBoot must be downloaded using the **Flash Loader Demonstrator** which can be downloaded from the page for the STM32F207IG CPU, in the *Design Support->Software & Development Tools->Software Demos* section of ST's website at http://www.st.com/internet/mcu/product/245085.jsp#SOFTWARE_AND_DEVELOPMENT_TOOLS. It must be at least version 2.4.0 in order to support the STM32F2xx devices. At time of writing, a direct link to this version is available at http://www.st.com/internet/com/SOFTWARE_RESOURCES/SW_COMPONENT/SW_DEMO/stm32-stm8_flash_loader_demo.zip.

The following are brief instructions for downloading RedBoot using the **Flash Loader Demonstrator**. For more complete usage instructions, consult the ST documentation for this tool at http://www.st.com/internet/com/TECHNICAL_RESOURCES/TECHNICAL_LITERATURE/USER_MANUAL/CD00171488.pdf

1. Download the **Flash Loader Demonstrator** from the ST website and install it on a PC running Windows that has an available RS232 serial port, or with a USB to RS232 adaptor.

2. Copy the file `redboot_ROM.bin` from the `loaders/stm32x0g_eval` sub-directory within your eCosPro installation to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the USART serial port (CN16) and the RS232 serial port on the Windows machine.

4. Move the *BOOT0/SW2* switch to the 1 position, ensuring the *BOOT1/SW1* switch remains in the 0 position, and press the reset button.

5. Start the **Flash Loader Demonstrator** and in the first screen select the COM port connected to the board under *Port Name*. Ensure that the baud rate is also set at *115200*, with *Even* parity, *Echo* disabled and *Flow control* off. Press *Next*. If you are succesfully connected to the board, you should see the message *Target is readable. Please click "Next" to proceed* . Press *Next* and you will be prompted to select a target. Select *STM32F2_1024K*, then *Next* to go to the Operation choice page. If any of these steps fail, follow the direction given by the loader to recover.

6. On the operation choice page select *"Download to device"* and under *"Download from file"* either type the location of the `redboot_ROM.bin` file, or browse to it. Ensure that the *"@"* field is set to *8000000*, the *"Global Erase"* radio button is selected and that all other options are clear except *"Verify after download"*.

7. Press *"Next"* and the loader should download and verify the binary file. The download or verify may fail if the flash has been previously locked, in which case you should select the *"Enable/Disable Flash protection"* radio button, *"Disable"* and *"Write Protection"* drop-down items, press *Next* and retry the download. Upon successful download press *"Close"* to exit the loader.

8. Move the *BOOT0/SW2* switch back to the 0 position and press the reset button.

The behaviour of the **Flash Loader Demonstrator** documented here is that of version 2.4.0. The actual behaviour of newer versions may vary slightly.

Whatever mechanism is used to program RedBoot, something similar to the following output should be seen on the RS232 serial port when the reset button is pressed:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database

RedBoot(tm) bootstrap and debug environment [ROM]

RedBoot>
```

You should now proceed to the section describing how to initialize RedBoot's flash configuration.

Programming RedBoot with Ronetix PEEDI

This section describes how to install RedBoot using a Ronetix PEEDI JTAG debugger.

The PEEDI must be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. It must then be used to download and program a RedBoot image into the internal flash. The following steps give a typical outline for doing this. Consult the PEEDI documentation for alternative approaches, such as using FTP or HTTP instead of TFTP.

Preparing the Ronetix PEEDI JTAG debugger

1. Prepare a PC to act as a host and start a TFTP server on it.

2. Connect the PEEDI JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the PEEDI (straight through, not null modem).

3. Verify the PEEDI is using up-to-date firmware, of version 11.10.1 or later. Older PEEDI firmware does not support the STM32 F2 family correctly, particularly if wishing to use the PEEDI's own '**flash**' commands to modify the on-chip Flash. If the firmware is not recent enough, follow the PEEDI User Manual's instructions which describe how to update the PEEDI firmware.

4. Locate the appropriate file `peedi.stm3220g.cfg` (STM3220G-EVAL) or `peedi.stm3240g.cfg` (STM3240G-EVAL and STM3241G-EVAL) within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm32x0g/`*`VERSION`*`/misc` relative to the root of your eCos installation.

5. Place the respective configuration file in a location on the PC accessible to the TFTP server. Later you will configure the PEEDI to load this file via TFTP as its configuration file.

6. Open `peedi.stm3220g.cfg` or `peedi.stm3240g.cfg` (as appropriate) in an editor such as emacs or notepad and insert your own license information in the `[LICENSE]` section.

7. Install and configure the PEEDI in line with the PEEDI Quick Start Guide or User's Manual, especially configuring PEEDI's RedBoot with the network information. Configure it to use the appropriate `peedi.stm3220g.cfg` or `peedi.stm3240g.cfg` target configuration file on the TFTP server at the appropriate point of the **config** process, for example with a path such as: `tftp://192.168.7.9/peedi.stm3220g.cfg`

8. Reset the PEEDI.

9. Connect to the PEEDI's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see output similar to the following:

```
$ telnet 192.168.7.225
Trying 192.168.7.225...
Connected to 192.168.7.225.
Escape character is '^]'.

```

Preparing the STM32X0G board for programming with PEEDI

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. Connect a null modem DB9 RS232 serial cable between the serial port on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** on Linux or PuTTY on Windows. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to the PEEDI using a 20-pin ARM/Xscale cable from the JTAG interface connector to the Target port on the PEEDI.

4. Power up the STM32X0G board.

5. Connect to the PEEDI's telnet CLI on port 23 as before.

6. Confirm correct connection with the PEEDI with the **reset reset** command as follows:

```
stm3220g> reset reset
++ info: RESET and TRST asserted
++ info: TRST released
++ info: BYPASS check passed
++ info: 2 TAP controller(s) detected
++ info: TAP 0 : IDCODE = 0x06411041, unknown ID
++ info: TAP 1 : IDCODE = 0x4BA00477, Cortex M3 JTAG
++ info: RESET released
++ info: core #0 connected
++ info: core 0: initialized

stm3220g>
```

Installation into Flash

The following describes the procedure for installing the RedBoot ROM monitor into on-chip Flash. It can also be adapted for installing user applications into Flash.

1. Locate the `redboot_ROM.bin` image within the `loaders` subdirectory of the base of the eCos installation. For applications, use **arm-eabi-objcopy -O binary** to convert the linked application, in ELF format, into binary format.

2. Copy the `redboot_ROM.bin` file into a location on the host computer accessible to its TFTP server.

3. Connect to the PEEDI's telnet interface, and program the RedBoot image into Flash with the following command, replacing *`TFTP_SERVER`* with the address of the TFTP server and *`/RBPATH`* with the location of the redboot_ROM.bin file relative to the TFTP server root directory:

   ```
   stm3220g> flash program tftp://TFTP_SERVER/RBPATH/redboot_ROM.bin bin 0x08000000 erase
   ++ info: Programming image file: tftp://TFTP_SERVER/RBPATH/redboot_ROM.bin
   ++ info: Programming using agent, buffer = 4096 bytes
   ++ info: At absolute address:    0x08000000
   erasing     at 0x08000000 (sector #0)
   programming at 0x08000000
   programming at 0x08001000
   programming at 0x08002000
   programming at 0x08003000
   erasing     at 0x08004000 (sector #1)
   programming at 0x08004000
   programming at 0x08005000
   programming at 0x08006000
   programming at 0x08007000
   erasing     at 0x08008000 (sector #2)
   programming at 0x08008000
   programming at 0x08009000
   programming at 0x0800A000
   programming at 0x0800B000
   erasing     at 0x0800C000 (sector #3)
   programming at 0x0800C000
   programming at 0x0800D000
   programming at 0x0800E000
   programming at 0x0800F000

   ++ info: successfully programmed 64.00 KB in 2.39 sec

   stm3220g>
   ```

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. The RedBoot banner should be visible on the serial port:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database

RedBoot(tm) bootstrap and debug environment [ROM]

RedBoot>
```

Note

An alternative approach would be to use **arm-eabi-gdb** to load and run the `redboot_JTAG.elf` file supplied as a prebuilt in the release. Once that instance of RedBoot is running, standard RedBoot commands such as **'load'** and **'fis'** can be used via the serial RS232 interface to program images to Flash, e.g.:

```
$ arm-eabi-gdb /path/to/redboot_JTAG.elf
GNU gdb (eCosCentric GNU tools 4.4.5c) 7.2

(gdb) c
Continuing.
```

Initializing RedBoot Flash Configuration

RedBoot manages the internal flash for the storage of application programs and configuration data. The flash needs to be initialized with the following commands:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x080e0000-0x080fffff: .
... Program from 0x641e0000-0x64200000 to 0x080e0000: .
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Console baud rate: 115200
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x080e0000-0x080fffff: .
... Program from 0x641e0000-0x64200000 to 0x080e0000: .
RedBoot>
```

Issue the **reset** command to RedBoot, and verify the the target board comes up as expected with the correct settings.

You may also need to run the **fconfig -i** command if you have updated your RedBoot from a previous version with a different configuration which might not have any new config fields used by the newly programmed RedBoot.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot are:

```
$ mkdir redboot_stm3220g_rom
$ cd redboot_stm3220g_rom
$ ecosconfig new stm3220g redboot
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm32x0g_eval/VERSION/misc/redboot_ROM.ecm
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This may be programmed to the board using the above procedure, or by using RedBoot's own flash update mechanisms.

The other versions of RedBoot - RAM or JTAG - may be similarly built by choosing the appropriate alternative .ecm file.

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32X0G-EVAL board platform HAL package is loaded automatically when eCos is configured for an `stm3220g`, `stm3240g` or `stm3241g` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32X0G-EVAL board platform HAL package supports five separate startup types:

RAM

> This is the startup type which is normally used during application development. The board has RedBoot programmed into internal Flash at location 0x08000000 and uses external RAM at location 0x64000000. arm-eabi-gdb is then used to load a RAM startup application into memory from 0x64008000 and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

ROM

> This startup type can be used for finished applications which will be programmed into internal ROM at location 0x08000000. Data and BSS will be put into external RAM starting from 0x64000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

ROMINT

> This startup type can be used for finished applications which will be programmed into internal ROM at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x20000284 (F2) or 0x20000288 (F4). Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

JTAG

> This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x64000000 and entered at that address. eCos startup code will perform all necessary hardware initialization.

SRAM

> This is a variation of the JTAG type that only uses internal memory. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000284 (F2) or 0x20000288 (F4) and entered at that address. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for

a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The STM32X0G-EVAL board uses the STM32's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and RedBoot / GDB stub communication, is only expected to be available to be used on the UART 4 port (counting the first UART as UART1). This is because only UART 4 is actually routed to an external connector.

As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_CORTEXM_STM32` package which contains all the code necessary to support interrupt-driven operation with greater functionality. All six UARTs can be supported by this driver Note: while it is possible for USART3 to be configured to use this connector, the only advantage of USART3 would be flow control lines, which are not routed to the connector on the STM32X0G board.

It is not recommended to use the interrupt-driven serial driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration. By default this will only enable support in the driver for the UART4 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports. Note that in this package, serial port numbering starts at 0, rather than 1. So for example, to enable the serial driver for ports USART1 and USART2, enable the configuration options "ST STM32 serial port 0 driver" (`CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL0`) and "ST STM32 serial port 1 driver" (`CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL1`).

Ethernet Driver

The STM32X0G-EVAL board is fitted with an Ethernet port connected via a DP83847 PHY to the STM32's on-chip Ethernet MAC. This is supported in eCosPro with a driver for the lwIP networking stack, contained in the package `CYGPKG_DEVS_ETH_CORTEXM_STM32`. At the present time it only supports the lwIP networking stack, and cannot be used for either the BSD networking stack, nor RedBoot.

The driver will be inactive (not built and greyed out in the eCos Configuration Tool) unless the platform HAL option "STM32 Ethernet Support" (`CYGPKG_HAL_CORTEXM_STM32_STM32X0G_EVAL_ETH0`) is enabled. This option in turn is only active if the "Common Ethernet support" (`CYGPKG_IO_ETH_DRIVERS`) package is included in your configuration. As the STM32 ethernet driver is an lwIP-only driver, it is most appropriate to choose the `lwip_eth` template as a starting point when choosing an eCos configuration, which will cause the necessary packages to be automatically included.

The platform HAL defines a further configuration option "Use MCO as PHY clock" (`CYGHWR_HAL_CORTEXM_STM32X0G_ETH_PHY_CLOCK_MCO`) which indicates whether the MCO1 clock signal is used as the 25MHz clock for the Ethernet PHY. With this option disabled, the on-board 25MHz crystal oscillator located at X1 can be used instead, although in that case the board jumper J5 must be changed. You may wish to make this change if you wish to use the MCO1 clock output for another purpose. Consult the STM32 clock and ethernet documentation for more details.

SPI Driver

An SPI bus driver is available for the STM32 in the package "ST STM32 SPI driver" (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

The only SPI device instantiated by default is for an external Aardvark SPI test board, connected to SPI bus 2 with pin PI0 selected as the chip select. To disable the Aardvark device support, the platform HAL contains an option "SPI devices" (`CYGPKG_HAL_CORTEXM_STM32_STM32X0G_EVAL_SPI`) which can be disabled. No other SPI devices are instantiated.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. But the platform I²C support can also be configured separately at `CYGPKG_HAL_CORTEXM_STM32_STM32X0G_EVAL_I2C`. This ensures that the M24C64 serial EEPROM is instantiated and becomes available for applications from `<cyg/io/i2c.h>`, and also ensures the STM32's I²C bus 1 is enabled for it. This option also allows the m24c64.c test is built. In order to allow writes to the serial EEPROM, you must ensure that the STM32X0G-EVAL jumper JP24 is fitted. The m24c64.c test will not pass otherwise.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM32X0G-EVAL platform HAL enables the support for the devices ADC1, ADC2 and ADC3 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

CAN Driver

The STM32 has a dual BXCAN device for CAN support. This consists of a master device, BXCAN1, and a slave device, BXCAN2. If BXCAN2 is to be used, BXCAN1 must be powered and clocked, regardless of whether it is to be used for CAN traffic. BXCAN1 shares IO pins with the FSMC, which controls the external SRAM. Therefore, BXCAN1 can only be used in ROMINT startup mode.

The board has a single external CAN socket, to which either BXCAN1 or BXCAN2 can be routed, based on the settings of JP3 and JP10. By default these jumpers are set to route neither CAN device to the socket, and jumpers must be fitted to route the desired CAN device as appropriate. See the board reference manual for details.

Consult the generic CAN driver API documentation in the eCosPro Reference Manual for further details on CAN support in eCosPro, along with the documentation and configuration options in the BXCAN device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the "STM32 Flash memory support" (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic "Flash device drivers" (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32X0G board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including RedBoot.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M3 core of the STM32 only supports two such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

Normally, a notable disadvantage with JTAG debugging is that it does not allow thread-aware debugging, such as the ability to inspect different eCos threads or their stack backtraces, set thread-specific breakpoints, and so on. Fortunately the Ronetix PEEDI JTAG unit does support thread-aware debugging of eCos applications, however extra configuration steps are required. Consult the PEEDI documentation for more details as usage is beyond the scope of this document.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.stm3220g.cfg` or `peedi.stm3240g.cfg` file supplied in the platform HAL package should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the clocks, GPIO lines, and FSMC memory controller for off-chip SRAM.

The `peedi.stm3220g.cfg` and `peedi.stm3240g.cfg` files also contain an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command, or in the eCosPro version of Eclipse by setting the Breakpoint Type - consult the “eCosPro CDT plug-in user's guide” manual for details. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the relevant `peedi.stm3220g.cfg` or `peedi.stm3240g.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset either with the '**reset**' command, or by pressing the reset button, and then the '**go**' command is given, the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the appropriate `peedi.stm3220g.cfg` or `peedi.stm3240g.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Finally, it is also possible to set a temporary default (unless the PEEDI is reset) by giving an argument to the **reset** command, for example **reset run**. Use the command **help reset** at the PEEDI command prompt for more options.

Suitably configured applications can be loaded either via GDB, or directly via the telnet CLI into RAM for execution. For example:

```
stm3220g> memory load tftp://192.168.7.9/test.bin bin 0x64000000
```

```
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x64000000
loading at 0x64000000
loading at 0x64004000

Successfully loaded 28KB (29064 bytes) in 0.1s
stm3220g> go 0x64000000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

For Eclipse users wishing to debug ROM startup programs resident in Flash, it is worth highlighting that it is possible to use the eCosCentric Eclipse plugin to automatically reprogram Flash as the load sequence. To do so, you will need to install and use a TFTP server so that your application can be accessed from the PEEDI from there. You may then use a GDB command file, as described in more detail in the “eCosPro CDT plug-in user's guide” manual. This file can then contain contents similar to the following example:

```
define doload
  shell arm-eabi-objcopy -O binary /path/to/eclipse/workspace/projectname/Debug/myapp /path/to/tftp/server/area/myapp.bin
  monitor flash program tftp://10.1.1.1/myapp.bin bin 0x08000000 erase
  set $pc=0x08000000
end
```

Obviously you will need to adjust the paths and names for your system and TFTP server requirements.

Configuration of JTAG applications

JTAG applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, it is recommended to use the JTAG startup type which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the JTAG startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel, usually a serial port. An eCosCentric extension allows diagnostic output to appear in GDB instead. For this to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package.

For details of using hardware debug with the Eclipse IDE see the “eCos Hardware Debugging” section of the “eCosPro CDT plug-in user's guide” manual.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32X0G-EVAL board hardware, and should be read in conjunction with that specification. The STM32X0G-EVAL platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM and JTAG startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32x0g_eval_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External RAM

> This is located at address 0x64000000 of the memory space, and is 1MiB long. For ROM applications, all of RAM is available for use. For RAM startup applications, RAM below 0x64008000 is reserved for RedBoot and the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack, the remainder is available for the application.

Internal RAM

> This is located at address 0x20000000 of the memory space, and is 128KiB in size. On the STM3220G, the eCos VSR table occupies the bottom 388 bytes, with the virtual vector table starting at 0x20000184 and extending to 0x20000284. On the STM3240G, the eCos VSR table occupies the bottom 392 bytes on the STM3220G, with the virtual vector table starting at 0x20000188 and extending to 0x20000288. For ROM, ROMINT, SRAM and JTAG startups, the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.
>
> The STM32F407IG based systems have a block of (close-coupled) SRAM located at address 0x10000000 of the memory space, and 64KiB in size.

Internal FLASH

> This is located at address 0x08000000 of the memory space and will be mapped to 0x00000000 at reset. This region is 1024KiB in size. ROM applications are by default configured to run from this memory. This memory is managed by RedBoot's FIS system.

On-Chip Peripherals

> These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table

This defines the location of the VSR table. This is set to 0x20000000 for all startup types, and space for either 97 (F2 processors) or 98 (F4 processors) entries is reserved.

hal_virtual_vector_table

This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20000184 (F2) or 0x20000188 (F4).

hal_interrupt_stack

This defines the location of the interrupt stack. For ROM and JTAG startups, this is allocated to the top of internal SRAM, 0x20020000. For RAM startups, it is allocated to the top of external SRAM, 0x64200000.

hal_startup_stack

This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Diagnostic LEDs

Four LEDs are fitted on the board for diagnostic purposes: LED1 (green), marked as LD1; LED2 (orange) marked as LD2; LED3 (red) marked as LD3; and LED4 (blue) marked as LD4.

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow the LEDs to be set:

```
       extern void hal_stm32x0_led(char c);
```

The lowest 4 bits of the argument `c` correspond to each of the 4 LEDs (with LED1 as the least significant bit).

The platform HAL will automatically light LED1 when the platform initialisation is complete, however the LEDs are free for application use.

Flash wait states

The STM32X0G-EVAL platform HAL provides a configuration option to set the number of Flash read wait states to use: `CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES`. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the STM32 Flash programming manual (PM0059) for appropriate values for different clock speeds or voltages. The default of 3 reflects a supply voltage of 3.3V and HCLK of 120MHz.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for ROMINT startup, which provided the best performance as both code and data could remain on-chip.

Example 299.1. stm32x0g_eval Real-time characterization

```
            Startup, main stack : stack used   348 size  3920
             Startup : Idlethread stack used    84 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    6.03 microseconds (6 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   5
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
```

```
  Semaphores:               32

Name

Test Programs — Details

Test Programs

The STM32X0G platform HAL contains some test programs which allow various aspects of the board to be tested.

ADC Test

This program tests the ADC driver for the STM32. The only device connected to the ADC on the board is the potentiometer connected to ADC3 logical channel 7. Therefore this test primarily tests that. However, in addition it also report the values of the temperature sensor, Vrefint and Vbat inputs that are sourced on-chip. The option `CYGBLD_HAL_CORTEXM_STM32X0G_EVAL_TEST_ADC` must be enabled to run this test since it needs human interaction.

Chapter 300. STM32F429I-DISCO Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32F429I_DISCO` — eCos Support for the STM32F429I-DISCO Board

Description

The STM32F429I-DISCO board has a STM32F429ZIT6U microcontroller that incorporates 2MiB of internal flash and 256KiB of internal SRAM. The board also has an additional 8MiB of external SDRAM, plus an I^{2}C touch-panel peripheral, a SPI motion sensor peripheral, and a USB connector (CN6 “USB USER”).

Since the board is equipped with an on-board ST-LINK/V2 hardware debugger interface (via the CN1 “USB ST-LINK” connector), and there are no UART or Ethernet connections, for typical eCos development test programs are downloaded and debugged via the SWD hardware debugger in conjunction with the relevant host-side tools.

This documentation describes platform-specific elements of the STM32F429I-DISCO board support within eCos. The STM32 variant HAL documentation covers various topics including HAL support common to STM32 variants, and on-chip device support. This document complements the STM32 documentation.

Supported Hardware

The STM32F429ZI has three main on-chip memory regions. The device has a SRAM region of 192KiB present at 0x20000000, and a 2MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution). There is also has another on-chip RAM region of 64KiB present at 0x10000000 that is only accessible via the CPU core. Also, the STM32F429I-DISCO motherboard has 8MiB of SDRAM memory mapped to address 0x90000000.

The STM32 variant HAL includes support for the eight on-chip serial devices which are documented in the variant HAL. However, the STM32F429I-DISCO motherboard does not provide a standard UART connector. To make use of serial devices suitable transceiver hardware and connectors would need to be attached via the relevant motherboard P1 or P2 expansion connectors.

The STM32 variant HAL also includes support for the I^{2}C buses. A single I^{2}C device is instantiated as part of the platform port, which is for the STMPE811 touch-panel sensor connected via bus I^{2}C3. It is exported to `<cyg/io/i2c.h>` with the name `hal_stm32f429i_disco_touchpanel` in the normal way.

Similarly the STM32 variant HAL includes support for the SPI buses. A single SPI device is instantiated as part of the platform port, which is for the L3GD20 MEMS (motion sensor) connected via bus SPI5. It is exported via `<cyg/io/spi.h>` with the name `cyg_stm32f429i_disco_mems` in the normal way.

Device drivers are also provided for the STM32 on-chip Ethernet MAC, ADC, BXCAN and SDIO interfaces, but similarly suitable hardware support via the motherboard P1 and P2 expansion connectors would be needed to utilise the drivers. Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

Note

The STM32 variant HAL support for the SDIO interface is currently limited to supporting MMC/SD cards. If the multi-bit MMC/SD support is used it is recommended that on-chip SRAM transfer buffers are used to avoid RX overrun or TX underrun due to the slow external SDRAM access speed.

The STM32F4 processor and the STM32F429I-DISCO board provide a wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3e, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.23.2.

Name

Setup — Preparing the STM32F429I-DISCO Board for eCos Development

Overview

Typically, since the STM32F429I-DISCO motherboard has a built-in ST-LINK/V2 interface providing hardware debug support, eCos applications are loaded and run via the debugger **arm-eabi-gdb** or via the Eclipse IDE. The debugger then communicates with the “GDB server” provided by the relevant host ST-LINK/V2 support tool being used (e.g. OpenOCD).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from SRAM, or where all of the SRAM and SDRAM is required for application run-time use.

Since the stand-alone STM32F429I-DISCO motherboard has limited I/O there is no support for either RedBoot or GDB stubs by default.

Nevertheless, it is still possible to program a GDB stub or RedBoot `ROM` image into on-chip Flash and download and debug via a serial UART, if pins for the UART are available. In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. By default for serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed in the eCos configuration used for building the GDB stub `ROM` image.

Preparing ST-LINK/V2 interface

The support for using the on-chip ITM stimulus ports for diagnostic and instrumentation output requires that the ST-LINK/V2 firmware is at least version `V2.J17.S0`. The firmware for the ST-LINK/V2 interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file). For example, the following OpenOCD output reports `JTAG v17`:

```
Info : STLINK v2 JTAG v17 API v2 SWIM v0 VID 0x0483 PID 0x3748
```

Unfortunately the official firmware updater is only available for the Windows platform at the moment. From a Windows machine:

1. Ensure that the Windows PC and STM32F429I-DISCO board are disconnected.

2. Download the STM32 ST-LINK Utility from ST's website.

   The page titled “STSW-LINK004 STM32 ST-LINK utility” provides a free download of the utility http://www.st.com/web/en/catalog/tools/PF258168

3. Install the ST-LINK Utility software on your Windows PC.

   Simply unzip the downloaded file `stsw-link004.zip` and run the `STM32 ST-LINK Utility_v3.0.0.exe` that was contained within it. Follow the on-screen instructions. This will install both the utility application and the ST-LINK/V2 USB driver.

4. Connect the STM32F429I-DISCO board to the PC.

   Connect the STM32F429I-DISCO board to the PC using the ST supplied mini-B USB cable. Windows should correctly identify the USB device and load the device driver. Windows Device Manager should now show “STMicroelectronics STLink dongle” under “Universal Serial Bus controllers”.

5. Run the ST-LINK Utility and ensure the ST-LINK firmware is up to date.

From the Windows “Start” menu run the “STM32 ST-LINK Utility”. Click on the `connect` icon, or select `Target->Connect` from the menu. This should confirm that a successful connection can be made to the board. To update the on-board ST-LINK/V2 firmware select `ST-LINK->Firmware Update` from the menu. In the ST-LINK dialog box that then appears click on the `Device Connect` button. This will likely result in a message “ST-Link is not in DFU mode. Please restart it.”. In this case simply disconnect the board from the PC and then reconnect it after a couple of seconds, then click the `OK` button on the message. In the original ST-Link dialog box click `Device Connect` again. The dialog box should now report the current on-board and available firmware versions, and enable you to upgrade the board by pressing the `Yes >>>>` button. We have tested the system with firmware version `V2.J17.SO` and would recommend this version as a minimum. Clicking `Yes >>>>` will cause a progress bar in the dialog to be animated and should eventually result in a “Update Successful” message. You can then close the various dialogs and exit the ST-LINK Utility. Disconnect and reconnect the board and it is now ready for use with OpenOCD.

Programming ROM images

Since the STM32F429I-DISCO board has a built-in ST-LINK/V2 SWD interface, if the `CN4` jumpers are closed then the micro USB host connection (CN1) and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash. Normally a default **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32F429I-DISCO board platform HAL package is loaded automatically when eCos is configured for the `stm32f429i_disco` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32F429I-DISCO board platform HAL package supports five separate startup types:

ROM

This startup type can be used for finished (stand-alone) applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into external SDRAM starting from 0x90000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

ROMINT

This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x20000288. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

The off-chip SDRAM memory from 0x90000000 is available, but is not referenced by the eCos run-time so is available for application use if required.

JTAG

This is the startup type used to build applications that are loaded via the hardware debugger interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x90000000 and entered at that address. eCos startup code will perform all necessary hardware initialization, though since the application is loaded via the hardware debugger interface the host debug environment is responsible for configuring the necessary I/O state to initialise the off-chip SDRAM.

This is the startup type normally used during application development, since the large SDRAM memory space allows for larger debug applications where compiler optimisation may be disable, and run-time assert checking enabled.

Note

Executing code from the SDRAM memory has a performance downside. It is significantly slower than execution from on-chip SRAM or flash. If performance is an issue then hardware debugging can be used for any of the startup types if required.

SRAM

This is a variation of the `JTAG` type that only uses internal memory. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000288 and entered at that address. eCos startup code will perform all necessary hardware initialization. Unlike the `JTAG` startup no explicit hardware debugger configuration is needed, since the application (like the ROM and ROMINT startup types) will initialise the off-chip SDRAM memory.

RAM

For the ST-LINK/V2 enabled STM32F429I-DISCO platform this startup type is unlikely to be used. It is provided for completeness.

When the board has RedBoot (or a GDB stub ROM) programmed into internal Flash at location 0x08000000 then the arm-eabi-gdb debugger can communicate with the relevant UART or Ethernet connection to load and debug applications. An application is loaded into memory from 0x90008000. It is assumed that the hardware has already been initialized by RedBoot. By default the application will not be stand-alone, and will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option CYGSEM_HAL_ROM_MONITOR should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option CYGSEM_HAL_USE_ROM_MONITOR should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

Note

Though, as previously discussed, since the option of hardware debugging is available as standard on the STM32F429I-DISCO platform it is unlikely that the RAM startup type would be used for development.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (CYGPKG_DEVS_SPI_CORTEXM_STM32).

The only SPI device instantiated by default is for an L3GD20 MEMS device connected to SPI bus 5 with pin PC1 selected as the chip select. To disable the device support, the platform HAL contains an option “SPI devices” (CYGPKG_HAL_CORTEXM_STM32_STM32F429I_DISCO_SPI) which can be disabled. No other SPI devices are instantiated.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at CYGPKG_HAL_STM32_I2C. But the platform I²C support can also be configured separately at CYGPKG_HAL_CORTEXM_STM32_STM32F429I_DISCO_I2C. This ensures that the STMPE811 touch-panel device is instantiated and becomes available for applications from <cyg/io/i2c.h>, and also ensures the STM32's I²C bus 5 is enabled for it.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM32F429I-DISCO platform HAL enables the support for the devices ADC1, ADC2 and ADC3 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic “Flash device drivers” (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32F429I-DISCO board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

Name

SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M4 core of the STM32F429ZI only supports six such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V2 interface.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. The architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

However, when using the STM32F429I-DISCO board via the ST-LINK/V2 interface then it is recommended that the `gdb_hwdebug_fileio` approach is used to provide access to diagnostics via the GDB debug connection. When ITM support is used it has been observed that the ST-LINK/V2 firmware can drop data, leading to the possibility of confusing output. However, with care the ITM system can be tuned to provide diagnostic and instrumentation via the host SWD debugger.

Using the ST-LINK/V2 connection allows for a single cable to provide board power, hardware debug support and diagnostic output.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board ST-LINK/V2 interface available via the USB CN1 connection, with the CN4 links closed to directly connect to the target STM32F429 CPU. When configuring the **openocd** tool build, the **configure** script can be given the option `--enable-stlink` to provide for ST-LINK support.

An example OpenOCD configuration file `openocd.stm32f429i_disco.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm32f429i_disco/current/misc` relative to the root of your eCos installation.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd.stm32f429i_disco.cfg
Open On-Chip Debugger 0.9.0 (2015-09-18-16:19)
Licensed under GNU GPL v2
For bug reports, read
    http://openocd.org/doc/doxygen/bugs.html
Info : The selected transport took over low-level target control. The results might differ compared to plain JTAG/SWD
adapter speed: 2000 kHz
adapter_nsrst_delay: 100
none separate
Info : Unable to match requested speed 2000 kHz, using 1800 kHz
Info : Unable to match requested speed 2000 kHz, using 1800 kHz
Info : clock speed 1800 kHz

Info : using stlink api v2
Info : Target voltage: 2.886506
Info : stm32f4x.cpu: hardware has 6 breakpoints, 4 watchpoints
```

By default **openocd** provides a console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb) monitor reset halt
target state: halted
target halted due to debug-request, current mode: Thread
xPSR: 0x01000000 pc: 0x0800422c msp: 0x20000c80
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then you will need to define a “preload” gdb macro to emit the **monitor reset halt** command to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

If the HAL diagnostics are configured to use ITM, and stimulus port 31 is configured as the HAL diagnostic destination, then the configuration example above will direct OpenOCD to direct ITM output (and also DWT and ETM) to a file named `tpiu.out` in the current directory of the shell which was used to run the **openocd** command. A more specific filename can be used by adjusting the OpenOCD configuration file.

To extract the ITM output, the Cortex-M architecture HAL package provides a helper program **parseitm** in the directory `packages/hal/cortexm/arch/current/host` relative to the root of your eCos installation. It can be compiled simply with:

```
$ gcc -o parseitm parseitm.c
```

You simply run it with the desired ITM stimulus port and name of the file containing the ITM output, for example:

```
$ parseitm -p 31 -f itm.out
```

It will echo all ITM stimulus for that port, continuing to read from the file until interrupted with Ctrl-C. Note that limited buffer space in debug hardware such as the ST-LINK can result in occasionally missed ITM data. eCosPro provides a workaround of throttling data within the `CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE` CDL configuration component in order to reduce or avoid lost ITM data. For further details, see the note in OpenOCD ITM support.

Similarly, if the eCos application is built with Kernel instrumentation enabled and configured for ITM output, then the default stimulus port 24 output can be captured. For example, assuming the application **cminfo** is the ELF file built from an eCos configuration with ITM instrumentation enabled, and is loaded and run via **openocd**, then we could run **parseitm** to capture instrumentation whilst the program executes, and then view the gathered data using the example **instdump** tool provided in the Kernel package.

```
$ parseitm -p 24 -f tpiu.out > inst.bin
^C
$ instdump -r inst.bin cminfo

```

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into SRAM or SDRAM without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support this mode, it is recommended to use the `JTAG` startup type which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the `JTAG` startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. An eCosCentric extension allows diagnostic output to appear in GDB, which is normally required for the STM32F429I-DISCO platform since it has no serial ports available. For this feature to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. Then, after you load your application but before running it, you must give GDB the command:

```
(gdb) set hwdebug on
```

Eclipse users can do this by creating a GDB command file with the contents:

```
define postload
  set hwdebug on
end
```

They may then reference it from their Eclipse debug launch configuration. Using GDB command files is described in more detail in the "Eclipse/CDT for eCos application development" manual.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32F429I-DISCO board hardware, and should be read in conjunction with that specification. The STM32F429I-DISCO platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For `ROM`, `ROMINT`, `SRAM` and `JTAG` startup types the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32f429i_disco_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM

> This is located at address `0x20000000` of the memory space, and is 192KiB in size. The eCos VSR table occupies the bottom 392 bytes of memory, with the virtual vector table starting at `0x200001AC` and extending to `0x200002AC`. For `ROM`, `ROMINT`, `SRAM` and `JTAG` startups, the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.
>
> For all configurations there is also a block of (close-coupled) SRAM located at address `0x10000000` of the memory space, and 64KiB in size.

External RAM

> This is located at address `0x90000000` of the memory space, and is 8MiB long. For `ROM` applications, all of the SDRAM is available for use. For `JTAG` applications the application is loaded from `0x90000000` with the remaining SDRAM after the code+data available for application use.
>
> For `RAM` startup applications, SDRAM below `0x90008000` is reserved for RedBoot and the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack, the remainder is available for the application.

Internal FLASH

> This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 2048KiB in size. `ROM` and `ROMINT` applications are by default configured to run from this memory.

On-Chip Peripherals

> These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 98 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x200001AC`.

hal_interrupt_stack
: This defines the location of the interrupt stack. For `ROM`, `ROMINT`, `SRAM` and `JTAG` startups, this is allocated to the top of internal SRAM, `0x20030000`. For `RAM` startups, it is allocated to the top of external SDRAM, `0x90800000`.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Diagnostic LEDs

Two LEDs are fitted on the board for diagnostic purposes: LED0 (green), marked as LD3; and LED1 (red) marked as LD4.

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow the LEDs to be set:

```
extern void hal_stm32f429i_disco_led(char c);
```

The lowest 2-bits of the argument `c` correspond to each of the 2 LEDs (with LED0 as the least significant bit).

The platform HAL will automatically light LED0 when the platform initialisation is complete, however the LEDs are free for application use.

Flash wait states

The STM32F429I-DISCO platform HAL provides a configuration option to set the number of Flash read wait states to use: `CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES`. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the STM32 Flash programming manual (PM0081) for appropriate values for different clock speeds or voltages. The default of 5 reflects a supply voltage of 3.3V and HCLK of 168MHz.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for `SRAM` startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 300.1. stm32f429i_disco Real-time characterization

```
eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Name

Test Programs — Details

Test Programs

The STM32F429I-DISCO platform HAL contains some test programs which allow various aspects of the board to be tested.

Manual Test

By default the **manual** test is not built by default. The configuration option `CYGPKG_HAL_CORTEXM_STM32_STM32F429I_DISCO_TESTS_MANUAL` should be enabled to allow the test to be built.

This program tests various aspects of the basic platform port, e.g. flashing LEDs, checking I²C and SPI device access and that the push-button GPIO operates.

Chapter 301. STM32F746G-DISCO Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32F746G_DISCO` — eCos Support for the STM32F746G-DISCO Board

Description

This documentation describes the platform-specific elements of the STM32F746G-DISCO board support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support. In addition ST's "Discovery kit for STM32F7 Series with STM32F746NG MCU" (ST User Manual id: UM1907) should be consulted for hardware setup and settings.

The board is equipped with an on-board ST-LINK/V2-1 hardware debugger interface (via the CN14 "USB ST-LINK" connector), which is typically used for eCos application development.

Supported Hardware

The STM32F746NG has two main on-chip memory regions. The device has a SRAM region of 320KiB present at 0x20000000, and a 1MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution). Also, the STM32F746G-DISCO motherboard has 8MiB of SDRAM memory mapped to address 0x60000000.

The STM32 variant HAL includes support for the eight on-chip serial devices which are documented in the variant HAL. However, the STM32F746G-DISCO motherboard only provides access to a single UART (no flow control signals, no RS-232 transceiver) via the CN4 connector.

The STM32 variant HAL also includes support for the I^{2}C buses. Two I^{2}C devices are instantiated as part of the platform port, one for the RK043FN48H touch-panel sensor and another for the WM8994 audio codec. Both are connected via bus I^{2}C3. The descriptors are exported in the normal way via `<cyg/io/i2c.h>`, with the names `hal_stm32f746g_disco_touchpanel` and `hal_stm32f746g_disco_audiocodec` respectively.

Similarly the STM32 variant HAL includes support for the SPI buses. Though the discovery board does not provide any SPI devices as standard.

USB host and peripheral modes are supported on both the FS OTG (connector CN13) and HS OTG (connector CN12) controllers available on the evaluation board. Consult the STM32 variant HAL documentation for USB driver details.

Device drivers are also provided for the STM32 on-chip Ethernet MAC, ADC and SDIO interfaces. Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

Note

The STM32 variant HAL support for the SDIO interface is currently limited to supporting MMC/SD cards. If the multi-bit MMC/SD support is used it is recommended that on-chip SRAM transfer buffers are used to avoid RX overrun or TX underrun due to the slow external SDRAM access speed.

The STM32F7 processor and the STM32F746G-DISCO board provide a wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3j, **arm-eabi-gdb** version 7.8.2, and **binutils** version 2.23.2.

Name

Setup — Preparing the STM32F746G-DISCO Board for eCos Development

Overview

Typically, since the STM32F746G-DISCO motherboard has a built-in ST-LINK/V2-1 interface providing hardware debug support, eCos applications are loaded and run via the debugger **arm-eabi-gdb** or via the Eclipse IDE. The debugger then communicates with the "GDB server" provided by the relevant host ST-LINK/V2-1 support tool being used (e.g. OpenOCD).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from on-chip SRAM, or where all of the SRAM and SDRAM is required for application run-time use.

If off-chip non-volatile memory (NVM) is used to hold the main application then the board can boot from the internal flash using a suitable boot loader. For example, the eCosPro BootUp ROM loader, where the BootUp code can start the main application (after an optional update sequence).

If required, it is still possible to program a GDB stub or RedBoot `ROM` image into on-chip Flash and download and debug via a serial connection (using the relevant CN4 pins). In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE as appropriate.

Preparing ST-LINK/V2-1 interface

The support for using the on-chip ITM stimulus ports for diagnostic and instrumentation output requires that the ST-LINK/V2-1 firmware is at least version `V2.J24.S11`. The firmware for the ST-LINK/V2-1 interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file). For example, the following OpenOCD output reports `JTAG v24`:

```
Info : STLINK v2 JTAG v24 API v2 SWIM v11 VID 0x0483 PID 0x374B
```

The user should refer to the ST "ST-LINK/V2-1 firmware upgrade" (RN0093) Release Note, which provides detail on the host requirements for upgrading the ST-Link firmware on Linux, Mac OS X and Windows hosts.

Programming ROM images

Since the STM32F746G-DISCO board has a built-in ST-LINK/V2-1 SWD interface, the USB host connection (CN14) and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash.

The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

Note

The **openocd** command being used should have been configured and built to support the ST-LINK/V2-1 interface. This is achieved by specifying the **--enable-stlink** when configuring the OpenOCD build. Additional information on running **openocd** may be found in the OpenOCD notes.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the "bootup.elf" application into the on-chip flash:

```
$ arm-eabi-gdb install/bin/bootup.elf
GNU gdb (eCosCentric GNU tools 4.7.3j) 7.8.2
[ … GDB output elided … ]
(gdb) target remote localhost:3333
hal_reset_vsr () at path/hal_misc.c:171
```

```
(gdb) load
Loading section .rom_vectors, size 0x14 lma 0x8000000
Loading section .text, size 0x3adc lma 0x8000018
Loading section .rodata, size 0x6c0 lma 0x8003af8
Loading section .data, size 0x6dc lma 0x80041b8
Start address 0x8000018, load size 18572
Transfer rate: 14 KB/sec, 4643 bytes/write.
(gdb)
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32F746G-DISCO board platform HAL package `CYGPKG_HAL_CORTEXM_STM32_STM32F746G_DISCO` is loaded automatically when eCos is configured for the `stm32f746g_disco` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32F746G-DISCO board platform HAL package supports five separate startup types:

ROM
: This startup type can be used for finished (stand-alone) applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into external SDRAM starting from 0x60000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

ROMINT
: This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x200002C8. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

The off-chip SDRAM memory from 0x60000000 is available, but is not referenced by the eCos run-time so is available for application use if required.

JTAG
: This is the startup type used to build applications that are loaded via the hardware debugger interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded into off-chip SDRAM from 0x60000000 and entered at that address. eCos startup code will perform all necessary hardware initialization, though since the application is loaded via the hardware debugger interface the host debug environment is responsible for configuring the necessary I/O state to initialise the off-chip SDRAM.

This is the startup type normally used during application development, since the large SDRAM memory space allows for larger debug applications where compiler optimisation may be disabled, and run-time assert checking enabled.

Note

Executing code from the SDRAM memory has a performance downside. It is significantly slower than execution from on-chip SRAM or flash. If performance is an issue then hardware debugging can be used for any of the startup types if required.

SRAM
: This is a variation of the `JTAG` type that only uses internal memory. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x200002C8 and entered at that address. eCos startup code will perform all necessary hardware initialization. Unlike the `JTAG` startup no explicit hardware debugger configuration is needed, since the application (like the `ROM` and `ROMINT` startup types) will initialise the off-chip SDRAM memory.

RAM
: For the ST-LINK/V2-1 enabled STM32F746G-DISCO platform this startup type is unlikely to be used. It is provided for completeness.

When the board has RedBoot (or a GDB stub ROM) programmed into internal Flash at location 0x08000000 then the arm-eabi-gdb debugger can communicate with a suitably configured UART connection to load and debug applications.

An application is loaded into memory from 0x60008000. It is assumed that the hardware has already been initialized by RedBoot. By default the application will *not* be stand-alone, and will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

Warning

RedBoot can have an adverse affect on the real-time performance of applications.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a `RAM` startup, disabled otherwise. It can be manually disabled for a `RAM` startup, making the application self-contained, as a testing step before switching to `ROM` startup.

Note

Though, as previously discussed, since the option of hardware debugging is available as standard on the STM32F746G-DISCO platform it is unlikely that the `RAM` startup type would be used for development.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

No SPI devices are instantiated for this platform by default.

Note

An example SPI M25PXX configuration can be enabled for boards suitably modified with an attached compatible flash device. The CDL option `CYGPKG_HAL_CORTEXM_STM32_STM32F746G_DISCO_SPI` can be enabled, and uses SPI bus 2 with the chip-select on PI0.

When configured the `m25pxx_flash_device` device is exported and can be accessed via the standard flash API. The device is given a logical base address of `0x00000000` but is *not* memory-mapped.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. However, the platform I²C support can also be configured separately at `CYGPKG_HAL_CORTEXM_STM32_STM32F746G_DISCO_I2C`. This enables I²C buses 1 and 3. The instantiated devices become available for applications via `<cyg/io/i2c.h>`.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic “Flash device drivers” (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32F746G-DISCO board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

Ethernet Driver

The Ethernet MAC is connected to a LAN8742A PHY via the RMII interface and thence to a RJ45 connector at CN9. The external 25MHz crystal is used to supply the clock.

Name

SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M7 core of the STM32F746NG only supports eight such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V2-1 interface.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. The architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

However, when using the STM32F746G-DISCO board via the ST-LINK/V2-1 interface then it is recommended that the `gdb_hwdebug_fileio` approach is used to provide access to diagnostics via the GDB debug connection. When ITM support is used it has been observed that the ST-LINK/V2-1 firmware can drop data, leading to the possibility of confusing output. However, with care the ITM system can be tuned to provide diagnostic and instrumentation via the host SWD debugger.

Using the ST-LINK/V2-1 connection allows for a single cable to provide power, hardware debug support and diagnostic output.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board ST-LINK/V2-1 interface available via the USB CN14 connection. When configuring the **openocd** tool build, the **configure** script can be given the option `--enable-stlink` to provide for ST-LINK support.

An example OpenOCD configuration file `openocd.stm32f746g_disco.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm32f746g_disco/current/misc` relative to the root of your eCos installation.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd.stm32f746g_disco.cfg

```

By default **openocd** provides a console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then, if required, you can define a “preload” gdb macro to emit any necessary commands to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

If the HAL diagnostics are configured to use ITM, and stimulus port 31 is configured as the HAL diagnostic destination, then the configuration example above will direct OpenOCD to direct ITM output (and also DWT and ETM) to a file named `tpiu.out` in the current directory of the shell which was used to run the **openocd** command. A more specific filename can be used by adjusting the OpenOCD configuration file.

To extract the ITM output, the Cortex-M architecture HAL package provides a helper program **parseitm** in the directory `packages/hal/cortexm/arch/current/host` relative to the root of your eCos installation. It can be compiled simply with:

```
$ gcc -o parseitm parseitm.c
```

You simply run it with the desired ITM stimulus port and name of the file containing the ITM output, for example:

```
$ parseitm -p 31 -f itm.out
```

and it will echo all ITM stimulus for that port, continuing to read from the file until interrupted with Ctrl-C. Note that limited buffer space in debug hardware such as the ST-LINK can result in occasionally missed ITM data. eCosPro provides a workaround of throttling data within the `CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE` CDL configuration component in order to reduce or avoid lost ITM data. For further details, see the note in OpenOCD ITM support.

Similarly, if the eCos application is built with Kernel instrumentation enabled and configured for ITM output, then the default stimulus port 24 output can be captured. For example, assuming the application **cminfo** is the ELF file built from an eCos configuration with ITM instrumentation enabled, and is loaded and run via **openocd**, then we could run **parseitm** to capture instrumentation whilst the program executes, and then view the gathered data using the example **instdump** tool provided in the Kernel package.

```
$ parseitm -p 24 -f tpiu.out > inst.bin
^C
$ instdump -r inst.bin cminfo

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into SRAM or SDRAM without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support this mode, it is recommended to use the JTAG startup type which will implicitly cause two important settings to change. Firstly, CYGSEM_HAL_USE_ROM_MONITOR must be disabled. Secondly the CYGDBG_HAL_DIAG_TO_DEBUG_CHAN option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the JTAG startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. An eCosCentric extension allows diagnostic output to appear in GDB. For this feature to work, you must enable the configuration option CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN in the common HAL package. If you are using the graphical configuration tool then you should then accept any suggested solutions to the subsequent configuration conflicts. Older eCos releases also required the gdb "set hwdebug on" command to be used to enable GDB or Eclipse console output, but this is no longer required with the latest tools.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32F746G-DISCO board hardware, and should be read in conjunction with that specification. The STM32F746G-DISCO platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For `ROM`, `ROMINT`, `SRAM` and `JTAG` startup types the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32f746g_disco_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. For all the STARTUP variations the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of the on-chip SRAM are reserved for the interrupt stack. The remainder of the internal SRAM is available for use by applications. The key memory locations are as follows:

Internal RAM
: This is located at address `0x20000000` of the memory space, and is 320KiB in size. The eCos VSR table occupies the bottom 456-bytes of memory, with the virtual vector table starting at `0x200001C8` and extending to `0x200002C8`.

  This memory region comprises three contiguous memory blocks, the DTCM (Data Tightly Coupled Memory), SRAM region 1 and SRAM region 2.

External SDRAM
: This is located at address `0x60000000` of the memory space, and is 8MiB long. For `ROM` applications, all of the SDRAM is available for use. For `JTAG` applications the application is loaded from `0x60000000` with the remaining SDRAM after the code+data available for application use.

  For `RAM` startup applications, SDRAM below `0x60008000` is reserved for the debug monitor (e.g. RedBoot).

Internal FLASH
: This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 1024KiB in size. `ROM` and `ROMINT` applications are by default configured to run from this memory.

On-Chip Peripherals
: These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 114 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x200001C8`.

hal_interrupt_stack — This defines the location of the interrupt stack. This is allocated to the top of internal SRAM, `0x20050000`.

hal_startup_stack — This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Flash wait states

The STM32F746G-DISCO platform HAL provides a configuration option to set the number of Flash read wait states to use: `CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES`. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the relevant STM32 datasheets and programming manuals for the STM32F746G parts for appropriate values for different clock speeds or voltages. The default of 5 reflects a supply voltage of 3.3V and HCLK of 180MHz.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for `SRAM` startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 301.1. stm32f746g_disco Real-time characterization

```
             Startup, main thrd : stack used   360 size  1536
             Startup : Idlethread stack used    84 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    3.03 microseconds (3 raw clock ticks)

Test Programs

The STM32F746G-DISCO platform HAL contains some test programs which allow various aspects of the board to be tested.

Manual Test

The **manual** test is not built by default. The configuration option `CYGBLD_HAL_CORTEXM_STM32F746G_DISCO_TESTS_MANUAL` should be enabled to allow the test to be built.

This program tests various aspects of the basic platform port, e.g. checking I²C device access and that the push-button GPIO operates.

Chapter 302. STM32H735-DISCO Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32H735_DISCO` — eCos Support for the STM32H735-DISCO Board

Description

This documentation describes the platform-specific elements of the STM32H735-DISCO board support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support. In addition ST's “Discovery kit with STM32H735IG MCU” (ST User Manual id: UM2679) should be consulted for hardware setup and settings.

The board is equipped with an on-board ST-LINK/V2-1 hardware debugger interface (via the CN15 “USB ST-LINK” connector), which is typically used for eCos application development.

Supported Hardware

The STM32H735IG has two main on-chip memory regions. The device has a SRAM region of 320KiB present at 0x24000000, and a 1MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution). A 512Mbit MX25LM51245G Octo SPI flash device is available through the OCTOSPI controller.

The STM32 variant HAL includes support for the eleven on-chip serial devices which are documented in the variant HAL. However, the STM32H735-DISCO motherboard only provides direct access to a single UART (no flow control signals, no RS-232 transceiver) via the CN8 connector. Indirect access to another UART is available via the ST-LINK hardware debugger.

The STM32 variant HAL also includes support for the I²C buses. There are no I²C devices on the board that eCos supports. I²C bus 4 is available on CN4.

Similarly the STM32 variant HAL includes support for the SPI buses. The discovery board does not provide any SPI devices as standard, but SPI bus 5 is available on CN4.

Device drivers are also provided for the STM32 on-chip Ethernet MAC and ADC controllers. Additionally, support is provided for the on-chip watchdog, and a Flash driver exists to permit management of the STM32's on-chip Flash.

The STM32H7 processor and the STM32H735-DISCO board provide a wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 7.3.0d, **arm-eabi-gdb** version 8.1, and **binutils** version 2.30.

Name

Setup — Preparing the STM32H735-DISCO Board for eCos Development

Overview

Typically, since the STM32H735-DISCO motherboard has a built-in ST-LINK/V2-1 interface providing hardware debug support, eCos applications are loaded and run via the debugger **arm-eabi-gdb** or via the Eclipse IDE. The debugger then communicates with the "GDB server" provided by the relevant host ST-LINK/V2-1 support tool being used (e.g. OpenOCD).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from on-chip SRAM, or where all of the SRAM is required for application run-time use.

If off-chip non-volatile memory (NVM) is used to hold the main application then the board can boot from the internal flash using a suitable boot loader. For example, the eCosPro BootUp ROM loader, where the BootUp code can start the main application (after an optional update sequence).

Preparing Board for Use

The STM32H735-DISCO board is distributed with some example firmware already loaded into the flash. This is useful for checking that the board is functional after unpacking. However, it is recommended that it be replaced before loading eCos applications for development since it can interfere with the board setup that eCos applications expect.

An executable, `stminfo.elf`, is provided as part of the release within the `prebuilt` subdirectory of the eCosPro release installation and this should be programmed into the ROM before use. Details on how to do this are described in the Programming ROM images section below.

Preparing ST-LINK/V3E interface

The ST-LINK/V3E firmware delivered with the board should be sufficiently up to date to work with debug servers like OpenOCD. The firmware for the ST-LINK/V3E interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file):

```
Info : STLINK V3J7M2 (API v3) VID:PID 0483:374E
```

The user should refer to the ST "ST-LINK/V3E firmware upgrade" Release Note, which provides detail on the host requirements for upgrading the ST-Link firmware on Linux, Mac OS X and Windows hosts.

Programming ROM images

Since the STM32H735-DISCO board has a built-in ST-LINK/V3E SWD interface, the USB host connection (CN15) and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash.

The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

Note

The **openocd** command provided with the eCosPro Host Tools has been configured and built to support the ST-LINK/V3E interface. Should you wish to rebuild **openocd** yourself, you must specify the **--enable-stlink** option when configuring the OpenOCD build. Additional information on running **openocd** may be found in the OpenOCD notes.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the `stminfo.elf` application into the on-chip flash:

```
$ arm-eabi-gdb stminfo.elf
GNU gdb (eCosCentric GNU tools 7.3.0d) 8.1
[ … GDB output elided … ]
(gdb) target extended-remote localhost:3333
Remote debugging using localhost:3333
=> 0x8000d40: push {r3, r4, r5, r6, r7, lr}
0x08000d40 in ?? ()
(gdb) load
Loading section .rom_vectors, size 0x8 lma 0x8000000
Loading section .text, size 0x3be8 lma 0x8000008
Loading section .rodata, size 0x6bc lma 0x8003bf0
Loading section .data, size 0x1c8 lma 0x80042b0
Start address 0x8000008, load size 17524
Transfer rate: 12 KB/sec, 4381 bytes/write.
(gdb) cont
```

Following the **cont** command, the following output should appear on the virtual UART:

```
INFO:<code from 0x08000008 -> 0x08003bf0, CRC 9425>
INFO:<STM32 CPU information>
INFO:<CDL Cortex-M7>
INFO:<MCU ID 10016483 DEV H72x/H73x REV Z>
INFO:<CPU reports flash size 1024K>
INFO:<Unique-ID: 0030001F 31395119 38323331>
INFO:<Variant Unique-ID maximum length 12>
INFO:<CYGARC_HAL_CORTEXM_STM32_INPUT_CLOCK 25000000>
INFO:<SYSCLK 550000000>
INFO:<HCLK   275000000>
INFO:<PCLK1  137500000>
INFO:<PCLK2  137500000>
INFO:<PCLK3  137500000>
INFO:<PCLK4  137500000>
INFO:<QCLK   68750000>
INFO:<Cortex-M systick 68750000>
PASS:<Done>
EXIT:<done>
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image stminfo.bin 0x08000000
Device: STM32H72x/73x
flash size probed value 1024
STM32H7 flash has a single bank
Bank (0) size is 1024 kb, base address is 0x08000000
Padding image section 0 at 0x08004318 with 8 bytes (bank write end alignment)
wrote 17184 bytes from file app.bin in 0.270935s (61.938 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32H735-DISCO board platform HAL package CYGPKG_HAL_CORTEXM_STM32_STM32H735_DISCO is loaded automatically when eCos is configured for the stm32h735_disco target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32H735-DISCO board platform HAL package supports five separate startup types:

ROM
: This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x240003CC. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

  This startup type will normally be used for production applications. It may also be used for development but over-use of flash during debugging may result in flash wear. It is advised to use the JTAG startup type during development if possible.

JTAG
: This is the startup type used to build applications that are loaded via the hardware debugger interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded into on-chip SRAM from 0x24000000 and entered at that address. eCos startup code will perform all necessary hardware initialization, though since the application is loaded via the hardware debugger interface the host debug environment may perform some initialization.

  This is the startup type normally used during application development, since it avoids wear on the flash memory. However, SRAM is only 320kiB and not all applications will fit solely into SRAM. In such cases, a ROM startup application should be used.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (CYGPKG_DEVS_SPI_CORTEXM_STM32).

SPI bus 5 is instantiated at CYGPKG_HAL_CORTEXM_STM32_STM32H735_DISCO_SPI and is available on Arduino header CN4. No SPI devices are instantiated for this platform by default.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at CYGPKG_HAL_STM32_I2C. However, the platform I²C support can also be configured separately at CYGPKG_HAL_CORTEXM_STM32_STM32H735_DISCO_I2C. This enables I²C bus 4 which is available on Arduino header CN4.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (CYGPKG_DEVS_FLASH_STM32) package. This driver is enabled automatically if the generic “Flash device drivers” (CYG-

PKG_IO_FLASH) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32H735-DISCO board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

OCTOSPI Flash Driver

When OCTOSPI NOR flash support is enabled in the configuration with CYGHWR_HAL_CORTEXM_STM32_FLASH_OCTOSPI, then the cyg_stm32_octospi1_device device is exported and can be accessed via the standard flash API. The device is given a logical base address to match its physical base address of 0x90000000 (corresponding to FMC bank 4) when it is memory mapped (if CYGFUN_DEVS_FLASH_OCTOSPI1_CORTEXM_STM32_MEMMAPPED is enabled in the OCTOSPI driver, which is not the default). When memory mapping is disabled, using the eCos Flash API will still allow the device to be read/written at that logical base address.

Ethernet Driver

The Ethernet MAC is connected to a LAN8742A PHY via the RMII interface and thence to a RJ45 connector at CN3. The external 25MHz crystal is used to supply the clock.

Note

It is **highly** recommended that the configuration option CYGHWR_HAL_CORTEXM_STM32_SRAM_ALTERNATE is **ENABLED**. Enabling that feature configures the Ethernet driver RX memory buffers to the SRAM2 space in the D2 domain. This is required to avoid an undocumented STM32H735 revZ errata where the Ethernet MAC would occasionally (rare) corrupt memory if the AXI SRAM was used for the RX buffers. The downside of the option is that it will mean a smaller number of RX buffers being available than is possible with the larger (main) AXI SRAM space.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM32H735-DISCO platform HAL enables the support for all three devices and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Name

SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M7 core of the STM32H735IG only supports eight such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V3E interface.

Using the ST-LINK/V3E USB connection allows for a single cable to provide power, hardware debug support and diagnostic output. The latter is provided via a virtual UART which instantiates an ACM compatible serial channel in the host which is connected to USART2 on the STM32H735IG. A separate application may be run alongside the debugger to capture the output from this UART, such as **minicom** under Linux or **PuTTY** under Windows.

OpenOCD notes

OpenOCD version `0.11.0` and above is required to support the STM32H735IG MCU. A prebuilt host **openocd** executable which also supports the on-board ST-LINK/V3E interface available via the USB CN15 connection has been provided with the eCosPro Host Tools version `5.0.0` and above.

Should you wish to rebuild **openocd** yourself, you must specify the `--enable-stlink` option when configuring the OpenOCD build to provide for ST-LINK support.

An example OpenOCD configuration file `openocd.stm32h735_disco.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm32h735_disco/current/misc` relative to the root of your eCosPro installation, but for convenience it is copied into the `install/etc` subdirectory as `openocd.cfg` during the **make etc** build process of the eCosPro library.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd.stm32h735_disco.cfg
Open On-Chip Debugger 0.11.0 (eCosCentric)
Licensed under GNU GPL v2
For bug reports, read
 http://openocd.org/doc/doxygen/bugs.html
Info : The selected transport took over low-level target control. The results might differ compared to plain JTAG/SWD
Info : Listening on port 6666 for tcl connections
Info : Listening on port 4444 for telnet connections
Info : clock speed 1800 kHz
Info : STLINK V3J7M2 (API v3) VID:PID 0483:374E
Info : Target voltage: 3.287824
Info : stm32h7x.cpu0: hardware has 8 breakpoints, 4 watchpoints
Info : starting gdb server for stm32h7x.cpu0 on 3333
Info : Listening on port 3333 for gdb connections
```

By default **openocd** provides a telnet console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target extended-remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
```

```
(gdb)
```

OpenOCD should report the following on its terminal when a GDB connection is made:

```
Info : accepting 'gdb' connection on tcp/3333

Initialising CPU...
target halted due to debug-request, current mode: Thread
xPSR: 0x01000000 pc: 0x08000d40 msp: 0x2404fc00
force hard breakpoints
Note: Breakpoints limited to 8 hardware breakpoints
Invalidate ICACHE
Invalidate DCACHE
Disable Caches

Info : Device: STM32H72x/73x
Info : flash size probed value 1024
Info : STM32H7 flash has a single bank
Info : Bank (0) size is 1024 kb, base address is 0x08000000
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then, if required, you can define a “preload” gdb macro to emit any necessary commands to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

Note

Incompatibilities between OpenOCD and the STM32H7 cache support mean that at present only hardware breakpoints should be used for debugging. The OpenOCD configuration file provided within the eCosPro Developer's kit enforces this.

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into SRAM without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support this mode, it is recommended to use the `JTAG` startup type which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the `JTAG` startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. An eCosCentric extension allows diagnostic output to appear in GDB. For this feature to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. If you are using the graphical configuration tool then you should then accept any suggested solutions to the subsequent configuration conflicts. Older eCos releases also required the gdb "set hwdebug on" command to be used to enable GDB or Eclipse console output, but this is no longer required with the latest tools.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32H735-DISCO board hardware, and should be read in conjunction with that specification. The STM32H735-DISCO platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. For both `ROM` and `JTAG` startup types the HAL will perform all initialization, programming the various internal registers including the PLLs, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32h735_disco_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. For all the STARTUP variations the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of the on-chip SRAM are reserved for the interrupt stack. The remainder of the internal SRAM is available for use by applications. The key memory locations are as follows:

Internal RAM
: This is located at address `0x24000000` of the memory space, and is 320KiB in size. The eCos VSR table occupies the bottom 716-bytes of memory, with the virtual vector table starting at `0x240002CC` and extending to `0x240003CC`.

This memory region comprises two contiguous memory blocks, the 128kiB AXI-SRAM plus 192kiB of shared SRAM in the default configuration where it is assigned to the AXI-SRAM.

SRAM1
: This is located at address `0x30000000` of the memory space, and is 16KiB in size. This is used to contain the Ethernet transmit and receive descriptor rings. It is mapped by an MPU region that disables caching for accesses.

Internal FLASH
: This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 1024KiB in size. `ROM` applications are by default configured to run from this memory. The 256kiB from offset 0xC0000 is used for flash testing. The test space is defined in `__STM32H735_DISCO_FLASHTEST_ONCHIP` in `plf_io.h`.

OCTOSPI NOR Flash
: The OCTOSPI NOR flash is accessible through the flash API. The 256kiB from offset 0x100000 is used for flash testing. The test space is defined in `__STM32H735_DISCO_FLASHTEST_OCTOSPI` in `plf_io.h`.

On-Chip Peripherals
: These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 114 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x200001C8`.

hal_interrupt_stack
This defines the location of the interrupt stack. This is allocated to the top of internal SRAM, `0x20050000`.

hal_startup_stack
This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Flash wait states

The STM32H735-DISCO platform HAL provides a configuration option to set the number of Flash read wait states to use: `CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES`. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the relevant STM32 datasheets and programming manuals for the STM32H735 parts for appropriate values for different clock speeds or voltages. The default of 5 reflects the default HCLK frequency.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for `ROM` startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 302.1. stm32h735_disco Real-time characterization

```
             Startup, main thrd : stack used   356 size  2048
             Startup : Idlethread stack used    76 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    1.00 microseconds (1 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  15
   Thread switches:         128
   Mutexes:                  32

Test Programs — Details

Test Programs

The STM32H735-DISCO platform HAL contains some test programs which allow various aspects of the board to be tested.

ADC Test

There are two tests for the ADC, which may be built by enabling `CYGBLD_HAL_CORTEXM_STM32H735_DISCO_TESTS_ADC`.

The **adc1** test reads the `Vrefint` ADC reference voltage, `Vsense` internal temperature, and `Vbat` battery voltage from channels 16, 17 and 18 of ADC3. These are printed out whenever any changes by a significant amount.

The **adc2** test reads the same sensors as **adc1** and in addition reads channel 10 of ADC1, which is connected to the A0 pin of Arduino connector CN9. A potentiometer attached to this pin allows various tests of the ADC system to be performed as prompted by the test itself.

Chapter 303. STM32H7 Nucleo-144 Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_NUCLEO144` — eCos Support for the STM32H7 Nucleo-144 Board

Description

This documentation describes the platform-specific elements of the STM32H7 Nucleo-144 (MB1364) board support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support. In addition ST's “STM32H7 Nucleo-144 boards” (ST User Manual id: UM2407) should be consulted for hardware setup and settings.

The board is equipped with an on-board ST-LINK-V3 hardware debugger interface (via the CN1 “USB ST-LINK” connector), which is typically used for eCos application development.

Note

The STM32H7 Nucleo-144 design has multiple motherboard variants and CPU combinations. Currently only the STM32H723ZG variant is supported by eCos using the `nucleo144_stm32h723` platform.

Supported Hardware

The STM32H723ZG has three main on-chip memory regions. The device has a SRAM region of 320KiB present at 0x24000000, a 16K SRAM region at 0x30000000 and a 1MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution).

Optionally a QSPI flash device can be connected to the relevant CN10 pins. When eCos is suitably configured access will be provided through the OCTOSPI1 controller.

The STM32 variant HAL includes support for the eleven on-chip serial devices which are documented in the variant HAL. However, the STM32H7 Nucleo-144 (MB1364) motherboard only provides direct access to a single UART (no RS-232 transceiver) via the CN9 connector. Indirect access to another UART is available via the ST-LINK hardware debugger.

The STM32 variant HAL also includes support for the I²C buses. There are no I²C devices on the board that eCos supports. I²C bus 1 or 4 is available on CN7. I²C bus 2 or 5 is available on CN9.

Similarly the STM32 variant HAL includes support for the SPI buses. The MB1364 board does not provide any SPI devices as standard, but SPI bus 1 is available on CN7 (MB1364 label SPI_A).

Device drivers are also provided for the STM32 on-chip Ethernet MAC and ADC controllers. Additionally, support is provided for the on-chip watchdog, and a Flash driver exists to permit management of the STM32's on-chip Flash.

The STM32H7 processor and the STM32H7 Nucleo-144 board provides for a wide variety of connected peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 7.3.0d, **arm-eabi-gdb** version 8.1, and **binutils** version 2.30.

Name

Setup — Preparing the STM32H7 Nucleo-144 Board for eCos Development

Overview

Typically, since the STM32H7 Nucleo-144 motherboard has a built-in STLINK-V3 interface providing hardware debug support, eCos applications are loaded and run via the debugger **arm-eabi-gdb** or via the Eclipse IDE. The debugger then communicates with the “GDB server” provided by the relevant host STLINK-V3 support tool being used (e.g. OpenOCD).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from on-chip SRAM, or where all of the SRAM is required for application run-time use.

If off-chip non-volatile memory (NVM) is used to hold the main application then the board can boot from the internal flash using a suitable boot loader. For example, the eCosPro BootUp ROM loader, where the BootUp code can start the main application (after an optional update sequence).

Preparing Board for Use

The STM32H7 Nucleo-144 board is distributed with some example firmware already loaded into the flash. This is useful for checking that the board is functional after unpacking. However, it is recommended that it be replaced before loading eCos applications for development since it can interfere with the board setup that eCos applications expect.

An executable, `stminfo.elf`, is provided as part of the release within the `prebuilt` subdirectory of the eCosPro release installation and this should be programmed into the ROM before use. Details on how to do this are described in the Programming ROM images section below.

Preparing the ST-LINK/V3E interface

The ST-LINK/V3E firmware delivered with the board should be sufficiently up to date to work with debug servers like OpenOCD. The firmware for the ST-LINK/V3E interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file):

```
Info : STLINK V3J8M3 (API v3) VID:PID 0483:374E
```

The user should refer to the ST “ST-LINK/V3E firmware upgrade” Release Note, which provides detail on the host requirements for upgrading the ST-Link firmware on Linux, Mac OS X and Windows hosts.

Programming ROM images

Since the STM32H7 Nucleo-144 board has a built-in ST-LINK/V3E SWD interface, the USB host connection (CN1) and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash.

The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

Note

The **openocd** command provided with the eCosPro Host Tools has been configured and built to support the ST-LINK/V3E interface. Should you wish to rebuild **openocd** yourself, you must specify the **--enable-stlink** option when configuring the OpenOCD build. Additional information on running **openocd** may be found in the OpenOCD notes.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the `stminfo.elf` application into the on-chip flash:

```
$ arm-eabi-gdb stminfo.elf
GNU gdb (eCosCentric GNU tools 7.3.0d) 8.1
[ … GDB output elided … ]
(gdb) target extended-remote localhost:3333
Remote debugging using localhost:3333
=> 0x8000d40: push {r3, r4, r5, r6, r7, lr}
0x08000d40 in ?? ()
(gdb) load
Loading section .rom_vectors, size 0x8 lma 0x8000000
Loading section .text, size 0x3be8 lma 0x8000008
Loading section .rodata, size 0x6bc lma 0x8003bf0
Loading section .data, size 0x1c8 lma 0x80042b0
Start address 0x8000008, load size 17524
Transfer rate: 12 KB/sec, 4381 bytes/write.
(gdb) cont
```

Following the **cont** command, the following output should appear on the virtual UART:

```
INFO:<code from 0x08000008 -> 0x08003f00, CRC c29f>
INFO:<STM32 CPU information>
INFO:<CDL Cortex-M7>
INFO:<MCU ID 10016483 DEV H72x/H73x REV Z>
INFO:<CPU reports flash size 1024K>
INFO:<Unique-ID: 000E000F 31395118 38323331>
INFO:<Variant Unique-ID maximum length 12>
INFO:<CYGARC_HAL_CORTEXM_STM32_INPUT_CLOCK 8000000>
INFO:<SYSCLK 400000000>
INFO:<HCLK   200000000>
INFO:<PCLK1  100000000>
INFO:<PCLK2  100000000>
INFO:<PCLK3  100000000>
INFO:<PCLK4  100000000>
INFO:<QCLK    50000000>
INFO:<Cortex-M systick 50000000>
INFO:<Dcache enabled>
INFO:<Icache enabled>
PASS:<Done>
EXIT:<done>
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image stminfo.bin 0x08000000
Padding image section 0 at 0x080047c4 with 28 bytes (bank write end alignment)
wrote 18400 bytes from file stminfo.bin in 0.073288s (245.180 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32H7 Nucleo-144 board platform HAL package `CYGPKG_HAL_CORTEXM_STM32_NUCLEO144` is loaded automatically when eCos is configured for the `nucleo144_stm32h723` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32H7 Nucleo-144 board platform HAL package supports two startup types:

ROM
: This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x240003CC. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

  This startup type will normally be used for production applications. It may also be used for development but over-use of flash during debugging may result in flash wear. It is advised to use the JTAG startup type during development if possible.

JTAG
: This is the startup type used to build applications that are loaded via the hardware debugger interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded into on-chip SRAM from 0x24000000 and entered at that address. eCos startup code will perform all necessary hardware initialization, though since the application is loaded via the hardware debugger interface the host debug environment may perform some initialization.

  This is the startup type normally used during application development, since it avoids wear on the flash memory. However, SRAM is only 320kiB and not all applications will fit solely into SRAM. In such cases, a ROM startup application should be used.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

SPI bus 1 is instantiated at `CYGPKG_HAL_CORTEXM_STM32_NUCLEO144_SPI` and is available on Arduino header CN7. No SPI devices are instantiated for this platform by default.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. However, the platform I²C support can also be configured separately at `CYGPKG_HAL_CORTEXM_STM32_NUCLEO144_I2C`. This enables I²C bus 4 which is available on Arduino header CN7.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic “Flash device drivers” (`CYG-`

PKG_IO_FLASH) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32H7 Nucleo-144 board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

OCTOSPI Flash Driver

When OCTOSPI NOR flash support is enabled in the configuration with CYGHWR_HAL_CORTEXM_STM32_FLASH_OCTOSPI, then the cyg_stm32_octospi1_device device is exported and can be accessed via the standard flash API. The device is given a logical base address to match its physical base address of 0x90000000 (corresponding to FMC bank 4) when it is memory mapped (if CYGFUN_DEVS_FLASH_OCTOSPI1_CORTEXM_STM32_MEMMAPPED is enabled in the OCTOSPI driver, which is not the default). When memory mapping is disabled, using the eCos Flash API will still allow the device to be read/written at that logical base address.

Ethernet Driver

The Ethernet MAC is connected to a LAN8742A PHY via the RMII interface and thence to a RJ45 connector at CN143. The external 25MHz crystal X4 is used to supply the clock.

Note

It is **highly** recommended that the configuration option CYGHWR_HAL_CORTEXM_STM32_SRAM_ALTERNATE is **ENABLED**. Enabling that feature configures the Ethernet driver RX memory buffers to the SRAM2 space in the D2 domain. This is required to avoid an undocumented STM32H723 revZ errata where the Ethernet MAC would occasionally (rare) corrupt memory if the AXI SRAM was used for the RX buffers. The downside of the option is that it will mean a smaller number of RX buffers being available than is possible with the larger (main) AXI SRAM space.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM32H7 Nucleo-144 platform HAL enables the support for all three devices and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Name

SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M7 core of the STM32H723ZG only supports eight such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V3E interface.

Using the ST-LINK/V3E USB connection allows for a single cable to provide power, hardware debug support and diagnostic output. The latter is provided via a virtual UART which instantiates an ACM compatible serial channel in the host which is connected to USART3 on the STM32H723ZG. A separate application may be run alongside the debugger to capture the output from this UART, such as **minicom** under Linux or **PuTTY** under Windows.

OpenOCD notes

OpenOCD version `0.11.0` and above is required to support the STM32H723ZG MCU. A prebuilt host **openocd** executable which also supports the on-board ST-LINK/V3E interface available via the USB CN1 connection has been provided with the eCosPro Host Tools version `5.0.0` and above.

Should you wish to rebuild **openocd** yourself, you must specify the `--enable-stlink` option when configuring the OpenOCD build to provide for ST-LINK support.

An example OpenOCD configuration file `openocd.nucleo144.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/nucleo144/current/misc` relative to the root of your eCosPro installation, but for convenience it is copied into the `install/etc` subdirectory as `openocd.cfg` during the **make etc** build process of the eCosPro library.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd.nucleo144_disco.cfg
Open On-Chip Debugger 0.11.0 (eCosCentric)
Licensed under GNU GPL v2
For bug reports, read
 http://openocd.org/doc/doxygen/bugs.html
Info : The selected transport took over low-level target control. The results might differ compared to plain JTAG/SWD
Info : Listening on port 6666 for tcl connections
Info : Listening on port 4444 for telnet connections
Info : clock speed 1800 kHz
Info : STLINK V3J8M3 (API v3) VID:PID 0483:374E
Info : Target voltage: 3.287824
Info : stm32h7x.cpu0: hardware has 8 breakpoints, 4 watchpoints
Info : starting gdb server for stm32h7x.cpu0 on 3333
Info : Listening on port 3333 for gdb connections
```

By default **openocd** provides a telnet console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target extended-remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
```

```
(gdb)
```

OpenOCD should report the following on its terminal when a GDB connection is made:

```
Info : accepting 'gdb' connection on tcp/3333

Initialising CPU...
target halted due to debug-request, current mode: Thread
xPSR: 0x01000000 pc: 0x08000d40 msp: 0x2404fc00
force hard breakpoints
Note: Breakpoints limited to 8 hardware breakpoints
Invalidate ICACHE
Invalidate DCACHE
Disable Caches

Info : Device: STM32H72x/73x
Info : flash size probed value 1024
Info : STM32H7 flash has a single bank
Info : Bank (0) size is 1024 kb, base address is 0x08000000
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then, if required, you can define a “preload” gdb macro to emit any necessary commands to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

Note

Incompatibilities between OpenOCD and the STM32H7 cache support mean that at present only hardware breakpoints should be used for debugging. The OpenOCD configuration file provided within the eCosPro Developer's kit enforces this.

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into SRAM without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support this mode, it is recommended to use the `JTAG` startup type which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the `JTAG` startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. An eCosCentric extension allows diagnostic output to appear in GDB. For this feature to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. If you are using the graphical configuration tool then you should then accept any suggested solutions to the subsequent configuration conflicts. Older eCos releases also required the gdb "set hwdebug on" command to be used to enable GDB or Eclipse console output, but this is no longer required with the latest tools.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32H7 Nucleo-144 board hardware, and should be read in conjunction with that specification. The NUCLEO-144 Board HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. For both `ROM` and `JTAG` startup types the HAL will perform all initialization, programming the various internal registers including the PLLs, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/nucleo144_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. For all the STARTUP variations the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of the on-chip SRAM are reserved for the interrupt stack. The remainder of the internal SRAM is available for use by applications. The key memory locations are as follows:

Internal RAM
: This is located at address `0x24000000` of the memory space, and is 320KiB in size. The eCos VSR table occupies the bottom 716-bytes of memory, with the virtual vector table starting at `0x240002CC` and extending to `0x240003CC`.

  This memory region comprises two contiguous memory blocks, the 128kiB AXI-SRAM plus 192kiB of shared SRAM in the default configuration where it is assigned to the AXI-SRAM.

SRAM1
: This is located at address `0x30000000` of the memory space, and is 16KiB in size. This is used to contain the Ethernet transmit and receive descriptor rings. It is mapped by an MPU region that disables caching for accesses.

Internal FLASH
: This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 1024KiB in size. `ROM` applications are by default configured to run from this memory. The 256kiB from offset 0xC0000 is used for flash testing. The test space is defined in `__NUCLEO144_FLASHTEST_ONCHIP` in `plf_io.h`.

QSPI NOR Flash
: The QSPI NOR flash is accessible through the flash API. The 256kiB from offset 0x100000 is used for flash testing. The test space is defined in `__NUCLEO144_FLASHTEST_OCTOSPI` in `plf_io.h`.

On-Chip Peripherals
: These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 114 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x240002cc`.

hal_interrupt_stack
: This defines the location of the interrupt stack. This is allocated to the top of internal SRAM, 0x24050000.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Flash wait states

The STM32H7 Nucleo-144 platform HAL provides a configuration option to set the number of Flash read wait states to use: CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the relevant STM32 datasheets and programming manuals for the STM32H723 parts for appropriate values for different clock speeds or voltages. The default of 5 reflects the default HCLK frequency.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for ROM startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 303.1. nucleo144_stm32h723 Real-time characterization

```
             Startup, main thrd : stack used   356 size  2048
             Startup : Idlethread stack used    76 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    1.00 microseconds (1 raw clock ticks)

Testing parameters:
   Clock samples:            32

Test Programs — Details

Test Programs

The eCos NUCLEO-144 Board HAL contains a test program which allow various aspects of the board to be tested.

Manual Test

The simple manual test may be built by enabling `CYGPKG_HAL_CORTEXM_STM32_NUCLEO144_TESTS_MANUAL`.

The **manual** test will flash the LEDs and allow track use of the user (normally blue) button B1.

Chapter 304. STM32F4DISCOVERY Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32F4DIS` — eCos Support for the STM32F4DISCOVERY Board

Description

The STMicroelectronics STM32F4DISCOVERY board has a STM32F407VG microcontroller which incorporates 1MiB of internal Flash ROM and 128KiB of internal SRAM. The microcontroller also has 64KiB of internal “core coupled” SRAM for CPU use.

The STM32F4DISCOVERY board has limited I/O interfaces, with most of the I/O signals being propogated via multi-pin connectors. The STM32F4DIS-BB daughterboard has a connector for Ethernet, a standard DB9 serial port, and a MicroSD interface. On both the main STMF4DISCOVERY motherboard and the STM32F4DIS-BB daughterboard it is possible to access signals for UARTs, I²C, and SPI, as well as various other devices.

For the STM32F4DISCOVERY board the expected eCos development model is that programs may be downloaded and debugged via a SWD debugger, normally attached via the on-board USB ST-LINK/V2 connector CN1. This differs from the traditional eCos development model, where RedBoot or a GDB stub image is programmed into internal FLASH and the CPU boots directly into that. However, due to the small amount of RAM available, the RAM requirements of a ROM monitor would further limit the size of applications that could be loaded via such a monitor. Nevertheless it is still possible to program a GDB stub image into Flash and download and debug eCos applications with the GDB debugger via available UART pins.

This documentation describes platform-specific elements of the STM32F4DISCOVERY board support within eCos. The STM32 variant HAL documentation covers various topics including HAL support common to STM32 variants, and on-chip device support. This document complements the STM32 documentation.

Supported Hardware

The STM32F407VG has three on-chip memory regions. A RAM region of 128KiB is present at 0x20000000, a 64KiB core coupled RAM region present at 0x1000000, and a 1MiB FLASH region is present at 0x08000000 which is aliased to 0x00000000 during normal execution.

The STM32 variant HAL includes support for the six on-chip serial devices which are documented in the variant HAL, however it is assumed that only USART6 is available when the STM32F4DIS-BB daughterboard is present. There is no connection for hardware flow control (RTS/CTS) lines.

The STM32 variant HAL also includes support for the I²C bus. However the STM32F4DISCOVRY mainboard I²C devices are not supported due to I/O pin clashes with the STM32F4DIS-BB daughterboard. Instead, testing has been performed using an external Total Phase Aardvark activity board with on-board I²C EEPROM.

Device drivers are also provided for the STM32 on-chip SPI and MMCSD interfaces, plus the Ethernet MAC. Additionally, support is provided for the on-chip watchdog, RTC (wallclock), and a Flash driver exists to permit management of the STM32's on-chip Flash.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.4.5, **arm-eabi-gdb** version 7.2, and **binutils** version 2.20.1.

Name

Setup — Preparing the STM32F4DISCOVERY Board for eCos Development

Overview

Given the limited available RAM memory, it is expected that the most common development method is to use JTAG/SWD for development, either by loading smaller applications into RAM, or by programming larger applications directly into on-chip Flash. In the first case, eCos applications should be configured for the `JTAG` startup type, and in the second case for the `ROM` startup type.

Nevertheless, it is still possible to program a GDB stub ROM image into on-chip Flash and download and debug via a serial UART, if pins for the UART are available. In that case, eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed in the eCos configuration used for building the GDB stub ROM image.

HAL startup types

The following startup types may be selected for applications:

Configuration	Description
ROM	Programs running from internal FLASH
JTAG	Programs running from RAM, loaded via JTAG or SWD debug hardware
RAM	Programs loading via a GDB stub ROM and serial connection into RAM

Further details are available later in this manual.

Preparing ST-LINK/V2 interface

The support for using the on-chip ITM stimulus ports for diagnostic and instrumentation output requires that the ST-LINK/V2 firmware is at least version `V2.J17.S0`. The firmware for the ST-LINK/V2 interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file). For example, the following OpenOCD output reports `JTAG v17`:

```
Info : STLINK v2 JTAG v17 API v2 SWIM v0 VID 0x0483 PID 0x3748
```

Unfortunately the official firmware updater is only available for the Windows platform at the moment. From a Windows machine:

1. Ensure that the Windows PC and STM32F4DISCOVERY board are disconnected.

2. Download the STM32 ST-LINK Utility from ST's website.

   The page titled “STSW-LINK004 STM32 ST-LINK utility” provides a free download of the utility http://www.st.com/web/en/catalog/tools/PF258168

3. Install the ST-LINK Utility software on your Windows PC.

   Simply unzip the downloaded file `stsw-link004.zip` and run the `STM32 ST-LINK Utility_v3.0.0.exe` that was contained within it. Follow the on-screen instructions. This will install both the utility application and the ST-LINK/V2 USB driver.

4. Connect the STM32F4DISCOVERY board to the PC.

   Connect the STM32F4DISCOVERY board to the PC using the ST supplied mini-B USB cable. Windows should correctly identify the USB device and load the device driver. Windows Device Manager should now show “STMicroelectronics STLink dongle” under “Universal Serial Bus controllers”.

5. Run the ST-LINK Utility and ensure the ST-LINK firmware is up to date.

   From the Windows “Start” menu run the “STM32 ST-LINK Utility”. Click on the `connect` icon, or select `Target->Connect` from the menu. This should confirm that a successful connection can be made to the board. To update the on-board ST-LINK/V2 firmware select `ST-LINK->Firmware Update` from the menu. In the ST-LINK dialog box that then appears click on the `Device Connect` button. This will likely result in a message “ST-Link is not in DFU mode. Please restart it.”. In this case simply disconnect the board from the PC and then reconnect it after a couple of seconds, then click the `OK` button on the message. In the original ST-Link dialog box click `Device Connect` again. The dialog box should now report the current on-board and available firmware versions, and enable you to upgrade the board by pressing the `Yes >>>>` button. We have tested the system with firmware version `V2.J17.S0` and would recommend this version as a minimum. Clicking `Yes >>>>` will cause a progress bar in the dialog to be animated and should eventually result in a “Update Successful” message. You can then close the various dialogs and exit the ST-LINK Utility. Disconnect and reconnect the board and it is now ready for use with OpenOCD.

Programming ROM images

To program ROM startup applications into Flash, including the GDB stub ROM, a JTAG/SWD debugger that understands the STM32 flash may be used, such as a Ronetix PEEDI.

However, since the STM32F4DISCOVERY board has a built-in ST-LINK/V2 SWD interface, if the `CN3` jumpers are closed then the micro USB host connection and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash. Normally a default **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

Programming ROM images with a Ronetix PEEDI

This section describes how to program ROM images using a Ronetix PEEDI debugger.

The PEEDI must be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. It must then be used to download and program the ROM image into the internal flash. The following steps give a typical outline for doing this. Consult the PEEDI documentation for alternative approaches, such as using FTP or HTTP instead of TFTP.

Preparing the Ronetix PEEDI JTAG debugger

1. Prepare a PC to act as a host and start a TFTP server on it.

2. Connect the PEEDI JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the PEEDI (straight through, not null modem).

3. Verify the PEEDI is using up-to-date firmware, of version 11.10.1 or later. Older PEEDI firmware does not support the STM32 F4 family correctly, particularly if wishing to use the PEEDI's own '**flash**' commands to modify the on-chip Flash. If the firmware is not recent enough, follow the PEEDI User Manual's instructions which describe how to update the PEEDI firmware.

4. Locate the PEEDI configuration file `peedi.stm32f4dis.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm32f4dis/current/misc` relative to the root of your eCos installation.

5. Place the PEEDI configuration file in a location on the PC accessible to the TFTP server. Later you will configure the PEEDI to load this file via TFTP as its configuration file.

6. Open `peedi.stm32f4dis.cfg` in an editor such as emacs or notepad and insert your own license information in the `[LICENSE]` section.

7. Install and configure the PEEDI in line with the PEEDI Quick Start Guide or User's Manual, especially configuring PEEDI's RedBoot with the network information. Configure it to use the `peedi.stm32f4dis.cfg` target configuration file on the TFTP server at the appropriate point of the **config** process, for example with a path such as: `tftp://192.168.7.9/peedi.stm32f4dis.cfg`

8. Reset the PEEDI.

9. Connect to the PEEDI's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see output similar to the following:

```
$ telnet 192.168.7.225
Trying 192.168.7.225...
Connected to 192.168.7.225.
Escape character is '^]'.

Preparing the STM32F4DISCOVERY board for programming with PEEDI

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

If programming a GDB stub ROM or an application which uses serial output, you should first:

1. Connect an adaptor from the serial pins on the board to an RS232 DB9 serial connector or cable, then connect from there to a serial port on the host computer with a null modem DB9 RS232 serial cable.

2. Start a suitable terminal emulator on the host computer such as **minicom** on Linux or PuTTY on Windows. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

For all applications, you must:

1. Connect the board to the PEEDI. Since the STM32F4DISCOVERY does not have a standard ARM Cortex-M connector a custom connection from the Target port on the PEEDI to the STM32F4DISCOVERY needs to be wired.

Note

This is a direct connection from the PEEDI *without* any PEEDI adapter installed. Also the STM32F4DISCOVERY CN3 jumpers should be removed to disconnect the ST-Link from driving the target STM32F4 SWD interface.

The following table maps the PEEDI TARGET connector pin numbers to the STM32F4DISCOVERY P1 and P2 connector pins, and assumes a standard PEEDI `PLATFORM = CortexM3_SWD` configuration.

	PEEDI TARGET	**STM32F4DISCOVERY**
Vdd	1	P1#3 (VDD)
SWCLK	3	P2#39 (PA14)

	PEEDI TARGET	STM32F4DISCOVERY
SWDIO	7	P2#42 (PA13)
SWO	11	P2#28 (PB3)
nRST	20	P1#6 (NRST)
GND	16	P1#49 (GND)

2. Power up the STMF4DISCOVERY board.

3. Connect to the PEEDI's telnet CLI on port 23 as before.

4. Confirm correct connection with the PEEDI with the **reset reset** command as follows:

   ```
   stm32f4discovery> reset reset
   ++ info: RESET and TRST asserted
   ++ info: TRST released
   ++ info: TAP : IDCODE = 0x2BA01477, Cortex M3 SWD
   ++ info: RESET released
   ++ info: core connected
   ++ info: core 0: initialized
   stm32f4discovery>
   ```

Installation into Flash

The following describes the procedure for installing a ROM application into on-chip Flash, using the GDB stub ROM image as an example of such an application.

1. Use **arm-eabi-objcopy** to convert the linked application, in ELF format, into binary format. For example:

   ```
   $ arm-eabi-objcopy -O binary programname programname.bin
   ```

   In the case of the GDB stub ROM image, a prebuilt image is available with the name `gdb_module.bin` within the `loaders` subdirectory of the base of the eCos installation.

2. Copy the binary file (.bin file) into a location on the host computer accessible to its TFTP server.

3. Connect to the PEEDI's telnet interface, and program the image into Flash with the following command, replacing *`TFTP_SERVER`* with the address of the TFTP server and *`/BINPATH`* with the location of the .bin file relative to the TFTP server root directory. For example for the GDB stub ROM:

   ```
   stm32f4discovery> flash program tftp://TFTP_SERVER/BINPATH/gdb_module.bin bin 0x08000000 erase
   ++ info: Programming image file: tftp://TFTP_SERVER/BINPATH/gdb_module.bin
   ++ info: Programming using agent, buffer = 4096 bytes
   ++ info: At absolute address:    0x08000000
   erasing     at 0x08000000 (sector #0)
   programming at 0x08000000
   programming at 0x08001000
   programming at 0x08002000
   programming at 0x08003000
   erasing     at 0x08004000 (sector #1)
   programming at 0x08004000

   ++ info: successfully programmed 20.00 KB in 1.11 sec

   stm32f4discovery>
   ```

The installation into Flash is now complete. For applications which print output on startup to the USART3 RS232 serial port, such as the GDB stub ROM application, this can easily by tested by powering off the board, disconnecting the JTAG, and then powering on the board again. In the case of the GDB stub ROM image, output similar to the following should be visible (although specific numbers may differ):

```
$T050f:72250008;0d:f0ff0120;#8a
```

Rebuilding the GDB stub

Should it prove necessary to rebuild the GDB stub ROM binary, this is done most conveniently at the command line. The steps needed are:

```
$ mkdir gdbstub_stm32f4dis
$ cd gdbstub_stm32f4dis
$ ecosconfig new stm32f4dis stubs
[ … ecosconfig output elided … ]
$ ecosconfig tree
$ make
```

At the end of the build, the `install/bin` subdirectory should contain the file `gdb_module.bin`. This may be programmed to the board using the above procedure.

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32F4DISCOVERY board platform HAL package is loaded automatically when eCos is configured for the `stm32f4dis` or `stm32f4disbb` targets. The `stm32f4dis` target enables the necessary hardware support for the bare STM32F4DISCOVERY board, whereas the `stm32f4disbb` target is intended to support the STM32F4DISCOVERY board stacked with a “STM32F4DISCOVERY Base Board” (STM32F4DIS-BB). The essential difference between the two targets being that the Base Board target adds Ethernet support. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32F4DISCOVERY board platform HAL package supports three separate startup types:

ROM

> This startup type can be used for finished applications which will be programmed into internal Flash ROM at location `0x08000000`. Data and BSS will be put into internal SRAM starting from `0x20000288`. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the `0x08000000` region. eCos startup code will perform all necessary hardware initialization.

RAM

> This is the startup type which is used if relying on a GDB stub ROM image programmed into internal Flash to download and run applications into RAM via **arm-eabi-gdb** and a serial UART. RAM from `0x20000000` to `0x20001000` is reserved for the GDB stub, but then the RAM startup application may be loaded into memory from `0x20001000` and debugged using GDB. It is assumed that the hardware has already been initialized by the GDB stub ROM. By default the application will use the eCos virtual vectors mechanism to obtain services from the GDB stub ROM, including diagnostic output.

JTAG

> This is the startup type used to build applications that are loaded via a JTAG/SWD interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from `0x20000288` and entered at that address. Memory from `0x20000000` to `0x20000288` is set aside for vector tables. eCos startup code will perform all necessary hardware initialization.

Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB stub ROM (or RedBoot).

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The STM32F4DISCOVERY board uses the STM32's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, is only expected to be available to be used on the UART6 port (counting the first UART as UART1). The bare STM32F4DISCOVERY board only exports the UART6 connection via connector P2, but the STM32F4DIS-BB daughterboard provides UART6 on the COM1 (DB9) connector.

Note

In reality when using a hardware SWD debugger (e.g. the on-board ST-LINK/V2 interface) it is preferable to use the on-chip ITM support for HAL diagnostic output. The ITM stimulus port HAL diagnostic interface is significantly faster than using a UART, and provides for a simpler, single cable, debug and diagnostic connection to the target board. The use of ITM for HAL diagnostics is configurable in the architecture HAL.

As well as the polled HAL diagnostic interface, there is also a CYGPKG_IO_SERIAL_CORTEXM_STM32 package which contains all the code necessary to support interrupt-driven operation with greater functionality. All six UARTs can be supported by this driver. Note that it is not recommended to use this driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option (within the generic serial driver support package CYGPKG_IO_SERIAL) is enabled in the configuration. By default this will only enable support in the driver for the USART6 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports. Note that in this package, serial port numbering starts at 0, rather than 1. So, for example, to enable the serial driver for ports USART1 and USART2, enable the configuration options "ST STM32 serial port 0 driver" (CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL0) and "ST STM32 serial port 1 driver" (CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL1).

Ethernet Driver

The STM32F4DIS-BB daughterboard is fitted with an Ethernet port connected via a SMSC LAN8720 PHY to the STM32's on-chip Ethernet MAC. This is supported in eCosPro with a driver for the lwIP networking stack, contained in the package CYGPKG_DEVS_ETH_CORTEXM_STM32. At the present time it only supports the lwIP networking stack, and cannot be used for either the BSD networking stack or RedBoot.

When using a default eCos configuration the driver will be inactive (not built and greyed out in the eCos Configuration Tool) since that configuration does not include the networking packages. The driver is enabled when the platform HAL option "STM32 Ethernet Support" (CYGPKG_HAL_CORTEXM_STM32_STM32F4DIS_ETH0) is enabled. This option in turn is only active if the "Common Ethernet support" (CYGPKG_IO_ETH_DRIVERS) package is included in your configuration. As the STM32 ethernet driver is an lwIP-only driver, it is most appropriate to choose the lwip_eth template as a starting point when choosing an eCos configuration, which will cause the necessary packages to be automatically included.

SPI Driver

An SPI bus driver is available for the STM32 in the package "ST STM32 SPI driver" (CYGPKG_DEVS_SPI_CORTEXM_STM32).

Two SPI device entries have been created for use, and the SPI devices structures are defined in the file stm32f4dis_spi.c.

The first device is configured for accessing the MEMS (LIS302DL motion Sensor) on SPI bus 1, using pin PE3 as the chip select.

The second SPI device is for use with the Aardvark SPI test board, which has an SPI EEPROM available. This is only intended for testing. If used, it is present on SPI bus 2 and will use pin PB14 as the SPI chip select pin.

To disable support for both the above SPI devices, the platform HAL contains an option "SPI devices" (CYGPKG_HAL_CORTEXM_STM32_STM32F4DIS_SPI) which can be disabled. No other SPI devices are instantiated.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. However, the platform I²C support can also be configured separately at `CYGPKG_HAL_CORTEXM_STM32_STM32F4DIS_I2C`. This option is present to allow use of the external Aardvark test board which has an I²C EEPROM fitted that is used for testing purposes. The option also ensures the STM32's I²C bus 1 is enabled as required.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the "STM32 Flash memory support" (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic "Flash device drivers" (`CYGPKG_IO_FLASH`) package is included in the eCos configuration.

The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32F4DISCOVERY board. However, if necessary the driver contains a configuration option "Flash size override (kb)" (`CYGNUM_DEVS_FLASH_STM32_FLASH_SIZE_OVERRIDE`) which allows the detected Flash size to be manually overriden, but this should not normally need to be changed.

A number of other aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and programburst size. Consult the driver for more details.

Name

JTAG/SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM, including the GDB stub ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M4 core of the STM32F407VG only supports six such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V2 interface.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. The architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

When using the STM32F4DISCOVERY board via the ST-LINK/V2 interface then it is recommended that the ITM stimulus port approach is used to provide access to diagnostics and instrumentation over the single USB host connection. This avoids the need for a seperate, and slower, UART connection for provision of the HAL diagnostic output, plus continuous streaming instrumentation can be output via ITM where only very small local RAM buffers would normally be available for the default “memory buffer” instrumentation support. This allows a single cable ST-LINK/V2 connection to provide board power, hardware debug support, diagnostic output and instrumentation capture features.

Normally a notable disadvantage with JTAG/SWD debugging is that it does not allow thread-aware debugging, such as the ability to inspect different eCos threads or their stack backtraces, set thread-specific breakpoints, and so on. Fortunately the Ronetix PEEDI JTAG unit does support thread-aware debugging of eCos applications, however extra configuration steps are required. Consult the PEEDI documentation for more details as usage is beyond the scope of this document.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board ST-LINK/V2 interface available via the USB CN1 connection, with the CN3 links closed to directly connect to the target STM32F407 CPU. When configuring the **openocd** tool build, the **configure** script can be given the option `--enable-stlink` to provide for ST-LINK support.

An example OpenOCD configuration file `openocd.stm32f4dis.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm32f4dis/current/misc` relative to the root of your eCos installation.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd.stm32f4dis.cfg
```

```
Open On-Chip Debugger 0.9.0 (2015-09-18-16:19)
Licensed under GNU GPL v2
For bug reports, read
    http://openocd.org/doc/doxygen/bugs.html
Info : The selected transport took over low-level target control. The results might differ compared to plain JTAG/SWD
adapter speed: 2000 kHz
adapter_nsrst_delay: 100

Info : stm32f4x.cpu: hardware has 6 breakpoints, 4 watchpoints
```

By default **openocd** provides a console on port 4444, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port 3333 for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb) monitor reset halt
target state: halted
target halted due to debug-request, current mode: Thread
xPSR: 0x01000000 pc: 0x0800422c msp: 0x20000c80
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then you will need to define a “preload” gdb macro to emit the **monitor reset halt** command to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

If the HAL diagnostics are configured to use ITM, and stimulus port 31 is configured as the HAL diagnostic destination, then the configuration example above will direct OpenOCD to direct ITM output (and also DWT and ETM) to a file named tpiu.out in the current directory of the shell which was used to run the **openocd** command. A more specific filename can be used by adjusting the OpenOCD configuration file.

To extract the ITM output, the Cortex-M architecture HAL package provides a helper program **parseitm** in the directory packages/hal/cortexm/arch/current/host relative to the root of your eCos installation. It can be compiled simply with:

```
$ gcc -o parseitm parseitm.c
```

You simply run it with the desired ITM stimulus port and name of the file containing the ITM output, for example:

```
$ parseitm -p 31 -f itm.out
```

It will echo all ITM stimulus for that port, continuing to read from the file until interrupted with Ctrl-C. Note that limited buffer space in debug hardware such as the ST-LINK can result in occasionally missed ITM data. eCosPro provides a workaround of throttling data within the CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE CDL configuration component in order to reduce or avoid lost ITM data. For further details, see the note in OpenOCD ITM support.

Similarly, if the eCos application is built with Kernel instrumentation enabled and configured for ITM output, then the default stimulus port 24 output can be captured. For example, assuming the application **cminfo** is the ELF file built from an eCos configuration with ITM instrumentation enabled, and is loaded and run via **openocd**, then we could run **parseitm** to capture instrumentation whilst the program executes, and then view the gathered data using the example **instdump** tool provided in the Kernel package.

```
$ parseitm -p 24 -f tpiu.out > inst.bin
^C
$ instdump -r inst.bin cminfo

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.stm32f4dis.cfg` file supplied in the platform HAL package should be used to setup and configure the hardware to an appropriate state to load programs.

The `peedi.stm32f4dis.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command, or in the eCosPro version of Eclipse by setting the Breakpoint Type - consult the "Eclipse/CDT for eCos application development" manual for details. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.stm32f4dis.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, and then the '**go**' command is given, the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after reset. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi.stm32f4dis.cfg` file. This conveniently allows the target to be connected to the PEEDI JTAG debugger, and be able to reset and run the resident Flash program without being required to always type '**go**' every time. Finally, it is also possible to set a temporary default (unless the PEEDI is reset) by giving an argument to the **reset** command, for example **reset run**. Use the command **help reset** at the PEEDI command prompt for more options.

Suitably configured applications can be loaded either via GDB, or directly via the telnet CLI into RAM for execution. For example:

```
stm32f4discovery> memory load tftp://192.168.7.9/test.bin bin 0x20000000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x20000000
loading at 0x20000000
loading at 0x20004000

Successfully loaded 28KB (29064 bytes) in 0.1s
stm32f4discovery> go 0x20000000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

For Eclipse users wishing to debug ROM startup programs resident in Flash, it is worth highlighting that it is possible to use the eCosCentric Eclipse plugin to automatically reprogram Flash as the load sequence. To do so, you will need to install and use a TFTP server so that your application can be accessed from the PEEDI from there. You may then use a GDB command file, as described in more detail in the "Eclipse/CDT for eCos application development" manual. This file can then contain contents similar to the following example:

```
define doload
  shell arm-eabi-objcopy -O binary /path/to/eclipse/workspace/projectname/Debug/myapp /path/to/tftp/server/area/myapp.bin
  monitor flash program tftp://10.1.1.1/myapp.bin bin 0x08000000 erase
  set $pc=0x08000000
```

```
end
```

Obviously you will need to adjust the paths and names for your system and TFTP server requirements.

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into RAM without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support this mode, it is recommended to use the `JTAG` startup type which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the `JTAG` startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel, usually a serial port. An eCosCentric extension allows diagnostic output to appear in GDB instead. For this to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. Then, after you load your application but before running it, you must give GDB the command:

```
(gdb) set hwdebug on
```

Eclipse users can do this by creating a GDB command file with the contents:

```
define postload
  set hwdebug on
end
```

Thay may then reference it from their Eclipse debug launch configuration. Using GDB command files is described in more detail in the "Eclipse/CDT for eCos application development" manual.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32F4DISCOVERY board hardware and should be read in conjunction with that specification. The STM32F4DISCOVERY platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For `ROM` and `JTAG` startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32f4dis_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM

> This is located at address `0x20000000` of the memory space, and is 128KiB in size. The eCos VSR table occupies the bottom 392-bytes. The virtual vector table starts at `0x20000188` and extends to `0x20000288`. For `ROM`, and `JTAG` startups, the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH

> This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 1MiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals

> These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32F4 Reference Manual (RM0090).

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table

> This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 98 entries is reserved due to the use of the STM32F4 processor.

hal_virtual_vector_table

> This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x20000188`.

hal_interrupt_stack

> This defines the location of the interrupt stack. For all startup types this is allocated to the top of available internal SRAM, which is normally `0x20020000`.

hal_startup_stack

> This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Diagnostic LEDs

Four LEDs are fitted on the board for diagnostic purposes:

Platform HAL manifest	Colour	Board Label
CYGHWR_HAL_STM32F4DIS_LED0	Orange	LD3
CYGHWR_HAL_STM32F4DIS_LED1	Green	LD4
CYGHWR_HAL_STM32F4DIS_LED2	Red	LD5
CYGHWR_HAL_STM32F4DIS_LED3	Blue	LD6

The platform HAL header file at <cyg/hal/plf_io.h> defines the following convenience function to allow the LEDs to be set:

```
extern void hal_stm32f4dis_led(char c);
```

The lowest 4-bits of the argument c correspond to each of the 4 LEDs (with LED0 as the least significant bit).

The platform HAL will automatically light LED0 when the platform initialisation is complete, however the LEDs are free for application use.

Flash wait states

The STM32F4DISCOVERY platform HAL provides a configuration option to set the number of Flash read wait states to use: CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the STM32F40xxx Flash programming manual (PM0081) for appropriate values for different clock speeds or voltages. The default of 5 reflects a supply voltage of 3.3V and HCLK of 168MHz.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for JTAG startup with optimization flag -O2.

Example 304.1. stm32f4dis Real-time characterization

```
            Startup, main stack : stack used    84 size  1536
             Startup : Idlethread stack used    80 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    4.13 microseconds (4 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   6

Chapter 305. STM324X9I-EVAL Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM324X9I_EVAL` — eCos Support for the STM324X9I-EVAL Board

Description

This documentation describes the platform-specific elements of the STM324X9I-EVAL board support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support. In addition ST's "STM32429I-EVAL evaluation board for the STM32F429 line" (ST User Manual id: UM1667) should be consulted for hardware setup and settings.

The board is equipped with an on-board ST-LINK/V2 hardware debugger interface (via the CN21 “USB ST-LINK” connector), which is typically used for eCos application development. Alternatively the CN13 trace and CN16 JTAG/SWD connectors are available for connecting off-board hardware debuggers.

Supported Hardware

The STM32F429NI has three main on-chip memory regions. The device has a SRAM region of 192KiB present at 0x20000000, and a 2MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution). There is another on-chip RAM region of 64KiB present at 0x10000000 that is only accessible via the CPU core. Also, the STM324X9I-EVAL motherboard has 32MiB of SDRAM memory mapped to address 0x80000000, 2MiB of SRAM memory mapped to address 0x64000000 and 16MiB of NOR-flash memory mapped to address 0x60000000.

Warning

Prior to silicon Rev3 an errata exists that precludes concurrent use of static and dynamic FMC memories. The eCos `STARTUP` type configures which RAM is used for the main application memory, and eCos does not provide any specific workaround. How the non-eCos memory is used is the domain of the application.

For example, if developing applications for silicon revisions that exhibit the problem then if the memory-mapped NOR flash is required a STARTUP selecting the off-chip PSRAM should be configured, and the off-chip SDRAM *not* accessed.

When targeting this STM324x9I-EVAL platform where an early chip revision is present then the STM32 variant option `CYGHWR_HAL_CORTEXM_STM32_F42_ERRATA_FMC_BANKSWITCH` can be enabled. This will ensure that the external NOR flash definitions are *NOT* provided for STARTUP types where SDRAM is selected for use. Alternatively the application developer is free to leave this `ERRATA` option disabled and use run-time logic to ascertain the chip revision from the relevant I/O registers. The application code can then allow NOR flash access as appropriate.

The STM32 variant HAL includes support for the eight on-chip serial devices which are documented in the variant HAL. However, the STM324X9I-EVAL motherboard only provides a single standard DB9 UART connector CN8.

The STM32 variant HAL also includes support for the I²C buses. A single I²C device is instantiated as part of the platform port, which is for the STMPE811 touch-panel sensor connected via bus I²C1. It is exported to `<cyg/io/i2c.h>` with the name `hal_stm324x9i_eval_touchpanel` in the normal way.

Similarly the STM32 variant HAL includes support for the SPI buses. Though the evaluation board does not provide any SPI devices as standard.

USB host and peripheral modes are supported on both the FS OTG1 (connector CN14) and HS OTG2 (connector CN9) controllers available on the evaluation board. The HS OTG2 controller support is currently limited to use at FS speed only. Consult the STM32 variant HAL documentation for USB driver details.

Note

The evaluation board does not support the use of the FS OTG2 (connector CN15) without a hardware modification detailed in the ST evaluation board user manual.

Device drivers are also provided for the STM32 on-chip Ethernet MAC, ADC, BXCAN and SDIO interfaces. Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

Note

The STM32 variant HAL support for the SDIO interface is currently limited to supporting MMC/SD cards. If the multi-bit MMC/SD support is used it is recommended that on-chip SRAM transfer buffers are used to avoid RX overrun or TX underrun due to the slow external SDRAM access speed.

The STM32F4 processor and the STM324X9I-EVAL board provide a wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3e, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.23.2.

Name

Setup — Preparing the STM324X9I-EVAL Board for eCos Development

Overview

Typically, since the STM324X9I-EVAL motherboard has a built-in ST-LINK/V2 interface providing hardware debug support, eCos applications are loaded and run via the debugger **arm-eabi-gdb** or via the Eclipse IDE. The debugger then communicates with the “GDB server” provided by the relevant host ST-LINK/V2 support tool being used (e.g. OpenOCD).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from on-chip SRAM, or where all of the SRAM and SDRAM is required for application run-time use.

If off-chip non-volatile memory (NVM) is used to hold the main application then the board can boot from the internal flash using the BootUp ROM loader. This BootUp code will then start the main application (after an optional update sequence).

If required, it is still possible to program a GDB stub or RedBoot `ROM` image into on-chip Flash and download and debug via the serial UART (CN8). In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. By default for serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed in the eCos configuration used for building the GDB stub `ROM` image.

Preparing ST-LINK/V2 interface

The support for using the on-chip ITM stimulus ports for diagnostic and instrumentation output requires that the ST-LINK/V2 firmware is at least version `V2.J17.S0`. The firmware for the ST-LINK/V2 interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file). For example, the following OpenOCD output reports `JTAG v23`:

```
Info : STLINK v2 JTAG v27 API v2 SWIM v0 VID 0x0483 PID 0x3748
```

Unfortunately the official firmware updater is only available for the Windows platform at the moment. From a Windows machine:

1. Ensure that the Windows PC and STM324X9I-EVAL board are disconnected.

2. Download the STM32 ST-Link USB driver from ST's website.

   The page titled “ST-Link, ST-Link/V2, ST-Link/V2-1 USB driver signed for XP, Windows7, Windows8” provides the driver download http://www.st.com/content/st_com/en/products/embedded-software/development-tool-software/stsw-link009.html

3. Install the ST-Link USB driver on your Windows PC, by simply unzipping the downloaded file and running the installer contained within.

4. Download the STM32 ST-LINK Utility from ST's website.

   The page titled “STSW-LINK004 STM32 ST-LINK utility” provides the download of the utility http://www.st.com/web/en/catalog/tools/PF258168

5. Install the ST-LINK Utility software on your Windows PC. This is achieved by simply unzipping the downloaded file `stsw-link004.zip` and running the `STM32 ST-LINK Utility_vX.X.0.exe` that was contained within it. Follow the on-screen instructions.

6. Connect the STM324X9I-EVAL board to the PC.

   Connect the STM324X9I-EVAL board to the PC using the ST supplied USB-B cable. Windows should correctly identify the USB device and load the device driver. Windows Device Manager should now show “STMicroelectronics STLink dongle” under “Universal Serial Bus controllers”.

7. Run the ST-LINK Utility and ensure the ST-LINK firmware is up to date.

   From the Windows “Start” menu run the “STM32 ST-LINK Utility”. Click on the `connect` icon, or select `Target->Connect` from the menu. This should confirm that a successful connection can be made to the board. To update the on-board ST-LINK/V2 firmware select `ST-LINK->Firmware Update` from the menu. In the ST-LINK dialog box that then appears click on the `Device Connect` button. This will likely result in a message “ST-Link is not in DFU mode. Please restart it.”. In this case simply disconnect the board from the PC, power cycle the board and then reconnect it after a couple of seconds. Click the `OK` button on the message. In the original ST-Link dialog box click `Device Connect` again. The dialog box should now report the current on-board and available firmware versions, and enable you to upgrade the board by pressing the `Yes >>>>` button. We have tested the system with firmware version `V2.J17.S0` and would recommend this version as a minimum. Clicking `Yes >>>>` will cause a progress bar in the dialog to be animated and should eventually result in a “Update Successful” message. You can then close the various dialogs and exit the ST-LINK Utility. Disconnect and power-cycle the board. Reconnect the board and it is now ready for use with OpenOCD.

Programming ROM images

Since the STM324X9I-EVAL board has a built-in ST-LINK/V2 SWD interface, the USB host connection (CN21) and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash.

The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

Note

The **openocd** command being used should have been configured and built to support the ST-LINK/V2 interface. This is achieved by specifying the **--enable-stlink** when configuring the OpenOCD build. Additional information on running **openocd** may be found in the OpenOCD notes.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the “bootup.elf” application into the on-chip flash:

```
$ arm-eabi-gdb install/bin/bootup.elf
GNU gdb (eCosCentric GNU tools 4.7.3c) 7.6.1
[ … GDB output elided … ]
(gdb) target remote localhost:3333
hal_reset_vsr () at path/hal_misc.c:171
(gdb) load
Loading section .rom_vectors, size 0x14 lma 0x8000000
Loading section .text, size 0x3adc lma 0x8000018
Loading section .rodata, size 0x6c0 lma 0x8003af8
Loading section .data, size 0x6dc lma 0x80041b8
Start address 0x8000018, load size 18572
Transfer rate: 14 KB/sec, 4643 bytes/write.
(gdb)
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a command-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM324X9I-EVAL board platform HAL package is loaded automatically when eCos is configured for the `stm32429i_eval` or `stm32439i_eval` targets. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM324X9I-EVAL board platform HAL package supports six separate startup types:

ROM

> This startup type can be used for finished (stand-alone) applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into external SDRAM starting from 0x80000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

ROMAPP

> This startup type can be used for finished applications which will be programmed into internal (on-chip) flash at the configured offset from location (0x08000000+`CYGIMP_BOOTUP_RESERVED`), and started via a suitably configured BootUp ROM loader. Data and BSS will be put into internal SRAM. The application will be self-contained with no dependencies on services provided by other software.

ROMINT

> This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x20000288. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.
>
> The off-chip SDRAM memory from 0x80000000 and off-chip SRAM memory from 0x64000000 are available, but are not referenced by the eCos run-time so are available for application use if required.

JTAG

> This is the startup type used to build applications that are loaded via the hardware debugger interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x80000000 and entered at that address. eCos startup code will perform all necessary hardware initialization, though since the application is loaded via the hardware debugger interface the host debug environment is responsible for configuring the necessary I/O state to initialise the off-chip SDRAM.
>
> This is the startup type normally used during application development, since the large SDRAM memory space allows for larger debug applications where compiler optimisation may be disabled, and run-time assert checking enabled.
>
> ### Note
>
> Executing code from the SDRAM memory has a performance downside. It is significantly slower than execution from on-chip SRAM or flash. If performance is an issue then hardware debugging can be used for any of the startup types if required.

SRAM

This is a variation of the JTAG type that only uses internal memory. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000288 and entered at that address. eCos startup code will perform all necessary hardware initialization. Unlike the JTAG startup no explicit hardware debugger configuration is needed, since the application (like the ROM and ROMINT startup types) will initialise the off-chip SDRAM memory.

SRAMEXT

This is a variation of the JTAG type that uses the external SRAM memory from 0x64000000.

RAM

For the ST-LINK/V2 enabled STM324X9I-EVAL platform this startup type is unlikely to be used. It is provided for completeness.

When the board has RedBoot (or a GDB stub ROM) programmed into internal Flash at location 0x08000000 then the arm-eabi-gdb debugger can communicate with the relevant UART connection to load and debug applications. An application is loaded into memory from 0x80008000. It is assumed that the hardware has already been initialized by RedBoot. By default the application will not be stand-alone, and will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a `RAM` startup, disabled otherwise. It can be manually disabled for a `RAM` startup, making the application self-contained, as a testing step before switching to `ROM` startup.

Note

Though, as previously discussed, since the option of hardware debugging is available as standard on the STM324X9I-EVAL platform it is unlikely that the `RAM` startup type would be used for development.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

No SPI devices are instantiated for this platform by default.

Note

An example SPI M25PXX configuration can be enabled for boards suitably modified with an attached compatible flash device. The CDL option `CYGPKG_HAL_CORTEXM_STM32_STM324X9I_EVAL_SPI1_FLASH` can be enabled, and uses SPI bus 1 with the chip-select on PA4.

When configured the `m25pxx_flash_device` device is exported and can be accessed via the standard flash API. The device is given a logical base address of `0x00000000` but is *not* memory-mapped.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. Since the platform uses an I²C bus 1 based I/O expander the I²C support is always enabled. The STMPE811 touch-panel device is instantiated and becomes available for applications from `<cyg/io/i2c.h>`.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM324X9I-EVAL platform HAL enables the support for the devices ADC1, ADC2 and ADC3 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

CAN Driver

The STM32 has a dual BXCAN device for CAN support. This consists of a master device, BXCAN1, and a slave device, BXCAN2. If BXCAN2 is to be used, BXCAN1 must be powered and clocked, regardless of whether it is to be used for CAN traffic. BXCAN1 is the only device connected to an external D-Sub socket at CN22. It shares an IO pin with the OTG FS controller. JP16 controls connection of CAN1_RX to PA11. By default this jumper is not fitted, so one must be fitted to enable BXCAN1. Additionally, the OTG_FS1 connector at CN14 cannot now be used and must be left unconnected. This means that the OTG_FS USB controller and CAN cannot be used concurrently.

Consult the generic CAN driver API documentation in the eCosPro Reference Manual for further details on CAN support in eCosPro, along with the documentation and configuration options in the BXCAN device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic “Flash device drivers” (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM324X9I-EVAL board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

Name

SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M4 core of the STM32F429ZI only supports six such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V2 interface.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. The architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

However, when using the STM324X9I-EVAL board via the ST-LINK/V2 interface then it is recommended that the `gdb_hwdebug_fileio` approach is used to provide access to diagnostics via the GDB debug connection. When ITM support is used it has been observed that the ST-LINK/V2 firmware can drop data, leading to the possibility of confusing output. However, with care the ITM system can be tuned to provide diagnostic and instrumentation via the host SWD debugger.

Using the ST-LINK/V2 connection allows for a single cable to provide power (JP12), hardware debug support and diagnostic output.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board ST-LINK/V2 interface available via the USB CN21 connection. When configuring the **openocd** tool build, the **configure** script can be given the option `--enable-stlink` to provide for ST-LINK support.

An example OpenOCD configuration file `openocd.stm324x9i_eval.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm324x9i_eval/current/misc` relative to the root of your eCos installation.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd.stm324x9i_eval.cfg
Open On-Chip Debugger 0.9.0 (2015-09-18-16:19)
Licensed under GNU GPL v2
For bug reports, read
    http://openocd.org/doc/doxygen/bugs.html
Info : The selected transport took over low-level target control. The results might differ compared \
       to plain JTAG/SWD
```

```
adapter speed: 2000 kHz
adapter_nsrst_delay: 100
none separate
Info : Unable to match requested speed 2000 kHz, using 1800 kHz
Info : Unable to match requested speed 2000 kHz, using 1800 kHz
Info : clock speed 1800 kHz
Info : STLINK v2 JTAG v17 API v2 SWIM v0 VID 0x0483 PID 0x3748
Info : using stlink api v2
Info : Target voltage: 2.886506
Info : stm32f4x.cpu: hardware has 6 breakpoints, 4 watchpoints
```

By default **openocd** provides a console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then see the “eCos Hardware Debugging” section of the “eCosPro CDT plug-in user's guide” document's “Debugging eCos applications” chapter.

If the HAL diagnostics are configured to use ITM, and stimulus port 31 is configured as the HAL diagnostic destination, then the configuration example above will direct OpenOCD to direct ITM output (and also DWT and ETM) to a file named `tpiu.out` in the current directory of the shell which was used to run the **openocd** command. A more specific filename can be used by adjusting the OpenOCD configuration file.

To extract the ITM output, the Cortex-M architecture HAL package provides a helper program **parseitm** in the directory `packages/hal/cortexm/arch/current/host` relative to the root of your eCos installation. It can be compiled simply with:

```
$ gcc -o parseitm parseitm.c
```

You simply run it with the desired ITM stimulus port and name of the file containing the ITM output, for example:

```
$ parseitm -p 31 -f itm.out
```

It will then echo all ITM stimulus for that port, continuing to read from the file until interrupted with Ctrl-C. Note that limited buffer space in debug hardware such as the ST-LINK can result in occasionally missed ITM data. eCosPro provides a workaround of throttling data within the `CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE` CDL configuration component in order to reduce or avoid lost ITM data. For further details, see the note in OpenOCD ITM support.

Similarly, if the eCos application is built with Kernel instrumentation enabled and configured for ITM output, then the default stimulus port 24 output can be captured. For example, assuming the application **cminfo** is the ELF file built from an eCos configuration with ITM instrumentation enabled, and is loaded and run via **openocd**, then we could run **parseitm** to capture instrumentation whilst the program executes, and then view the gathered data using the example **instdump** tool provided in the Kernel package.

```
$ parseitm -p 24 -f tpiu.out > inst.bin
^C
$ instdump -r inst.bin cminfo

```

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into SRAM or SDRAM without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support this mode, it is recommended to use the JTAG startup type which will implicitly cause two important settings to change. Firstly, CYGSEM_HAL_USE_ROM_MONITOR must be disabled. Secondly the CYGDBG_HAL_DIAG_TO_DEBUG_CHAN option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the JTAG startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. An eCosCentric extension allows diagnostic output to appear in GDB. For this feature to work, you must enable the configuration option CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN in the common HAL package.

For details of using hardware debug with the Eclipse IDE see the “eCos Hardware Debugging” section of the “eCosPro CDT plug-in user's guide” manual.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM324X9I-EVAL board hardware, and should be read in conjunction with that specification. The STM324X9I-EVAL platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For `ROM`, `ROMINT`, `SRAM`, `JTAG` and `SRAMEXT` startup types the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm324x9i_eval_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. For all the STARTUP variations the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of the on-chip SRAM are reserved for the interrupt stack. The remainder of the internal SRAM is available for use by applications. The key memory locations are as follows:

Internal RAM

> This is located at address `0x20000000` of the memory space, and is 192KiB in size. The eCos VSR table occupies the bottom 392 bytes of memory, with the virtual vector table starting at `0x200001AC` and extending to `0x200002AC`.
>
> For all configurations there is also a block of (close-coupled) SRAM located at address `0x10000000` of the memory space, and 64KiB in size.

External SDRAM

> This is located at address `0x80000000` of the memory space, and is 32MiB long. For `ROM` applications, all of the SDRAM is available for use. For `JTAG` applications the application is loaded from `0x80000000` with the remaining SDRAM after the code+data available for application use.
>
> For `RAM` startup applications, SDRAM below `0x80008000` is reserved for the debug monitor (e.g. RedBoot).

External SRAM

> This is located at address `0x64000000` of the memory space, and is 2MiB long. For `SRAMEXT` applications, all of the external SRAM is available for use.

Internal FLASH

> This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 2048KiB in size. `ROM` and `ROMINT` applications are by default configured to run from this memory.

External FLASH

> This is located at address `0x60000000` of the memory space. This region is 16MiB in size.

On-Chip Peripherals

These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 98 entries is reserved.

hal_virtual_vector_table
This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x200001AC`.

hal_interrupt_stack
This defines the location of the interrupt stack. This is allocated to the top of internal SRAM, `0x20030000`.

hal_startup_stack
This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

I/O expander

If the `CYGPKG_KERNEL` is configured then a "helper" thread is created to handle forwarding of signals received by the I²C bus 1 based STMPE1600 I/O expander as eCos interrupts. The design approach minimises the overall system ISR latency which would occur if the I²C was directly accessed from the system ISR processing, at the cost of deferring the demultiplexing of the I/O expander interrupt source.

Device drivers and applications can access the signals using the same APIs as for standard STM32 GPIO lines, with respect to attaching interrupt handlers or examining/setting pin state.

Note

The priority of the `ioexp_helper_thread()` should be configured as high as possible, to minimise the latency in forwarding the de-multiplexed "virtual" interrupt sources to the relevant device driver (e.g. Ethernet PHY status change).

Diagnostic LEDs

Four LEDs are fitted on the board for diagnostic purposes and are labelled LD1 (green), LD2 (orange), LD3 (red) and LD4 (blue).

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow the LEDs to be set:

```
extern void hal_stm324x9i_eval_led(char c);
```

The lowest 4-bits of the argument `c` correspond to each of the 4 LEDs (with LED0 as the least significant bit).

Table 305.1. LEDs

eCos LED GPIO manifest	STM32F4 GPIO	Bit number	Board label	Colour
`CYGHWR_HAL_STM324X9I_EVAL_LED0`	`PG6`	`0`	`LD1`	Green
`CYGHWR_HAL_STM324X9I_EVAL_LED1`	`PG7`	`1`	`LD2`	Orange
`CYGHWR_HAL_STM324X9I_EVAL_LED2`	`PG10`	`2`	`LD3`	Red

eCos LED GPIO manifest	STM32F4 GPIO	Bit number	Board label	Colour
CYGHWR_HAL_STM324X9I_EVAL_LED3	PG12	3	LD4	Blue

The platform HAL will automatically light LED0 when the platform initialisation is complete, however the LEDs are then free for application use.

Note

If the CDL option CYGPKG_HAL_CORTEXM_STM32_STM324X9I_EVAL_SPI1_FLASH is configured (for example, as is the case for the modified “drb” platform with externally attached SPI flash) then the HAL_PLF_DEVS_DISK_MMC_FEEDBACK macro is defined by the platform plf_io.h to provide MMC/SD card access feedback using the CYGHWR_HAL_STM324X9I_EVAL_LED3 (blue) LED.

Flash wait states

The STM324X9I-EVAL platform HAL provides a configuration option to set the number of Flash read wait states to use: CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the STM32 Flash programming manual (PM0081) for appropriate values for different clock speeds or voltages. The default of 5 reflects a supply voltage of 3.3V and HCLK of 168MHz.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for SRAM startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 305.1. stm324x9i_eval Real-time characterization

```
             Startup, main thrd : stack used   344 size  1536
             Startup : Idlethread stack used    84 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    5.00 microseconds (5 raw clock ticks)

Testing parameters:
   Clock samples:            32

Name

Test Programs — Details

Test Programs

The STM324X9I-EVAL platform HAL contains some test programs which allow various aspects of the board to be tested.

Manual Test

The **manual** test is not built by default. The configuration option `CYGPKG_HAL_CORTEXM_STM32_STM324X9I_EVAL_TESTS_MANUAL` should be enabled to allow the test to be built.

This program tests various aspects of the basic platform port, e.g. flashing LEDs, checking I²C device access and that the push-button GPIO operates.

SPI Flash Test

The **m25pxx1** test is not built by default, since the standard (unmodifed) STM324x9I-EVAL platform does not provide a suitable SPI flash device. The configuration option `CYGPKG_HAL_CORTEXM_STM32_STM324X9I_EVAL_SPI1_FLASH` should be enabled to allow the test to be built if a suitably modified board is being used.

This program tests the M25Pxx compatible serial flash connected to SPI bus 1. It erases, programs and reads a number of sectors in the flash, and should therefore not be run if the flash contains data that should be retained. The `CYGPKG_IO_FLASH` package must be present to allow this test to be built.

ADC Test

The **adc1** program tests the ADC driver for the STM32. The only device connected to the ADC on the board is the potentiometer connected to ADC3 logical channel 8, named RV1 “ADC channel PF10” on the motherboard. Therefore this test primarily tests that. However, in addition it also report the values of the Vrefint and Vbat+Temp inputs that are sourced on-chip. The option `CYGBLD_HAL_CORTEXM_STM324X9I_EVAL_TEST_ADC` must be enabled to run this test since it needs human interaction.

Name

BootUp Integration — Detail

BootUp

The BootUp support for the STM324x9I-EVAL target is primarily implemented in the `stm324x9i_eval_support.c` file. The majority of the functions provided by that source file are only included when the `CYGPKG_BOOTUP` package is being used to construct the actual BootUp ROM loader binary.

The BootUp code is designed to be very simple, and it is envisaged that once its implementation has been tested and validated, the binary will only need to be installed onto a device once. Its only purpose is to allow the safe updating and startup of the main application. If the BootUp code ever needs to be replaced then it is a “factory” operation, for example using JTAG/SWD to reprogram the on-chip flash.

This platform specific documentation should be read in conjunction with the generic BootUp package and bundle image support documentation.

The BootUp package provides a basic but fully functional implementation for the platform. This has been tested to ensure that the underlying mechanism is sound. It is envisaged that the developer will customize and further extend the platform side support to meet their specific application update requirements.

BootUp loaded applications

Applications started via the BootUp loader, since they cannot include the `CYGPKG_BOOTUP` package themselves, may need access to some related configuration state. The platform is responsible for providing such “common” information. For example, the CDL option `CYGIMP_BOOTUP_RESERVED` specifies the amount of on-chip flash set aside for BootUp. Applications can then ensure that they do not interfere with the BootUp loader if using the remaining on-chip flash for their own purposes.

Warning

Care must be taken to ensure that the target application configuration matches the BootUp configuration, since it is normally expected that the applications to be loaded will be independent of the initial BootUp build environment. This includes the fundamental on-chip flash space set aside for the BootUp ROM loader code (`CYGIMP_BOOTUP_RESERVED`) as well as, when using `CYGPKG_BUNDLE` support, where the bundle image is located (selected Non-Volatile Memory (NVM) and offset/partition information). It is expected that such values, for a particular platform instance, will be *fixed* at a suitable point during development, and definitely before products are shipped. It is the responsibility of the developer to ensure a consistent configuration between the BootUp ROM loader and any applications that may be installed/started by that BootUp code.

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function for BootUp, and applications started by BootUp, to ascertain the configured off-chip bundle/update location:

```
extern struct cyg_flash_dev *hal_stm324x9i_eval_source_flash( cyg_flashaddr_t *pbase,
                                                              cyg_flashaddr_t *plimit );
```

The function will return a pointer to the relevant flash device. The passed *`pbase`* parameter is a pointer to the value to be filled with the base address for the image (or `NULL` if the value is not needed by the caller). Similarly the *`plimit`* parameter is a pointer to the value to be filled with the limiting address for any image, or `NULL` if the address is not needed.

Primarily to avoid source duplication, the `hal_stm324x9i_eval_source_flash()` function provides common run-time access to the settings derived from the CDL options `CYGIMP_BOOTUP_STM324X9I_EVAL_SOURCE`, `CYGNUM_BOOTUP_STM324X9I_EVAL_SOURCE_OFFSET` and `CYGNUM_BOOTUP_STM324X9I_EVAL_SOURCE_LIMIT`.

Bundle based applications

When the CDL option `CYGIMP_BOOTUP_STM324X9I_EVAL_BUNDLE` is enabled, the STM324x9I-EVAL platform BootUp code incorporates the `CYGPKG_BUNDLE` package and support for bundle based application distribution.

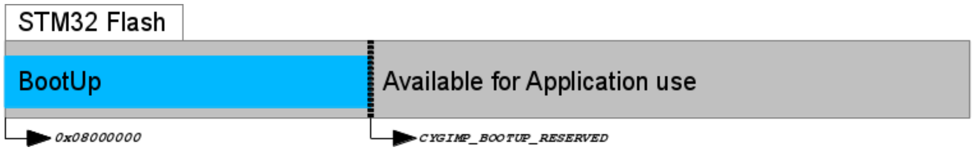
The current STM324x9I-EVAL platform BootUp bundle support is limited (by design) to starting SDRAM based applications. i.e. `CYG_HAL_STARTUP_JTAG` startup type. This has implications for early EVAL hardware containing parts that suffer from the FMC errata since that precludes the use of the off-chip PSRAM and NOR memories when targetting SDRAM for main application code+data.

Note

The (slightly misleading) `JTAG` startup type name is used for standalone SDRAM based applications for historical reasons. The `RAM` startup name is assumed by some systems to refer to an application that relies on the presence of a debug monitor. BootUp is purely a “loader” and does *NOT* provide GDB stubs, so cannot support `CYG_HAL_STARTUP_RAM` applications.

The platform HAL and `CYGPKG_BUNDLE` package provide a common set of routines shared by both BootUp and applications. This ensures that all bundle operations are carried out in a compatible and consistent manner.

Figure 305.1. On-chip flash



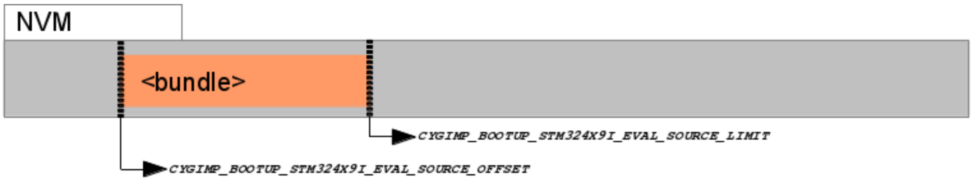
BootUp `ROMINT` application in on-chip flash

On startup the BootUp loader will use the `hal_stm324x9i_eval_source_flash()` function to ascertain the NVM memory used to hold the source bundle image. If a valid bundle image is found, then the configured “main application” item tag as specified by the CDL option `CYGNUM_BOOTUP_STM324X9I_EVAL_BUNDLE_TAG` is searched for within the bundle. If a valid matching tag item is found, then the data from that item is loaded into SDRAM and executed.

Note

This simple approach of using a fixed, pre-allocated, area for holding the bundle image simplifies the BootUp (and similarly any main application based update) code without the issues that would need to be considered if the bundle was stored in a filesystem. e.g. a JFFS2 filesystem on the SPI flash, with potentially slow JFFS2 mount performance, inability to ascertain how much “true” free space is available on the filesystem, programmatic support for deletion of “data” to free space for a bundle as part of an update, etc. The normal “lifetime” cycles of NOR flash (e.g. S25FL256S) should be more than sufficient for the “limited” number of in-field updates that may be undertaken on a specific board over its lifetime.

Figure 305.2. NVM bundle



<bundle>
NVM
CYGIMP_BOOTUP_STM324X9I_EVAL_SOURCE_LIMIT
CYGIMP_BOOTUP_STM324X9I_EVAL_SOURCE_OFFSET

Main application held in bundle stored in NVM

If a valid bundle exists and contains a valid `CYGNUM_BOOTUP_STM324X9I_EVAL_BUNDLE_TAG` item, then the BootUp loader will always start that application. The BootUp loader itself does NOT perform any update revision based automatic update support. That support is entirely within the domain of the started application program, which is responsible for all system update decisions and processing.

The only case where BootUp will initiate a system update is when a bundle is not present or is invalid, or when an otherwise valid bundle doesn't contain a valid `CYGNUM_BOOTUP_STM324X9I_EVAL_BUNDLE_TAG` item. In this case BootUp will attempt to install a bundle from external media. The current example implementation uses a FATFS formatted SD Card for this purpose.

Note

A beneficial side-effect of this approach is that it can help simplify the board production process. Boards only need to be pre-initialized with the stable BootUp binary, which can then be used to install the latest application firmware in NVM.

The example BootUp bundle support provided for this platform expects a single release bundle to be stored in the root directory of an inserted FATFS SD Card. The first file found that matches the `CYGDAT_BOOTUP_STM324X9I_EVAL_BUNDLE_PREFIX` prefix is used. Any filename text after the prefix is ignored and can contain human-readable or customer specific identification information as required. For example, assuming `CYGDAT_BOOTUP_STM324X9I_EVAL_BUNDLE_PREFIX` is configured as `“MyProductName_”`, then files named `MyProductName_1.02`, `MyProductName_1.03.B99.1234`, `MyProductName_example.bin` would all be matched.

The SD Card FATFS filesystem is mounted read-only, so any interrupted update operations (e.g. loss-of-power, reset condition) should not affect the “validity” of the FATFS filesystem held on the SD Card.

Since only a single bundle image is held in the SPI flash there is a chance for the SPI flash based bundle to be in a “corrupt” state if an update fails (power-loss, CPU reset, etc.) during an active update. However, since an update is only manually started when a validated image is available on an SDcard, if the update is interrupted the same SDcard (and field-engineer/operator) should be available to re-apply the update on the system restart. This avoids the (normal) “robustness” requirement of providing two application images to be held in the SPI flash to ensure “safe” updates.

To reiterate, the BootUp code will *ONLY* perform an update from an SD Card to the NVM when there is *NO* valid main application bundle/item pair (missing or corrupted). For in-field upgrades any update process will be instigated under the control of the BootUp started “main application”. For example, the application could use the `CYGPKG_BUNDLE` API to validate a bundle image from whatever source it has access to, and then to update the relevant NVM image itself. If the update is provided on an SD Card then (after ensuring the SD Card does contain a valid bundle image) the main application just needs to invalidate the current NVM bundle image, and then force a CPU reset to have BootUp detect the now invalid main application and apply the update. It is up to the developer to decide the best approach for their particular needs in how point-revision updates are installed, and is beyond the scope of this documentation.

The bundle implementation currently limits the number of automatic update attempts when a missing/invalid bundle is detected. This is a deliberate choice to avoid continually failing attempts that could eventually wear out a flash device. The platform `hal_stm324x9i_eval_badapp()` function implementation, when bundle support is configured, will reset the system to allow another restart attempt if the “Tamper/Key” (`CYGHWR_HAL_STM324X9I_EVAL_BUTTON_USER`) button is pressed for more than one second. This can be used to manually force another “automatic” update attempt to be started.

When BootUp has installed a bundle to the SPI flash, the last 4-bytes of the SPI flash area (partition) set aside for the bundle will be erased to 0xFFFFFFFF. This location and value can be used by the customer main application to ascertain that an install/update has just been performed (since sector erase will only occur as part of a bundle install/update). It is the responsibility of the main application to update this single location (clearing at minimum 1-bit) if it wants to track “post update” state. This can by used by the main application to acknowledge the update, and can ensure, for example, that any (potentially slow) “post update” main application specific functionality is not performed on every normal startup. For example, the main application may need to check and update the software components of attached daughter-boards from the bundle, and can use this mechanism to ensure it is only performed *once* after an update. This simple (erased flash) mechanism avoids complicated support for passing non-volatile “log” information between the seperate BootUp and main application worlds.

Note

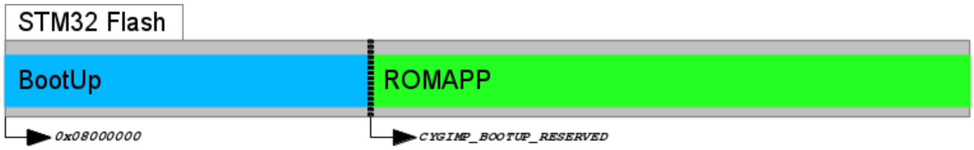
The main application should *NOT* use bit 31 of this field (treating the 32-bit value as being stored in little-endian format) since it is reserved as a flag for the BootUp loader update processing. The main application should *ALWAYS* leave bit 31 set.

On-Chip ROMAPP applications

If the CDL option `CYGIMP_BOOTUP_STM324X9I_EVAL_BUNDLE` is not enabled, then BootUp provides an alternative mechanism that supports the safe update of on-chip flash resident (`CYG_HAL_STARTUP_ROMAPP`) applications.

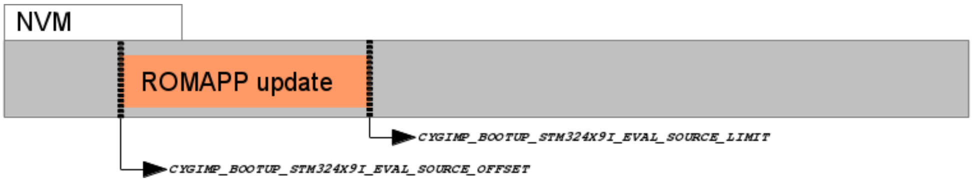
Updates using this mechanism are initiated and directed solely by the application itself. The application is responsible for locating, acquiring and verifying a new update, and placing it into NVM storage. If BootUp detects a verified update in NVM, it installs the update into the on-chip flash, overwriting and replacing the existing application. The updated application is then executed.

Figure 305.3. BootUp and Application



BootUp `ROMINT` loader and `ROMAPP` main application held in on-chip flash

Figure 305.4. Application Update image



NVM
ROMAPP update
CYGIMP_BOOTUP_STM324X9I_EVAL_SOURCE_LIMIT
CYGIMP_BOOTUP_STM324X9I_EVAL_SOURCE_OFFSET

Update for `ROMAPP` main application held in NVM

The example implementation uses a simple scheme that checks a fixed-format contiguous structure near the start of the binary application image file. Other than the fields used to identify the structure, the BootUp code does not interpret the hal_stm324x9i_eval_bootup_structure_t structure `identity` field.

Depending on how the alternative (pending update) application is downloaded and installed in the NVM, it may be more relevant to have the `tail` marker at the very end of the binary image. The developer may wish to update the build/release process so that the actual binary length is held in the application description structure, since that could avoid the overhead of unnecessary flash reads and writes when processing updates. Similarly, instead of a simple binary number being used to differentiate application images, the choice may be made to use the 64-bit UTC timestamp the application was created, or a human-readable string as the unique identification for a release. It is the responsibility of the build/release engineer to ensure individual releases are uniquely identifiable.

It is *critical* that the main application, when storing a pending update, stores the `tail` marker as the last bytes written. It is the responsibility of the main application to verify the data written, prior to placing the `tail` marker. This ensures that a partial image is not treated as a valid update. For example the sequence undertaken by the main application would be:

Table 305.2. Pending update sequence

Operation	**Details**
Invalidate “previous” alternative image	At a minimum ensure an invalid signature `tail` marker is written. Erasing the flash is normally required anyway, and would invalidate any previous image.

Operation	Details
Receive update application image and write to alternative image location	NOT writing the `tail` marker. The code that stores the application should leave a “hole” where the `tail` marker resides to ensure a partial image is not incorrectly treated as valid
Verify downloaded contents	e.g. CRC or binary comparison. Normally this would be done as individual application chunks are downloaded and written to the alternative storage
Write `tail` marker	This is the very last operation after validating that the alternative image has been stored correctly. If an error has occured during the download then not-writing the `tail` ensures that the BootUp loader will not interpret the data written as a pending update
Force system RESET to start update	e.g. using the `HAL_PLATFORM_RESET` macro

The BootUp loader code will only READ from the alternative image location. This ensures that if an in-progress update is interrupted (e.g. power-loss) then when the system restarts the BootUp code will restart the application update as required.

If the BootUp platform implementation for validating the alternative image is extended to include a CRC, or similar “slow” processing, it may be worth considering whether the main application on startup will always invalidate the `tail` marker after an update to avoid subsequent system resets having to re-validate the alternative image prior to discovering that it is the same as the current main application.

Note

We cannot have the SIGNATURE support purely conditional on the BOOTUP support; since non-BOOTUP applications need to be built leaving the space. For the moment this is only enforced for ROMAPP applications, since that is all that the simple (non-BUNDLE) BootUp update support implements.

Building BootUp

The `ROMINT` startup type is chosen for BootUp so that the loader uses the on-chip SRAM for its workspace, to avoid the overhead of managing off-chip memory where the target application will be loaded.

Example eCos configuration templates for BootUp are provided in the `misc` directory of the release. The `hostboot_ROMINT.ecm` configuration file can be used to construct a bundle based BootUp loader and `bootup_ROMINT.ecm` for the simpler on-chip ROMAPP update BootUp loader.

Building a BootUp ROM image is most conveniently done at the command line. For the `stm32429i_eval_drb` (SPI modified board), the steps needed to rebuild the bundle based ROMINT version of BootUp on linux are:

```
$ mkdir hostboot_romint
$ cd hostboot_romint
$ ecosconfig new stm32429i_eval_drb minimal
[ … ecosconfig output elided … ]
$ ecosconfig import \
  $ECOS_REPOSITORY/hal/cortexm/stm32/stm324x9i_eval/current/misc/hostboot_ROMINT.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The steps needed to rebuild the bundle based ROMINT version of BootUp on Windows within the Shell Environment are

```
C:\Users\demo> mkdir hostboot_romint
C:\Users\demo> cd hostboot_romint
C:\Users\demo\hostboot_romint> ecosconfig new stm32429i_eval_drb minimal
[ … ecosconfig output elided … ]
C:\Users\demo\hostboot_romint> ecosconfig import \
  %ECOS_REPOSITORY%/hal/cortexm/stm32/stm324x9i_eval/current/misc/hostboot_ROMINT.ecm
C:\Users\demo\hostboot_romint> ecosconfig resolve
C:\Users\demo\hostboot_romint> ecosconfig tree
C:\Users\demo\hostboot_romint> make
```

The resulting `install/bin/bootup.bin` binary can then be programmed into the on-chip flash from address `0x08000000`.

It is expected that the BootUp binary is installed onto the STM32F427 on-chip flash either via JTAG/SWD or by utilising the on-chip `BootROM` USB based DFU process. This is a factory or in-field process requiring specific equipment/host-software.

Once BootUp is installed it is not normally expected to require updating. Its purpose is to bootstrap the main application, and provide a standard mechanism for installing the main application. The update mechanism does *NOT* provide a method for updating the BootUp loader itself. If in-field updates of the BootUp binary are necessary, this could be achieved via the STM32 on-chip `BootROM` USB based DFU process.

BootUp Test Programs

The `tests/bundle_example.c` source implements a simple example of an application that utilises the `CYGPKG_BUNDLE` package. Its code could serve as a useful starting point when adding bundle update support to your own application.

Normally a standard `CYG_HAL_STARTUP_JTAG` configured build of the **bundle_example** would be used. If the **bootup** application is used to bootstrap the processor and is built as described in Building BootUp, the eCos Configuration against which **bundle_example** is linked must also include “CRC Support” (`CYGPKG_CRC`), “Zlib compress/decompress support” (`CYGPKG_COMPRESS_ZLIB`), “File IO” (`CYGPKG_IO_FILEIO`) and “Generic FLASH memory support” (`CYGPKG_IO_FLASH`). The “ST STM32 SPI bus 1 option” (`CYGHWR_DEVS_SPI_CORTEXM_STM32_BUS1`) must also be enabled.

As well as ensuring the required packages are present in the configuration, the CDL option `CYGBLD_HAL_CORTEXM_STM324X9I_EVAL_TESTS_MANUAL`, and its sub-option `CYGBLD_HAL_CORTEXM_STM324X9I_EVAL_TEST_BOOTUP`, should be enabled to allow **bundle_example** to be built.

Note

If required, the release provides an example “default” template for the `stm32429i_eval_drb` platform in the `misc/bundle_example.ecm` file which includes all the necessary packages and defines the necessary options. This can be imported to a configuration (using either the command-line **ecosconfig import**, or the GUI **configtool** “File->Import...” support).

Once built, a raw binary copy of the application would be extracted for adding to a bundle using the **arm-eabi-objcopy** command. For example:

```
$ arm-eabi-objcopy -O binary bundle_example bundle_example.bin
```

The resulting binary could then be added to a bundle image using the host-based **bundle** tool:

```
$ bundle MyProductName_example.bin create add 0x0001:bundle_example.bin:C:md5
```

Refer to the bundle host tool section for detailed information on the bundle host tool.

In this example the bundle image would then be placed onto a suitably formatted FATFS SD Card. The bundle would then be installed into the NVM either by a pre-existing main application, or by the BootUp loader if a valid bundle is not currently installed in the NVM.

Note

When placing the bundle image onto a FATFS SD Card only the `CYGDAT_BOOTUP_STM324X9I_EVAL_BUNDLE_PREFIX` configured filename prefix is checked by the BootUp code. It is expected that only a single, suitably prefixed, bundle is present on an SD Card used for update/installation.

The provided **bundle_invalidate** test can be used during BootUp bundle testing to explicitly invalidate any NVM held bundle. This can be done to check the BootUp operation when no valid bundle containing a main application is available, e.g. to test installation from FATFS SD Card.

Chapter 306. STM32F7XX-EVAL Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32F7XX_EVAL` — eCos Support for the STM32F7XX-EVAL Board

Description

The STM32F7XX-EVAL board has a STM32F746NG microcontroller that incorporates 1MiB of internal flash and 320KiB of internal SRAM. The board also has an additional 32MiB of external SDRAM, 2Mib of external SRAM, 16MiB NOR-flash, 64MiB Quad-SPI NOR-flash, and a variety of I/O devices and interfaces.

Since the board is equipped with an on-board ST-LINK/V2 hardware debugger interface (via the CN21 “USB ST-LINK” connector) for typical eCos development test programs are downloaded and debugged via the hardware debugger in conjunction with the relevant host-side tools. Alternatively the CN12 and CN15 connectors are available for connecting off-board hardware debuggers.

This documentation describes platform-specific elements of the STM32F7XX-EVAL board support within eCos. The STM32 variant HAL documentation covers various topics including HAL support common to STM32 variants, and on-chip device support. This document complements the STM32 documentation.

This HAL provides support for two variants of the STM32F7XX evaluation board. The original prototype board was essentially a STM324x9I-EVAL with the processor chip replaced. The STM32F746NG-EVAL2 board is a similar but reworked board with several differences. By default, this HAL, and this documentation concentrates on the STM32F746NG-EVAL2 board.

Supported Hardware

The STM32F746NG has two main on-chip memory regions. The device has a SRAM region of 320KiB present at 0x20000000, and a 1MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution). In addition, the STM32F7XX-EVAL motherboard has 32MiB of SDRAM memory mapped to address 0x60000000, 2MiB of SRAM memory mapped to address 0x64000000, 16MiB of conventional NOR-flash memory mapped to address 0xC0000000, and a 64MiB Quad-SPI NOR-flash device which, if the relevant driver is configured, can be memory mapped to address 0x90000000.

The STM32 variant HAL includes support for the eight on-chip serial devices which are documented in the variant HAL. However, the STM32F7XX-EVAL motherboard only provides a single standard DB9 UART connector CN7.

The STM32 variant HAL also includes support for the I²C buses. Devices are instantiated for the audio codec, touch panel controller and MFX IO expander. The latter is used to control various IO pins for other devices.

Similarly the STM32 variant HAL includes support for the SPI buses. Though the motherboard does not provide any SPI devices as standard.

Device drivers are also provided for the STM32 on-chip Ethernet MAC, ADC, BXCAN and SDIO interfaces.

Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

Note

The STM32 variant HAL support for the SDIO interface is currently limited to supporting MMC/SD cards. If the multi-bit MMC/SD support is used it is recommended that on-chip SRAM transfer buffers are used to avoid RX overrun or TX underrun due to the slow external SDRAM access speed.

The STM32F7 processor and the STM32F7XX-EVAL board provide a wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included in this eCos port.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3g, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.23.2.

Name

Setup — Preparing the STM32F7XX-EVAL Board for eCos Development

Overview

Typically, since the STM32F7XX-EVAL motherboard has a built-in ST-LINK/V2 interface providing hardware debug support, eCos applications are loaded and run via the debugger **arm-eabi-gdb** or via the Eclipse IDE. The debugger then communicates with the "GDB server" provided by the relevant host ST-LINK/V2 support tool being used (e.g. OpenOCD).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from on-chip SRAM, or where all of the SRAM and SDRAM is required for application run-time use.

If off-chip non-volatile memory (NVM) is used to hold the main application then the board can boot from the internal flash using the BootUp ROM loader. This BootUp code will then start the main application (after an optional update sequence).

If required, it is still possible to program a GDB stub or RedBoot `ROM` image into on-chip Flash and download and debug via the serial UART (CN8). In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. By default for serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed in the eCos configuration used for building the `ROM` image.

Preparing ST-LINK/V2 interface

The support for using the on-chip ITM stimulus ports for diagnostic and instrumentation output requires that the ST-LINK/V2 firmware is at least version `V2.J17.SO`. The firmware for the ST-LINK/V2 interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file). For example, the following OpenOCD output reports `JTAG v17`:

```
Info : STLINK v2 JTAG v17 API v2 SWIM v0 VID 0x0483 PID 0x3748
```

Unfortunately the official firmware updater is only available for the Windows platform at the moment. From a Windows machine:

1. Ensure that the Windows PC and STM32F7XX-EVAL board are disconnected.
2. Download the STM32 ST-LINK Utility from ST's website.

   The page titled "STSW-LINK004 STM32 ST-LINK utility" provides a free download of the utility http://www.st.com/web/en/catalog/tools/PF258168

3. Install the ST-LINK Utility software on your Windows PC.

   Simply unzip the downloaded file `stsw-link004.zip` and run the `STM32 ST-LINK Utility_v3.0.0.exe` that was contained within it. Follow the on-screen instructions. This will install both the utility application and the ST-LINK/V2 USB driver.

4. Connect the STM32F7XX-EVAL board to the PC.

   Connect the STM32F7XX-EVAL board to the PC using the ST supplied mini-B USB cable. Windows should correctly identify the USB device and load the device driver. Windows Device Manager should now show "STMicroelectronics STLink dongle" under "Universal Serial Bus controllers".

5. Run the ST-LINK Utility and ensure the ST-LINK firmware is up to date.

   From the Windows "Start" menu run the "STM32 ST-LINK Utility". Click on the `connect` icon, or select `Target->Connect` from the menu. This should confirm that a successful connection can be made to the board. To update the on-board ST-

LINK/V2 firmware select `ST-LINK->Firmware Update` from the menu. In the ST-LINK dialog box that then appears click on the `Device Connect` button. This will likely result in a message “ST-Link is not in DFU mode. Please restart it.”. In this case simply disconnect the board from the PC and then reconnect it after a couple of seconds, then click the `OK` button on the message. In the original ST-Link dialog box click `Device Connect` again. The dialog box should now report the current on-board and available firmware versions, and enable you to upgrade the board by pressing the `Yes >>>>` button. We have tested the system with firmware version `V2.J17.S0` and would recommend this version as a minimum. Clicking `Yes >>>>` will cause a progress bar in the dialog to be animated and should eventually result in a “Update Successful” message. You can then close the various dialogs and exit the ST-LINK Utility. Disconnect and reconnect the board and it is now ready for use with OpenOCD.

Programming ROM images

Since the STM32F7XX-EVAL board has a built-in ST-LINK/V2 SWD interface, the micro USB host connection (CN21) and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash.

The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

Note

The **openocd** command being used should have been configured and built to support the ST-LINK/V2 interface. This is achieved by specifying the **--enable-stlink** when configuring the OpenOCD build. Additional information on running **openocd** may be found in the OpenOCD notes.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the “bootup.elf” application into the on-chip flash:

```
$ arm-eabi-gdb install/bin/bootup.elf
GNU gdb (eCosCentric GNU tools 4.7.3c) 7.6.1
[ … GDB output elided … ]
(gdb) target remote localhost:3333
hal_reset_vsr () at path/hal_misc.c:171
(gdb) load
Loading section .rom_vectors, size 0x14 lma 0x8000000
Loading section .text, size 0x3adc lma 0x8000018
Loading section .rodata, size 0x6c0 lma 0x8003af8
Loading section .data, size 0x6dc lma 0x80041b8
Start address 0x8000018, load size 18572
Transfer rate: 14 KB/sec, 4643 bytes/write.
(gdb)
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a command-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32F7XX-EVAL board platform HAL package is loaded automatically when eCos is configured for the `stm32f746g_eval2` or `stm32f746g_proto` targets. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32F7XX-EVAL board platform HAL package supports six separate startup types.

Note

Due to Cortex-M limitations regarding executable addresses, and the STM32F7 FMC memory bank address locations, it is not possible to have a configuration with code executing from SDRAM and PSRAM/NOR without runtime support for manipulating FMC_MEMRMP when moving between regions. The eCos run-time does *not* provide such support. The relevant `CYG_HAL_STARTUP` configuration should be chosen for the desired application CODE +DATA memory usage, with the other external memory being used purely for DATA storage.

ROM

This startup type can be used for finished (stand-alone) applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into external SDRAM starting from 0x60000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

The off-chip SRAM memory from 0xC8000000 is available, but is not referenced by the eCos run-time. It is available for application DATA use if required.

ROMAPP

This startup type can be used for finished applications which will be programmed into internal (on-chip) flash at the configured offset from location (0x08000000+`CYGIMP_BOOTUP_RESERVED`), and started via a suitably configured BootUp ROM loader. Data and BSS will be put into internal SRAM. The application will be self-contained with no dependencies on services provided by other software.

ROMINT

This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x200002C8. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

The off-chip SDRAM memory from 0x60000000 and off-chip SRAM memory from 0xC8000000 are available, but are not referenced by the eCos run-time so are available for application use if required. The SDRAM can be used for CODE+DATA, with the external SRAM for DATA.

JTAG

This is the startup type used to build applications that are loaded via the hardware debugger interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from

0x60000000 and entered at that address. eCos startup code will perform all necessary hardware initialization, though since the application is loaded via the hardware debugger interface the host debug environment is responsible for configuring the necessary I/O state to initialise the off-chip SDRAM.

This is the startup type normally used during application development, since the large SDRAM memory space allows for larger debug applications where compiler optimisation may be disabled, and run-time assert checking enabled.

Note

Executing code from the SDRAM memory has a performance downside. It is significantly slower than execution from on-chip SRAM or flash. If performance is an issue then hardware debugging can be used for any of the startup types if required.

The off-chip SRAM memory from 0xC8000000 is available, but is not referenced by the eCos run-time. It is available for application DATA use if required.

SRAM

This is a variation of the `JTAG` type that only uses internal memory. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x200002C8 and entered at that address. eCos startup code will perform all necessary hardware initialization. Unlike the `JTAG` startup no explicit hardware debugger configuration is needed, since the application (like the `ROM` and `ROMINT` startup types) will initialise the off-chip SDRAM memory as required.

The off-chip SRAM memory from 0xC8000000 is also available, but is not referenced by the eCos run-time. It is available for application DATA use if required.

SRAMEXT

This is a variation of the `JTAG` type that uses the external SRAM memory addressed from 0x68000000.

The off-chip SDRAM memory from 0xC0000000 is also available, but is not referenced by the eCos run-time. It is available for application DATA use if required.

RAM

For the ST-LINK/V2 enabled STM32F7XX-EVAL platform this startup type is unlikely to be used. It is provided for completeness.

When the board has RedBoot (or a GDB stub ROM) programmed into internal Flash at location 0x08000000 then the arm-eabi-gdb debugger can communicate with the relevant UART connection to load and debug applications. An application is loaded into memory from 0x60100000. It is assumed that the hardware has already been initialized by RedBoot. By default the application will not be stand-alone, and will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

Note

As well as having a memory footprint cost, RedBoot use can adversely affect the real-time performance of an eCos application.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a `RAM` startup, disabled otherwise. It can be manually disabled for a `RAM` startup, making the application self-contained, as a testing step before switching to `ROM` startup.

Note

Though, as previously discussed, since the option of hardware debugging is available as standard on the STM32F7XX-EVAL platform it is unlikely that the `RAM` startup type would be used for development.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

When QSPI NOR flash support is enabled in the configuration with `CYGHWR_HAL_CORTEXM_STM32_FLASH_QSPI`, then the `m25pxx_flash_device` device is exported and can be accessed via the standard flash API. The device is given a logical base address to match its physical base address of `0x90000000` (corresponding to FMC bank 4) when it is memory mapped (if `CYGFUN_DEVS_FLASH_QSPI_CORTEXM_STM32_MEMMAPPED` is enabled in the QSPI driver, which is the default). Even if memory mapping is disabled, using the eCos Flash API will still allow the device to be read/written at that logical base address.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. Since the platform uses an I²C bus 1 based I/O expander the I²C support is always enabled. The touch-panel device is instantiated and becomes available for applications from `<cyg/io/i2c.h>`.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM32F7XX-EVAL platform HAL enables the support for the devices ADC1, ADC2 and ADC3 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Ethernet Driver

The Ethernet MAC is connected to a DP83848 PHY via the MII interface and thence to a RJ45 connector at CN9. By default the external 25MHz crystal is used to supply the clock and JP6 must be set to the 1-2 position, which should be the default setting. The MMIO and MDC signals must be connected to PA2 and PC1, so JP21 and JP22 should be set to the 1-2 position, which should also be the default settings.

By default solder bridges SB36, SB47 and SB9 are open, which means that MII_CRS, MII_COL and MII_RX_ER are not connected to the PHY. Without MII_CRS and MII_COL, the MAC will only operate in full duplex mode and not half duplex. This means that it will work with Ethernet switches, but not with older hubs.

CAN Driver

The STM32 has a dual BXCAN device for CAN support. This consists of a master device, BXCAN1, and a slave device, BXCAN2. If BXCAN2 is to be used, BXCAN1 must be powered and clocked, regardless of whether it is to be used for CAN traffic. BXCAN1 is the only device connected to an external D-Sub socket at CN22. It shares an IO pin with the OTG FS controller. JP8 controls connection of CAN1_RX to PA11. By default this jumper is not fitted, so one must be fitted to enable BXCAN1. Additionally, the OTG_FS1 connector at CN13 cannot now be used and must be left unconnected. This means that the OTG_FS USB controller and CAN cannot be used concurrently.

Consult the generic CAN driver API documentation in the eCosPro Reference Manual for further details on CAN support in eCosPro, along with the documentation and configuration options in the BXCAN device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic “Flash device drivers” (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32F7XX-EVAL board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

Name

SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M7 core of the STM32F7 only supports eight such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V2 interface.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. The architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

However, when using the STM32F7XX-EVAL board via the ST-LINK/V2 interface then it is recommended that the `gdb_hwdebug_fileio` approach is used to provide access to diagnostics via the GDB debug connection. When ITM support is used it has been observed that the ST-LINK/V2 firmware can drop data, leading to the possibility of confusing output. However, with care the ITM system can be tuned to provide diagnostic and instrumentation via the host SWD debugger.

Using the ST-LINK/V2 connection allows for a single cable to provide power (JP12), hardware debug support and diagnostic output.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board ST-LINK/V2 interface available via the USB CN21 connection. When configuring the **openocd** tool build, the **configure** script can be given the option `--enable-stlink` to provide for ST-LINK support.

Two example OpenOCD configuration files, `openocd.stm32f7xx_eval.sdram.cfg` and `openocd.stm32f7xx_eval.psram.cfg`, are provided within the eCos platform HAL package in the source repository. The latter file is used for SRAMEXT startup types (although it can also be used for SRAM and ROMINT startup types) with the former used for all other startup types. These are in the directory `packages/hal/cortexm/stm32/stm32f7xx_eval/current/misc` relative to the root of your eCos installation and the appropriate OpenOCD configuration configuration file will be copied as the file *`PREFIX`*`/etc/openocd.cfg` when you build the `target.ld` for your configuration.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f PREFIX/etc/openocd.cfg
Open On-Chip Debugger 0.9.0 (2015-09-18-16:19)
Licensed under GNU GPL v2
For bug reports, read
```

```
    http://openocd.org/doc/doxygen/bugs.html

adapter_nsrst_delay: 100
none separate
Info : Unable to match requested speed 2000 kHz, using 1800 kHz
Info : Unable to match requested speed 2000 kHz, using 1800 kHz
Info : clock speed 1800 kHz
Info : STLINK v2 JTAG v17 API v2 SWIM v0 VID 0x0483 PID 0x3748
Info : using stlink api v2
Info : Target voltage: 2.886506
Info : stm32f4x.cpu: hardware has 6 breakpoints, 4 watchpoints
```

Note

Do not edit the *PREFIX*`/etc/openocd.cfg` directly for use by **openocd** as this will be over-written by the original when the eCos configuration changes and `target.ld` is rebuilt. Instead, create a copy of the file for local changes and specify the copy as the `-f` argument to **openocd**.

By default **openocd** provides a console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb) monitor reset halt
target state: halted
target halted due to debug-request, current mode: Thread
xPSR: 0x01000000 pc: 0x0800422c msp: 0x20000c80
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then you can review the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter for further details.

If the HAL diagnostics are configured to use ITM, and stimulus port 31 is configured as the HAL diagnostic destination, then the configuration example above will direct OpenOCD to direct ITM output (and also DWT and ETM) to a file named `tpiu.out` in the current directory of the shell which was used to run the **openocd** command. A more specific filename can be used by adjusting the OpenOCD configuration file.

To extract the ITM output, the Cortex-M architecture HAL package provides a helper program **parseitm** in the directory `packages/hal/cortexm/arch/current/host` relative to the root of your eCos installation. It can be compiled simply with:

```
$ gcc -o parseitm parseitm.c
```

You simply run it with the desired ITM stimulus port and name of the file containing the ITM output, for example:

```
$ parseitm -p 31 -f itm.out
```

It will then echo all ITM stimulus for that port, continuing to read from the file until interrupted with Ctrl-C. Note that limited buffer space in debug hardware such as the ST-LINK can result in occasionally missed ITM data. eCosPro provides a workaround of throttling data within the `CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE` CDL configuration component in order to reduce or avoid lost ITM data. For further details, see the note in OpenOCD ITM support.

Similarly, if the eCos application is built with Kernel instrumentation enabled and configured for ITM output, then the default stimulus port 24 output can be captured. For example, assuming the application **cminfo** is the ELF file built from an eCos configuration with ITM instrumentation enabled, and is loaded and run via **openocd**, then we could run **parseitm** to capture instrumentation whilst the program executes, and then view the gathered data using the example **instdump** tool provided in the Kernel package.

```
$ parseitm -p 24 -f tpiu.out > inst.bin
^C
$ instdump -r inst.bin cminfo
```

```

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into SRAM or SDRAM without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support this mode, it is recommended to use the `JTAG` startup type which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the `JTAG` startup type will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. An eCosCentric extension allows diagnostic output to appear in GDB. For this feature to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. If you are using the graphical configuration tool then you should then accept any suggested solutions to the subsequent configuration conflicts. Older eCos releases also required the gdb "set hwdebug on" command to be used to enable GDB or Eclipse console output, but this is no longer required with the latest tools.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32F7XX-EVAL board hardware, and should be read in conjunction with that specification. The STM32F7XX-EVAL platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For `ROM`, `ROMINT`, `SRAM`, `JTAG` and `SRAMEXT` startup types the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32f7xx_eval_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. For all the STARTUP variations the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of the on-chip SRAM are reserved for the interrupt stack. The remainder of the internal SRAM is available for use by applications. The key memory locations are as follows:

Internal RAM

> This is located at address `0x20000000` of the memory space, and is 320KiB in size. The eCos VSR table occupies the bottom 392 bytes of memory, with the virtual vector table starting at `0x200001AC` and extending to `0x200002AC`.
>
> This memory region comprises three contiguous memory blocks, the DTCM (Data Tightly Coupled Memory), SRAM region 1 and SRAM region 2.

External SDRAM

> This is located at address `0x60000000` of the memory space, and is 32MiB long. For `ROM` applications, all of the SDRAM is available for use. For `JTAG` applications the application is loaded from `0x80000000` with the remaining SDRAM after the code+data available for application use.
>
> For `RAM` startup applications, SDRAM below `0x60008000` is reserved for the debug monitor (e.g. RedBoot).

External SRAM

> This is located at address `0x64000000` of the memory space, and is 2MiB long. For `SRAMEXT` applications, all of the external SRAM is available for use.

Internal FLASH

> This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 1024KiB in size. `ROM` and `ROMINT` applications are by default configured to run from this memory.

External FLASH

> This is located at address `0xC0000000` of the memory space. This region is 16MiB in size.

On-Chip Peripherals

These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to 0x20000000 for all startup types, and space for 98 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x200001AC.

hal_interrupt_stack
: This defines the location of the interrupt stack. This is allocated to the top of internal SRAM, 0x20030000.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Diagnostic LEDs

Four LEDs are fitted on the board for diagnostic purposes and are labelled LD1 (green), LD2 (orange), LD3 (red) and LD4 (blue).

The platform HAL header file at <cyg/hal/plf_io.h> defines the following convenience function to allow LEDs LD1 and LD3 to be set:

```
extern void hal_stm32f7xx_eval_led(char c);
```

However, LEDs LD2 and LD4 cannot be set with this function as it is intended for low level control of the LEDs, but LD2 and LD4 are under MFX_GPO control. This means setting them would result in I²C transactions which in turn means the function could not be called from ISR/DSR or system-critical code.

Nevertheless, the lowest 4-bits of the argument c correspond to the LED number (with LED0/LD1 as the least significant bit). Attempting to set the bits for LD2/LD4 will have no effect.

Table 306.1. LEDs

eCos LED GPIO manifest	STM32F7 GPIO	Bit number	Board label	Colour
CYGHWR_HAL_STM32F7XX_EVAL_LED0	PF10	0	LD1	Green
CYGHWR_HAL_STM32F7XX_EVAL_LED2	PB7	2	LD3	Red

The platform HAL will automatically light LED0 when the platform initialisation is complete, however the LEDs are then free for application use.

Flash wait states

The STM32F7XX-EVAL platform HAL provides a configuration option to set the number of Flash read wait states to use: CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the STM32 Flash programming manual (PM0081) for appropriate values for different clock speeds or voltages. The default of 5 reflects a supply voltage of 3.3V and HCLK of 168MHz.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for `SRAM` startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 306.1. stm32f7xx_eval Real-time characterization

```
             Startup, main thrd : stack used   352 size  1536
             Startup : Idlethread stack used    76 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    3.13 microseconds (3 raw clock ticks)

Testing parameters:

Name

Test Programs — Details

Test Programs

The STM32F7XX-EVAL platform HAL contains some test programs which allow various aspects of the board to be tested.

Manual Test

The **manual** test is not built by default. The configuration option `CYGPKG_HAL_CORTEXM_STM32_STM32F7XX_EVAL_TESTS_MANUAL` should be enabled to allow the test to be built.

This program tests various aspects of the basic platform port, e.g. flashing LEDs, checking I²C device access and that the push-button GPIO operates.

Name

BootUp Integration — Detail

BootUp

The BootUp support for the STM32F7xx-EVAL target is primarily implemented in the `stm32f7xx_eval_support.c` file. The majority of the functions provided by that source file are only included when the `CYGPKG_BOOTUP` package is being used to construct the actual BootUp ROM loader binary.

The BootUp code is designed to be very simple, and it is envisaged that once its implementation has been tested and validated, the binary will only need to be installed onto a device once. Its only purpose is to allow the safe updating and startup of the main application. If the BootUp code ever needs to be replaced then it is a “factory” operation, for example using JTAG/SWD to reprogram the on-chip flash.

This platform specific documentation should be read in conjunction with the generic BootUp package and bundle image support documentation.

The BootUp package provides a basic but fully functional implementation for the platform. This has been tested to ensure that the underlying mechanism is sound. It is envisaged that the developer will customize and further extend the platform side support to meet their specific application update requirements.

BootUp loaded applications

Applications started via the BootUp loader, since they cannot include the `CYGPKG_BOOTUP` package themselves, may need access to some related configuration state. The platform is responsible for providing such “common” information. For example, the CDL option `CYGIMP_BOOTUP_RESERVED` specifies the amount of on-chip flash set aside for BootUp. Applications can then ensure that they do not interfere with the BootUp loader if using the remaining on-chip flash for their own purposes.

Warning

Care must be taken to ensure that the target application configuration matches the BootUp configuration, since it is normally expected that the applications to be loaded will be independent of the initial BootUp build environment. This includes the fundamental on-chip flash space set aside for the BootUp ROM loader code (`CYGIMP_BOOTUP_RESERVED`) as well as, when using `CYGPKG_BUNDLE` support, where the bundle image is located (selected Non-Volatile Memory (NVM) and offset/partition information). It is expected that such values, for a particular platform instance, will be *fixed* at a suitable point during development, and definitely before products are shipped. It is the responsibility of the developer to ensure a consistent configuration between the BootUp ROM loader and any applications that may be installed/started by that BootUp code.

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function for BootUp, and applications started by BootUp, to ascertain the configured off-chip bundle/update location:

```
extern struct cyg_flash_dev *hal_stm32f7xx_eval_source_flash(cyg_flashaddr_t *pbase,cyg_flashaddr_t *plimit);
```

The function will return a pointer to the relevant flash device. The passed *`pbase`* parameter is a pointer to the value to be filled with the base address for the image (or `NULL` if the value is not needed by the caller). Similarly the *`plimit`* parameter is a pointer to the value to be filled with the limiting address for any image, or `NULL` if the address is not needed.

Primarily to avoid source duplication, the `hal_stm32f7xx_eval_source_flash()` function provides common run-time access to the settings derived from the CDL options `CYGIMP_BOOTUP_STM32F7XX_EVAL_SOURCE`, `CYGNUM_BOOTUP_STM32F7XX_EVAL_SOURCE_OFFSET` and `CYGNUM_BOOTUP_STM32F7XX_EVAL_SOURCE_LIMIT`.

Bundle based applications

When the CDL option `CYGIMP_BOOTUP_STM32F7XX_EVAL_BUNDLE` is enabled, the STM32F7xx-EVAL platform BootUp code incorporates the `CYGPKG_BUNDLE` package and support for bundle based application distribution.

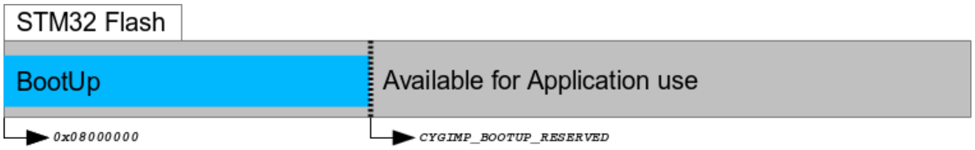
The current STM32F7xx-EVAL platform BootUp bundle support is limited (by design) to starting SDRAM based applications. i.e. `CYG_HAL_STARTUP_JTAG` startup type.

Note

The (slightly misleading) `JTAG` startup type name is used for standalone SDRAM based applications for historical reasons. The `RAM` startup name is assumed by some systems to refer to an application that relies on the presence of a debug monitor. BootUp is purely a “loader” and does *NOT* provide GDB stubs, so cannot support `CYG_HAL_STARTUP_RAM` applications.

The platform HAL and `CYGPKG_BUNDLE` package provide a common set of routines shared by both BootUp and applications. This ensures that all bundle operations are carried out in a compatible and consistent manner.

Figure 306.1. On-chip flash



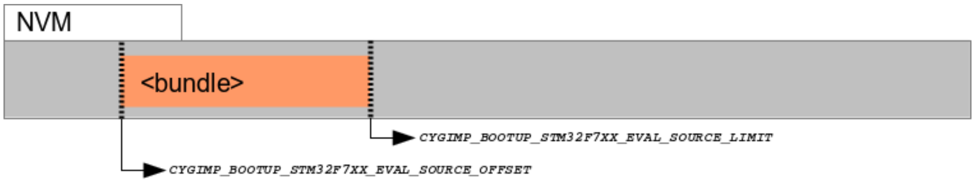
BootUp `ROMINT` application in on-chip flash

On startup the BootUp loader will use the `hal_stm32f7xx_eval_source_flash()` function to ascertain the NVM memory used to hold the source bundle image. If a valid bundle image is found, then the configured “main application” item tag as specified by the CDL option `CYGNUM_BOOTUP_STM32F7XX_EVAL_BUNDLE_TAG` is searched for within the bundle. If a valid matching tag item is found, then the data from that item is loaded into SDRAM and executed.

Note

This simple approach of using a fixed, pre-allocated, area for holding the bundle image simplifies the BootUp (and similarly any main application based update) code without the issues that would need to be considered if the bundle was stored in a filesystem. e.g. a JFFS2 filesystem on the SPI flash, with potentially slow JFFS2 mount performance, inability to ascertain how much “true” free space is available on the filesystem, programmatic support for deletion of “data” to free space for a bundle as part of an update, etc. The normal “lifetime” cycles of NOR flash (e.g. S25FL256S) should be more than sufficient for the “limited” number of in-field updates that may be undertaken on a specific board over its lifetime.

Figure 306.2. NVM bundle



NVM
<bundle>
CYGIMP_BOOTUP_STM32F7XX_EVAL_SOURCE_LIMIT
CYGIMP_BOOTUP_STM32F7XX_EVAL_SOURCE_OFFSET

Main application held in bundle stored in NVM

If a valid bundle exists and contains a valid `CYGNUM_BOOTUP_STM32F7XX_EVAL_BUNDLE_TAG` item, then the BootUp loader will always start that application. The BootUp loader itself does NOT perform any update revision based automatic update support. That support is entirely within the domain of the started application program, which is responsible for all system update decisions and processing.

The only case where BootUp will initiate a system update is when a bundle is not present or is invalid, or when an otherwise valid bundle doesn't contain a valid `CYGNUM_BOOTUP_STM32F7XX_EVAL_BUNDLE_TAG` item. In this case BootUp will attempt to install a bundle from external media. The current example implementation uses a FATFS formatted SD Card for this purpose.

Note

A beneficial side-effect of this approach is that it can help simplify the board production process. Boards only need to be pre-initialized with the stable BootUp binary, which can then be used to install the latest application firmware in NVM.

The example BootUp bundle support provided for this platform expects a single release bundle to be stored in the root directory of an inserted FATFS SD Card. The first file found that matches the `CYGDAT_BOOTUP_STM32F7XX_EVAL_BUNDLE_PREFIX` prefix is used. Any filename text after the prefix is ignored and can contain human-readable or customer specific identification information as required. For example, assuming `CYGDAT_BOOTUP_STM32F7XX_EVAL_BUNDLE_PREFIX` is configured as `“MyProductName_”`, then files named `MyProductName_1.02`, `MyProductName_1.03.B99.1234`, `MyProductName_example.bin` would all be matched.

The SD Card FATFS filesystem is mounted read-only, so any interrupted update operations (e.g. loss-of-power, reset condition) should not affect the “validity” of the FATFS filesystem held on the SD Card.

Since only a single bundle image is held in the SPI flash there is a chance for the SPI flash based bundle to be in a “corrupt” state if an update fails (power-loss, CPU reset, etc.) during an active update. However, since an update is only manually started when a validated image is available on an SDcard, if the update is interrupted the same SDcard (and field-engineer/operator) should be available to re-apply the update on the system restart. This avoids the (normal) “robustness” requirement of providing two application images to be held in the SPI flash to ensure “safe” updates.

To reiterate, the BootUp code will *ONLY* perform an update from an SD Card to the NVM when there is *NO* valid main application bundle/item pair (missing or corrupted). For in-field upgrades any update process will be instigated under the control of the BootUp started “main application”. For example, the application could use the `CYGPKG_BUNDLE` API to validate a bundle image from whatever source it has access to, and then to update the relevant NVM image itself. If the update is provided on an SD Card then (after ensuring the SD Card does contain a valid bundle image) the main application just needs to invalidate the current NVM bundle image, and then force a CPU reset to have BootUp detect the now invalid main application and apply the update. It is up to the developer to decide the best approach for their particular needs in how point-revision updates are installed, and is beyond the scope of this documentation.

The bundle implementation currently limits the number of automatic update attempts when a missing/invalid bundle is detected. This is a deliberate choice to avoid continually failing attempts that could eventually wear out a flash device. The platform `hal_stm32f7xx_eval_badapp()` function implementation, when bundle support is configured, will reset the system to allow another restart attempt if the “Wakeup/Tamper” (`CYGHWR_HAL_STM32F7XX_EVAL_BUTTON_USER`) button is pressed for more than one second. This can be used to manually force another “automatic” update attempt to be started.

When BootUp has installed a bundle to the SPI flash, the last 4-bytes of the SPI flash area (partition) set aside for the bundle will be erased to 0xFFFFFFFF. This location and value can be used by the customer main application to ascertain that an install/update has just been performed (since sector erase will only occur as part of a bundle install/update). It is the responsibility of the main application to update this single location (clearing at minimum 1-bit) if it wants to track “post update” state. This can by used by the main application to acknowledge the update, and can ensure, for example, that any (potentially slow) “post update” main application specific functionality is not performed on every normal startup. For example, the main application may need to check and update the software components of attached daughter-boards from the bundle, and can use this mechanism to ensure it is only performed *once* after an update. This simple (erased flash) mechanism avoids complicated support for passing non-volatile “log” information between the seperate BootUp and main application worlds.

Note

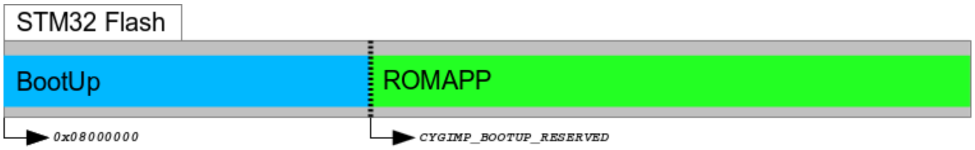
The main application should *NOT* use bit 31 of this field (treating the 32-bit value as being stored in little-endian format) since it is reserved as a flag for the BootUp loader update processing. The main application should *ALWAYS* leave bit 31 set.

On-Chip ROMAPP applications

If the CDL option `CYGIMP_BOOTUP_STM32F7XX_EVAL_BUNDLE` is not enabled, then BootUp provides an alternative mechanism that supports the safe update of on-chip flash resident (`CYG_HAL_STARTUP_ROMAPP`) applications.

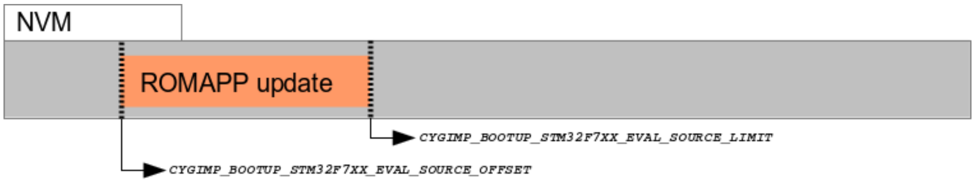
Updates using this mechanism are initiated and directed solely by the application itself. The application is responsible for locating, acquiring and verifying a new update, and placing it into NVM storage. If BootUp detects a verified update in NVM, it installs the update into the on-chip flash, overwriting and replacing the existing application. The updated application is then executed.

Figure 306.3. BootUp and Application



BootUp `ROMINT` loader and `ROMAPP` main application held in on-chip flash

Figure 306.4. Application Update image



NVM
ROMAPP update
CYGIMP_BOOTUP_STM32F7XX_EVAL_SOURCE_LIMIT
CYGIMP_BOOTUP_STM32F7XX_EVAL_SOURCE_OFFSET

Update for `ROMAPP` main application held in NVM

The example implementation uses a simple scheme that checks a fixed-format contiguous structure near the start of the binary application image file. Other than the fields used to identify the structure, the BootUp code does not interpret the hal_stm32f7xx_eval_bootup_structure_t structure `identity` field.

Depending on how the alternative (pending update) application is downloaded and installed in the NVM, it may be more relevant to have the `tail` marker at the very end of the binary image. The developer may wish to update the build/release process so that the actual binary length is held in the application description structure, since that could avoid the overhead of unnecessary flash reads and writes when processing updates. Similarly, instead of a simple binary number being used to differentiate application images, the choice may be made to use the 64-bit UTC timestamp the application was created, or a human-readable string as the unique identification for a release. It is the responsibility of the build/release engineer to ensure individual releases are uniquely identifiable.

It is *critical* that the main application, when storing a pending update, stores the `tail` marker as the last bytes written. It is the responsibility of the main application to verify the data written, prior to placing the `tail` marker. This ensures that a partial image is not treated as a valid update. For example the sequence undertaken by the main application would be:

Table 306.2. Pending update sequence

Operation	Details
Invalidate “previous” alternative image	At a minimum ensure an invalid signature `tail` marker is written. Erasing the flash is normally required anyway, and would invalidate any previous image.
Receive update application image and write to alternative image location	NOT writing the `tail` marker. The code that stores the application should leave a “hole” where the `tail` marker resides to ensure a partial image is not incorrectly treated as valid

Operation	Details
Verify downloaded contents	e.g. CRC or binary comparison. Normally this would be done as individual application chunks are downloaded and written to the alternative storage
Write `tail` marker	This is the very last operation after validating that the alternative image has been stored correctly. If an error has occured during the download then not-writing the `tail` ensures that the BootUp loader will not interpret the data written as a pending update
Force system RESET to start update	e.g. using the `HAL_PLATFORM_RESET` macro

The BootUp loader code will only READ from the alternative image location. This ensures that if an in-progress update is interrupted (e.g. power-loss) then when the system restarts the BootUp code will restart the application update as required.

If the BootUp platform implementation for validating the alternative image is extended to include a CRC, or similar “slow” processing, it may be worth considering whether the main application on startup will always invalidate the `tail` marker after an update to avoid subsequent system resets having to re-validate the alternative image prior to discovering that it is the same as the current main application.

Note

We cannot have the SIGNATURE support purely conditional on the BOOTUP support; since non-BOOTUP applications need to be built leaving the space. For the moment this is only enforced for ROMAPP applications, since that is all that the simple (non-BUNDLE) BootUp update support implements.

Building BootUp

The `ROMINT` startup type is chosen for BootUp so that the loader uses the on-chip SRAM for its workspace, to avoid the overhead of managing off-chip memory where the target application will be loaded.

Example eCos configuration templates for BootUp are provided in the `misc` directory of the release. The `hostboot_ROMINT.ecm` configuration file can be used to construct a bundle based BootUp loader and `bootup_ROMINT.ecm` for the simpler on-chip ROMAPP update BootUp loader.

Building a BootUp ROM image is most conveniently done at the command line. For the `stm32f746g_eval2`, the steps needed to rebuild the bundle based ROMINT version of BootUp on linux are:

```
$ mkdir hostboot_romint
$ cd hostboot_romint
$ ecosconfig new stm32f746g_eval2 minimal
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm32f7xx_eval/current/misc/hostboot_ROMINT.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The steps needed to rebuild the bundle based ROMINT version of BootUp on Windows within the Shell Environment are

```
C:\Users\demo> mkdir hostboot_romint
C:\Users\demo> cd hostboot_romint
C:\Users\demo\hostboot_romint> ecosconfig new stm32f746g_eval2 minimal
[ … ecosconfig output elided … ]
C:\Users\demo\hostboot_romint> ecosconfig import \
    %ECOS_REPOSITORY%/hal/cortexm/stm32/stm32f7xx_eval/current/misc/hostboot_ROMINT.ecm
C:\Users\demo\hostboot_romint> ecosconfig resolve
C:\Users\demo\hostboot_romint> ecosconfig tree
C:\Users\demo\hostboot_romint> make
```

The resulting `install/bin/bootup.bin` binary can then be programmed into the on-chip flash from address `0x08000000`.

It is expected that the BootUp binary is installed onto the STM32F427 on-chip flash either via JTAG/SWD or by utilising the on-chip `BootROM` USB based DFU process. This is a factory or in-field process requiring specific equipment/host-software.

Once BootUp is installed it is not normally expected to require updating. Its purpose is to bootstrap the main application, and provide a standard mechanism for installing the main application. The update mechanism does *NOT* provide a method for updating the BootUp loader itself. If in-field updates of the BootUp binary are necessary, this could be achieved via the STM32 on-chip `BootROM` USB based DFU process.

BootUp Test Programs

The `tests/bundle_example.c` source implements a simple example of an application that utilises the `CYGPKG_BUNDLE` package. Its code could serve as a useful starting point when adding bundle update support to your own application.

Normally a standard `CYG_HAL_STARTUP_JTAG` configured build of the **bundle_example** would be used. If the **bootup** application is used to bootstrap the processor and is built as described in Building BootUp, the eCos Configuration against which **bundle_example** is linked must also include “CRC Support” (`CYGPKG_CRC`), “Zlib compress/decompress support” (`CYGPKG_COMPRESS_ZLIB`), “File IO” (`CYGPKG_IO_FILEIO`) and “Generic FLASH memory support” (`CYGPKG_IO_FLASH`).

As well as ensuring the required packages are present in the configuration, the CDL option `CYGBLD_HAL_CORTEXM_STM32F7XX_EVAL_TESTS_MANUAL`, and its sub-option `CYGBLD_HAL_CORTEXM_STM32F7XX_EVAL_TEST_BOOTUP`, should be enabled to allow **bundle_example** to be built.

Note

If required, the release provides an example “default” template for the `stm32f746g_eval2` platform in the `misc/bundle_example.ecm` file which includes all the necessary packages and defines the necessary options. This can be imported to a configuration (using either the command-line **ecosconfig import**, or the GUI **configtool** “File->Import...” support).

Once built, a raw binary copy of the application would be extracted for adding to a bundle using the **arm-eabi-objcopy** command. For example:

```
$ arm-eabi-objcopy -O binary bundle_example bundle_example.bin
```

The resulting binary could then be added to a bundle image using the host-based **bundle** tool:

```
$ bundle MyProductName_example.bin create add 0x0001:bundle_example.bin:C:md5
```

Refer to the bundle host tool section for detailed information on the bundle host tool.

In this example the bundle image would then be placed onto a suitably formatted FATFS SD Card. The bundle would then be installed into the NVM either by a pre-existing main application, or by the BootUp loader if a valid bundle is not currently installed in the NVM.

Note

When placing the bundle image onto a FATFS SD Card only the `CYGDAT_BOOTUP_STM32F7XX_EVAL_BUNDLE_PREFIX` configured filename prefix is checked by the BootUp code. It is expected that only a single, suitably prefixed, bundle is present on an SD Card used for update/installation.

The provided **bundle_invalidate** test can be used during BootUp bundle testing to explicitly invalidate any NVM held bundle. This can be done to check the BootUp operation when no valid bundle containing a main application is available, e.g. to test installation from FATFS SD Card.

Chapter 307. STM32L476-DISCO Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32L476_DISCO` — eCos Support for the STM32L476-DISCO Board

Description

This documentation describes the platform-specific elements of the ST STM32L476 board support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support.

The board is equipped with an on-board ST-LINK/V2 hardware debugger interface (via the CN1 “USB ST-LINK” connector), which is typically used for eCos application development.

Supported Hardware

The STM32L476VG has two main on-chip memory regions. The device has a SRAM region of 96KiB present at 0x20000000, and a 1MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution). A 128Mbit N25Q SPI flash device it available through the QSPI controller.

The STM32 variant HAL includes support for the six on-chip serial devices. These consist of three USARTs, two UARTs and a LPUART. These are all supported by a common driver and are documented in the variant HAL. However, the STM32L476-DISCO motherboard has no direct UART connectors. It is possible to use USART1 on PIO pins PB6 and PB7 which are connected to pins 15 and 16 of the P1 header.

The STM32 variant HAL also includes support for the I²C buses. A number of I²C devices are present on the board, but none are currently supported by eCosPro. Connections for external I²C devices on bus 1 can be made either via the CN2 I²C extension connector or pins 15 and 16 of P1. Note that these are the same pins as used by USART1, so these two devices cannot be used simultaneously.

Similarly the STM32 variant HAL includes support for the SPI buses. There are a number of SPI devices on the board, but none are currently supported by eCosPro. External access to SPI bus 1 can be had via P2 header pins 15 to 18 which are connected to PIO pins PE12-15. However, these pins are also used for the QSPI memory, so it is not possible to use SPI and QSPI simultaneously.

Device drivers are also provided for the STM32 on-chip, ADC devices. There are no usable analog inputs on the board, only the internal sources are generally available. Only a limited number of PIO pins that connect to the ADCs are accessible. These are mainly limited to PA0-3 and PA5 on the P1 header, which are shared with the joystick switch. If the LCD is removed then further pins are accessible via the socket.

Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash.

The STM32L4 processor and the STM32L476-DISCO board provide a wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3j, **arm-eabi-gdb** version 7.8.2, and **binutils** version 2.23.2.

Name

Setup — Preparing the STM32L476-DISCO Board for eCos Development

Overview

Typically, since the STM32L476-DISCO motherboard has a built-in ST-LINK/V2-1 interface providing hardware debug support, eCos applications are loaded and run via the debugger **arm-eabi-gdb** or via the Eclipse IDE. The debugger then communicates with the “GDB server” provided by the relevant host ST-LINK/V2-1 support tool being used (e.g. OpenOCD).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from on-chip SRAM, or where all of the SRAM is required for application run-time use.

If off-chip Non-Volatile Memory (NVM) is used to hold the main application then the board can boot from the internal flash using a suitable boot loader. For example, the eCosPro BootUp ROM loader, where the BootUp code can start the main application (after an optional update sequence).

If required, it is still possible to program a GDB stub or RedBoot `ROM` image into on-chip Flash and download and debug via a serial connection (using USART3 on J8). In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE as appropriate. However, the space available to applications with this approach is so limited as to make it essentially impractical.

Preparing ST-LINK/V2-1 interface

Use of the ST-LINK with STM32L4 microcontrollers and OpenOCD currently requires that the ST-LINK/V2-1 firmware is version `V2.J20.XXX` and not a more recent version. The firmware for the ST-LINK/V2-1 interface can be checked, and updated if needed, using a tool available from STMicroelectronics. The firmware version is also reported when the **openocd** command is executed (using a suitable configuration file). For example, the following OpenOCD output reports `JTAG v20`:

```
Info : STLINK v2 JTAG v20 API v2 SWIM v11 VID 0x0483 PID 0x374B
```

Future revisions of ST-LINK firmware may restore compatibility, but would require testing to confirm this. The user should refer to the ST “ST-LINK/V2-1 firmware upgrade” (RN0093) Release Note, which provides details on upgrading the ST-Link firmware on Linux, Mac OS X and Windows hosts.

Programming ROM images

Since the STM32L476-DISCO board has a built-in ST-LINK/V2-1 SWD interface, the USB host connection (CN1) and suitable host software (e.g. The OpenOCD package **openocd** tool) can be used to program the flash.

The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

Note

The **openocd** command being used should have been configured and built to support the ST-LINK/V2-1 interface. This is achieved by specifying the **--enable-stlink** when configuring the OpenOCD build. Additional information on running **openocd** may be found in the OpenOCD notes.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the “bootup.elf” application into the on-chip flash:

```
$ arm-eabi-gdb install/bin/bootup.elf
GNU gdb (eCosCentric GNU tools 4.7.3j) 7.8.2
```

```
[ … GDB output elided … ]
(gdb) target remote localhost:3333
hal_reset_vsr () at path/hal_misc.c:171
(gdb) load
Loading section .rom_vectors, size 0x14 lma 0x8000000
Loading section .text, size 0x3adc lma 0x8000018
Loading section .rodata, size 0x6c0 lma 0x8003af8
Loading section .data, size 0x6dc lma 0x80041b8
Start address 0x8000018, load size 18572
Transfer rate: 14 KB/sec, 4643 bytes/write.
(gdb)
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32L476-DISCO board platform HAL package `CYGPKG_HAL_CORTEXM_STM32_STM32L476_DISCO` is loaded automatically when eCos is configured for the `stm32l476_disco` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32L476-DISCO board platform HAL package supports four separate startup types:

ROM

> This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x20000288. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

ROMAPP

> This startup type can be used for finished applications which will be programmed into internal flash at location 0x08008000. Data and BSS will be put into internal SRAM starting from 0x20000288. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.
>
> This startup type is identical to the ROM startup with the exception of the flash base address. It is used for applications that can be started or updated by BootUp.

SRAM

> This startup type can be used for finished applications which will be loaded into internal SRAM via a JTAG interfae. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000288 and entered at that address. eCos startup code will perform all necessary hardware initialization.

RAM

> When the board has RedBoot (or a GDB stub ROM) programmed into internal Flash at location 0x08000000 then the arm-eabi-gdb debugger can communicate with a suitably configured UART connection to load and debug applications. An application is loaded into memory from 0x20001000. It is assumed that the hardware has already been initialized by RedBoot. By default the application will *not* be stand-alone, and will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

Warning

RedBoot can have an adverse affect on the real-time performance of applications.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a `RAM` startup, disabled otherwise. It can be manually disabled for a `RAM` startup, making the application self-contained, as a testing step before switching to `ROM` startup.

Note

Though, as previously discussed, since the option of hardware debugging is available as standard on the STM32L476-DISCO platform, and space in the SRAM is limited, it is unlikely that the `RAM` startup type would be used for development.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

No SPI devices are instantiated for this platform by default.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I^{2}C Driver

The STM32 variant HAL provides the main I^{2}C hardware driver itself, configured at `CYGPKG_HAL_STM32_I2C`. However, the platform I^{2}C support can also be configured separately at `CYGPKG_HAL_CORTEXM_STM32_STM32L476_DISCO_I2C`. This enables I^{2}C bus 1. A CAT2C128 EEPROM is available on this bus and is instantiated with the name `hal_stm32l476_disco_eeprom`. The instantiated device is available for applications via `<cyg/io/i2c.h>`.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM32L476-DISCO platform HAL enables the support for the devices ADC1, ADC2 and ADC3 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic “Flash device drivers” (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32L476-DISCO board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

QSPI Flash Driver

When QSPI NOR flash support is enabled in the configuration with `CYGHWR_HAL_CORTEXM_STM32_FLASH_QSPI`, then the `m25pxx_flash_device` device is exported and can be accessed via the standard flash API. The device is given a logical base address to match its physical base address of `0x90000000` (corresponding to FMC bank 4) when it is memory mapped (if `CYGFUN_DEVS_FLASH_QSPI_CORTEXM_STM32_MEMMAPPED` is enabled in the QSPI driver, which is the default). Even if memory mapping is disabled, using the eCos Flash API will still allow the device to be read/written at that logical base address.

Name

SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M7 core of the STM32L476 only supports eight such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger such as the on-board ST-LINK/V2-1 interface.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. The architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

However, when using the STM32L476-DISCO board via the ST-LINK/V2-1 interface then it is recommended that the `gdb_hwdebug_fileio` approach is used to provide access to diagnostics via the GDB debug connection. When ITM support is used it has been observed that the ST-LINK/V2-1 firmware can drop data, leading to the possibility of confusing output. However, with care the ITM system can be tuned to provide diagnostic and instrumentation via the host SWD debugger.

Using the ST-LINK/V2-1 connection allows for a single cable to provide power, hardware debug support and diagnostic output.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board ST-LINK/V2-1 interface available via the USB CN14 connection. When configuring the **openocd** tool build, the **configure** script can be given the option `--enable-stlink` to provide for ST-LINK support.

An example OpenOCD configuration file `openocd.stm32l476_disco.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/stm32l476_disco/current/misc` relative to the root of your eCos installation.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd.stm32l476_disco.cfg
Open On-Chip Debugger 0.10.0-dev-00371-g81631e4 (2016-09-08-17:23)
Licensed under GNU GPL v2
For bug reports, read
  http://openocd.org/doc/doxygen/bugs.html
Info : The selected transport took over low-level target control. The results might differ compared to plain JTAG/SWD
adapter speed: 480 kHz
adapter_nsrst_delay: 100
srst_only separate srst_nogate srst_open_drain connect_assert_srst
Info : clock speed 480 kHz

Info : using stlink api v2
Info : Target voltage: 3.227369
Info : stm32l4x.cpu: hardware has 6 breakpoints, 4 watchpoints
```

By default **openocd** provides a console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then, if required, you can define a “preload” gdb macro to emit any necessary commands to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

If the HAL diagnostics are configured to use ITM, and stimulus port 31 is configured as the HAL diagnostic destination, then the configuration example above will direct OpenOCD to direct ITM output (and also DWT and ETM) to a file named `tpiu.out` in the current directory of the shell which was used to run the **openocd** command. A more specific filename can be used by adjusting the OpenOCD configuration file.

To extract the ITM output, the Cortex-M architecture HAL package provides a helper program **parseitm** in the directory `packages/hal/cortexm/arch/current/host` relative to the root of your eCos installation. It can be compiled simply with:

```
$ gcc -o parseitm parseitm.c
```

You simply run it with the desired ITM stimulus port and name of the file containing the ITM output, for example:

```
$ parseitm -p 31 -f itm.out
```

It will then echo all ITM stimulus for that port, continuing to read from the file until interrupted with Ctrl-C. Note that limited buffer space in debug hardware such as the ST-LINK can result in occasionally missed ITM data. eCosPro provides a workaround of throttling data within the `CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE` CDL configuration component in order to reduce or avoid lost ITM data. For further details, see the note in OpenOCD ITM support.

Similarly, if the eCos application is built with Kernel instrumentation enabled and configured for ITM output, then the default stimulus port 24 output can be captured. For example, assuming the application **cminfo** is the ELF file built from an eCos configuration with ITM instrumentation enabled, and is loaded and run via **openocd**, then we could run **parseitm** to capture instrumentation whilst the program executes, and then view the gathered data using the example **instdump** tool provided in the Kernel package.

```
$ parseitm -p 24 -f tpiu.out > inst.bin
^C
$ instdump -r inst.bin cminfo

```

Configuration of JTAG/SWD applications

JTAG/SWD applications can be loaded directly into SRAM or flash without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support these modes, it is recommended to use the `SRAM`, `ROM` or `ROMAPP` startup types which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the aformentioned startup types will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. An eCosCentric extension allows diagnostic output to appear in GDB. For this feature to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. If you are using the graphical configuration tool then you should then accept any suggested solutions to the subsequent configuration conflicts. Older eCos releases also required the gdb "set hwdebug on" command to be used to enable GDB or Eclipse console output, but this is no longer required with the latest tools.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32L476-DISCO board hardware, and should be read in conjunction with that specification. The STM32L476-DISCO platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For `ROM`, `ROMAPP` and `SRAM` startup types the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32l476_disco_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. For all the STARTUP variations the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of the on-chip SRAM are reserved for the interrupt stack. The remainder of the internal SRAM is available for use by applications. The key memory locations are as follows:

Internal SRAM
: This is located at address `0x20000000` of the memory space, and is 192KiB in size. The eCos VSR table occupies the bottom 392 bytes of memory, with the virtual vector table starting at `0x20000188` and extending to `0x20000288`.

Internal FLASH
: This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 1024KiB in size. `ROM` and `ROMAPP` applications are by default configured to run from this memory.

On-Chip Peripherals
: These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 98 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x20000188`.

hal_interrupt_stack
: This defines the location of the interrupt stack. This is allocated to the top of internal SRAM, from `0x20018000` down.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Flash wait states

The STM32L476-DISCO platform HAL provides a configuration option to set the number of Flash read wait states to use: `CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES`. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the relevant STM32 datasheets and programming manuals for the STM32L476 parts for appropriate values for different clock speeds or voltages. The default of 4 reflects a supply voltage in Vcore range 1 and HCLK of 80MHz.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for `SRAM` startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 307.1. stm32l476_disco Real-time characterization

```
             Startup, main thrd : stack used   360 size  1536
             Startup : Idlethread stack used    76 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   13.03 microseconds (13 raw clock ticks)

Testing parameters:
   Clock samples:            32

Test Programs — Details

Test Programs

The STM32L476-DISCO platform HAL contains some test programs which allow various aspects of the board to be tested.

ADC Test

The **adc1** program tests the ADC driver for the STM32. In order to run this test a potentiometer needs to be connected to the board; outer pins to 3V3 and GND (P1:1 and P1:2 are convienient), and the center pin to P1:10, which is attached to PA0. This test primarily tests that the external input functions correctly. However, in addition it also reports the values of the Vrefint, Vbat and Vts inputs that are sourced on-chip. The option `CYGBLD_HAL_CORTEXM_STM32L476_DISCO_TESTS_ADC` must be enabled to run this test since it needs human interaction.

Name

BootUp Integration — Detail

BootUp

The BootUp support for the STM32L476-DISCO target is primarily implemented in the `stm32l476_disco_support.c` file. The majority of the functions provided by that source file are only included when the `CYGPKG_BOOTUP` package is being used to construct the actual BootUp ROM loader binary.

The BootUp code is designed to be very simple, and it is envisaged that once its implementation has been tested and validated, the binary will only need to be installed onto a device once. Its only purpose is to allow the safe updating and startup of the main application. If the BootUp code ever needs to be replaced then it is a “factory” operation, for example using JTAG to re-program the on-chip flash.

This platform specific documentation should be read in conjunction with the generic BootUp package.

The BootUp package provides a basic but fully functional implementation for the platform. This has been tested to ensure that the underlying mechanism is sound. It is envisaged that the developer will customize and further extend the platform side support to meet their specific application update requirements.

BootUp loaded applications

Applications started via the BootUp loader, since they cannot include the `CYGPKG_BOOTUP` package themselves, may need access to some related configuration state. The platform is responsible for providing such “common” information. For example, the CDL option `CYGIMP_BOOTUP_RESERVED` specifies the amount of on-chip flash set aside for BootUp. Applications can then ensure that they do not interfere with the BootUp loader if using the remaining on-chip flash for their own purposes.

Warning

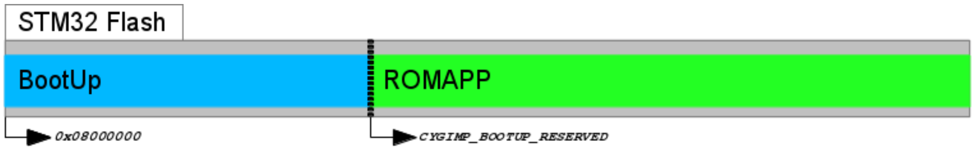
Care must be taken to ensure that the target application configuration matches the BootUp configuration, since it is normally expected that the applications to be loaded will be independent of the initial BootUp build environment. This includes the fundamental on-chip flash space set aside for the BootUp ROM loader code (`CYGIMP_BOOTUP_RESERVED`). It is expected that such values, for a particular platform instance, will be *fixed* at a suitable point during development, and definitely before products are shipped. It is the responsibility of the developer to ensure a consistent configuration between the BootUp ROM loader and any applications that may be installed/started by that BootUp code.

On-Chip ROMAPP applications

BootUp provides an alternative mechanism that supports the safe update of on-chip flash resident (`CYG_HAL_STARTUP_ROMAPP`) applications.

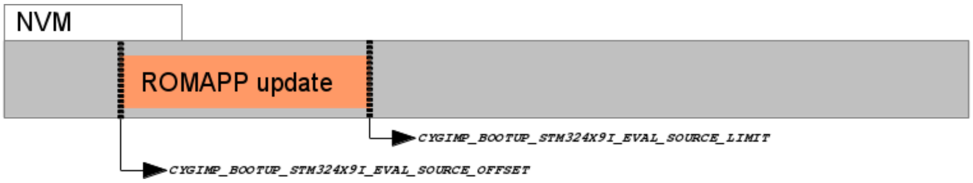
Updates using this mechanism are initiated and directed solely by the application itself. The application is responsible for locating, acquiring and verifying a new update, and placing it into Non-Volatile Memory (NVM) storage. If BootUp detects a verified update in NVM, it installs the update into the on-chip flash, overwriting and replacing the existing application. The updated application is then executed.

Figure 307.1. BootUp and Application



BootUp `ROM` loader and `ROMAPP` main application held in on-chip flash

Figure 307.2. Application Update image



NVM
ROMAPP update
CYGIMP_BOOTUP_STM324X9I_EVAL_SOURCE_LIMIT
CYGIMP_BOOTUP_STM324X9I_EVAL_SOURCE_OFFSET

Update for `ROMAPP` main application held in NVM

The example implementation uses a simple scheme that checks a fixed-format contiguous structure near the start of the binary application image file. Other than the fields used to identify the structure, the BootUp code does not interpret the hal_stm32l476_disco_bootup_structure_t in any other way.

Depending on how the alternative (pending update) application is downloaded and installed in the NVM, it may be more relevant to have the `tail` marker at the very end of the binary image. The developer may wish to update the build/release process so that the actual binary length is held in the application description structure, since that could avoid the overhead of unnecessary flash reads and writes when processing updates. Similarly, instead of a simple binary number being used to differentiate application images, the choice may be made to use the 64-bit UTC timestamp the application was created, or a human-readable string as the unique identification for a release. It is the responsibility of the build/release engineer to ensure individual releases are uniquely identifiable.

It is *critical* that the main application, when storing a pending update, stores the `tail` marker as the last bytes written. It is the responsibility of the main application to verify the data written, prior to placing the `tail` marker. This ensures that a partial image is not treated as a valid update. For example the sequence undertaken by the main application would be:

Table 307.1. Pending update sequence

Operation	**Details**
Invalidate “previous” alternative image	At a minimum ensure an invalid signature `tail` marker is written. Erasing the flash is normally required anyway, and would invalidate any previous image.
Receive update application image and write to alternative image location	NOT writing the `tail` marker. The code that stores the application should leave a “hole” where the `tail` marker resides to ensure a partial image is not incorrectly treated as valid
Verify downloaded contents	e.g. CRC or binary comparison. Normally this would be done as individual application chunks are downloaded and written to the alternative storage
Write `tail` marker	This is the very last operation after validating that the alternative image has been stored correctly. If an error has occured during the download then not-writing the `tail` ensures that the BootUp loader will not interpret the data written as a pending update
Force system RESET to start update	e.g. using the `HAL_PLATFORM_RESET` macro

The BootUp loader code will only READ from the alternative image location. This ensures that if an in-progress update is interrupted (e.g. power-loss) then when the system restarts the BootUp code will restart the application update as required.

If the BootUp platform implementation for validating the alternative image is extended to include a CRC, or similar “slow” processing, it may be worth considering whether the main application on startup will always invalidate the `tail` marker after an update to avoid subsequent system resets having to re-validate the alternative image prior to discovering that it is the same as the current main application.

Note

We cannot have the SIGNATURE support purely conditional on the BOOTUP support; since non-BOOTUP applications need to be built leaving the space. For the moment this is only enforced for ROMAPP applications, since that is all that the simple BootUp update support implements.

Building BootUp

The `ROM` startup type is chosen for BootUp so that the loader uses the on-chip SRAM for its workspace.

Example eCos configuration templates for BootUp are provided in the `misc` directory of the release. The `bootup_ROM.ecm` configuration file can be used to configure the BootUp loader.

Building a BootUp ROM image is most conveniently done at the command line. The steps needed to rebuild the ROM version of BootUp on linux are:

```
$ mkdir bootup_rom
$ cd bootup_rom
$ ecosconfig new stm32l476-disco minimal
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm32l476_disco/current/misc/bootup_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The steps needed to rebuild the bundle based ROM version of BootUp on Windows within the Shell Environment are:

```
C:\Users\demo> mkdir bootup_rom
C:\Users\demo> cd bootup_rom
C:\Users\demo\bootup_rom> ecosconfig new stm32429i_eval_drb minimal
[ … ecosconfig output elided … ]
C:\Users\demo\bootup_rom> ecosconfig import %ECOS_REPOSITORY%/hal/cortexm/stm32/stm32l476_disco/current/misc/bootup_rom.ecm
C:\Users\demo\bootup_rom> ecosconfig resolve
C:\Users\demo\bootup_rom> ecosconfig tree
C:\Users\demo\bootup_rom> make
```

The resulting `install/bin/bootup.bin` binary can then be programmed into the on-chip flash from address `0x08000000`.

It is expected that the BootUp binary is installed onto the STM32L476 on-chip flash either via JTAG or by utilising the on-chip `BootROM` USB based DFU process. This is a factory or in-field process requiring specific equipment/host-software.

Once BootUp is installed it is not normally expected to require updating. Its purpose is to bootstrap the main application, and provide a standard mechanism for installing the main application. The update mechanism does *NOT* provide a method for updating the BootUp loader itself. If in-field updates of the BootUp binary are necessary, this could be achieved via the STM32 on-chip `BootROM` USB based DFU process.

Altinit Test

This application is used to test BootUp support for updating a ROMAPP application from the QSPI flash. Since there is no Ethernet available on the board, this test uses the application already programmed in to the on-chip flash.

The test expects a ROMAPP application to be stored in the on-chip flash. It erases the alternate application in the QSPI flash, copies the ROMAPP application from on-chip flash into QSPI, and then invalidates the signature of the application in on-chip flash. When BootUp starts it will discover that the main application is invalid, copy the alternate application from the QSPI and then run it.

An example eCos configuration template for building the altinit application is provided in the `misc` directory. The steps needed to build this application are as follows:

```
$ mkdir altinit
$ cd altinit
$ ecosconfig new stm32l476-disco kernel
[ … ecosconfig output elided … ]
```

```
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm32l476_disco/current/misc/altinit_SRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
$ make -C hal/cortexm/stm32/stm32l476_disco/current tests
```

Following this, the **altinit** executable can be found in `install/tests/hal/cortexm/stm32/stm32l476_disco/current/tests/altinit`. running this will produce the following output:

```
INFO:<STM32L4_M25P64_ALTERNATIVE_OFFSET 00008000>
INFO:<STM32L4_M25P64_ALTERNATIVE_MAXLEN 000F8000>
INFO:<CYGNUM_BOOTUP_SIGNATURE_OFFSET 8>
INFO:<CYGNUM_BOOTUP_SIGNATURE_LENGTH 16>
INFO:<Erasing M25P64 area for alternative image>
INFO:<Copy main image to alt>
INFO:<Set signature in alt image>
INFO:<Invalidate main image>
INFO:<Update done>
```

The erase and copy operations here may take a some time, do not reset the board until the program is finished.

Chapter 308. BCM943362WCD4 Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_BCM943362WCD4` — eCos Support for the BCM943362WCD4 WICED Module

Description

This documentation describes the platform-specific elements of the STM32F205 based BCM943362WCD4 WICED module support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support.

For this platform, the expected eCos development model is that programs may be downloaded and debugged via a hardware JTAG debugger. Nevertheless it is still possible to program a GDB stub image into the on-chip Flash and download and debug eCos applications with the GDB debugger via available UART pins.

Supported Hardware

The BCM943362WCD4 module consists primarily of a STM32F205RG CPU and a WM-N-BM-02 SiP (BCM43362 Wi-Fi) module.

The base BCM943362WCD4 module exposes a set of I/O pins that are used to provide functionality based on the configuration of the STM32F2 host CPU on the module. This platform HAL optionally provides the ability to target the module as installed on the BCM943362WCD4_EVB development kit (a BCM943362WCD4 module installed on a BCM9WCD1EVAL1 motherboard).

Note

The BCM9WCD1EVAL1 motherboard is intended for evaluating 31-pin WICED modules, and currently supports the following modules: BCM943362WCD2, BCM943362WCD4, BCM943362WCD6, BCM943362WCD8 and BCM9WCDUSI09.

The STM32F205RG has two main on-chip memory regions. The device has a SRAM region of 128KiB present at 0x20000000, and a 1MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution).

The STM32 variant HAL includes support for the six on-chip serial devices which are documented in the variant HAL, however it is assumed that only USART1 is available. There is no connection for hardware flow control (RTS/CTS) lines for USART1.

Device drivers are also provided for the STM32 on-chip SPI interfaces, watchdog, RTC (wallclock) and Flash.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3g, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.32.2.

Name

Setup — Preparing the Broadcom BCM943362WCD4 for eCos Development

Overview

Given the limited available RAM memory, it is expected that the most common development method is to use JTAG for development, either by loading smaller applications into the on-chip SRAM, or by programming larger applications directly into on-chip Flash. In the first case, eCos applications should be configured for the `SRAM` startup type, and in the second case for `ROM` startup type.

Nevertheless, it is still possible to program a GDB stub ROM image into on-chip Flash and download and debug via a serial UART, if pins for the UART are available. In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed in the eCos configuration used for building the GDB stub ROM image.

HAL startup types

The following startup types may be selected for applications:

Configuration	Description
SRAM	Stand-alone programs running from on-chip SRAM, loaded via JTAG hardware debugger
ROM	Stand-alone programs running from on-chip FLASH
ROMAPP	Stand-alone programs running from an offset into the on-chip FLASH, that are started by a separate boot loader
RAM	Programs loading via a GDB stub ROM into on-chip RAM, which rely on a debug monitor

Further details are available later in this manual.

Programming ROM images

To program ROM startup applications into Flash, including the GDB stub ROM, a JTAG debugger that understands the STM32 flash may be used, such as the OpenOCD tool. The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the “bootup.elf” application into the on-chip flash:

```
$ arm-eabi-gdb install/bin/bootup.elf
GNU gdb (eCosCentric GNU tools 4.7.3g) 7.6.1
[ … GDB output elided … ]
(gdb) target remote localhost:3333
hal_reset_vsr () at path/hal_misc.c:171
(gdb) load
Loading section .rom_vectors, size 0x14 lma 0x8000000
Loading section .text, size 0x3adc lma 0x8000018
Loading section .rodata, size 0x6c0 lma 0x8003af8
Loading section .data, size 0x6dc lma 0x80041b8
Start address 0x8000018, load size 18572
Transfer rate: 14 KB/sec, 4643 bytes/write.
(gdb)
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Rebuilding the GDB stub

Should it prove necessary to rebuild a GDB stub ROM binary, this is done most conveniently at the command line. For the `bcm943362wcd4_evb` platform the steps needed are:

```
$ mkdir gdbstub_bcm943362wcd4_evb
$ cd gdbstub_bcm943362wcd4_evb
$ ecosconfig new bcm943362wcd4_evb stubs
[ … ecosconfig output elided … ]
$ ecosconfig tree
$ make
```

At the end of the build, the `install/bin` subdirectory should contain the file `gdb_module.bin`. This may be programmed to the board using the above procedure.

Name

Configuration — Platform-specific Configuration Options

Overview

The Broadcom BCM943362WCD4 module platform HAL package is loaded automatically when eCos is configured for the `bcm943362wcd4` or `bcm943362wcd4_evb` targets. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The Broadcom BCM943362WCD4 module platform HAL package supports four separate startup types:

SRAM

> This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from `hal_virtual_vector_table_end` and entered at that address. Memory below `hal_virtual_vector_table_end` is set aside for vector tables. eCos startup code will perform all necessary hardware initialization.

ROM

> This startup type can be used for finished applications which will be programmed into internal Flash ROM at location `0x08000000`. Data and BSS will be put into internal SRAM starting from `hal_virtual_vector_table_end`. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the `0x08000000` region. eCos startup code will perform all necessary hardware initialization.

ROMAPP

> This startup type can be used for finished applications which will be programmed into internal Flash ROM at the `CYGIMP_BOOTUP_RESERVED` configured offset. This is a variation of the `ROM` startup type for applications that are started by a smaller boot loader application. eCos startup code will perform all necessary hardware initialization.

RAM

> This is the startup type which is used if relying on a GDB stub ROM image programmed into internal Flash to download and run applications into SRAM via arm-eabi-gdb and a serial UART. RAM from `0x20000000` to `0x20001000` is reserved for the GDB stub, but then the RAM startup application may be loaded into memory from `0x20001000` and debugged using GDB. It is assumed that the hardware has already been initialized by the GDB stub ROM. By default the application will use the eCos virtual vectors mechanism to obtain services from the GDB stub ROM, including diagnostic output.

Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB stub ROM (or RedBoot).

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a `RAM` startup, and disabled otherwise. It can be manually disabled for a `RAM` startup, making the application self-contained, as a testing step before switching to `ROM` startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The BCM943362WCD4 module uses the STM32's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, is only expected to be available to be used on the USART1 port (counting the first UART as UART1).

As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_CORTEXM_STM32` package which contains all the code necessary to support interrupt-driven operation with greater functionality. All six UARTs can be supported by this driver. For the BCM943362WCD4 module however the available I/O pins impose a limit on the available functionality.

Note

It is not recommended to use this driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option (within the generic serial driver support package `CYGPKG_IO_SERIAL`) is enabled in the configuration. By default this will only enable support in the driver for the USART1 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports. Note that in this package, serial port numbering starts at 0, rather than 1. So for example, to enable the serial driver for ports USART1 and USART2, enable the configuration options “ST STM32 serial port 0 driver” (`CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL0`) and “ST STM32 serial port 1 driver” (`CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL1`).

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (`CYGPKG_DEVS_SPI_CORTEXM_STM32`).

For the base BCM943362WCD4 module SPI bus 1 is configured for off-module SPI connections. If SPI is being used to communicate with the on-module WM-N-BM-02 SiP tne SPI bus 2 is also configured. Suitable device entries are created as appropriate for application use.

When `CYGPKG_HAL_CORTEXM_STM32_BCM943362WCD4_SPI_ACCESS` is configured then the SPI2 device `spi_device_wm_n_bm_02` is enumerated.

When targetting the BCM9WCD1EVAL1 based `bcm943362wcd4_evb` platform then the SPI1 device `m25pxx_spi_device` is enumerated.

To disable support for both the above SPI devices, the platform HAL contains an option “SPI devices” (`CYGPKG_HAL_CORTEXM_STM32_BCM943362WCD4_SPI`) which can be disabled. No other SPI devices are instantiated.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (`CYGPKG_DEVS_FLASH_STM32`) package. This driver is enabled automatically if the generic “Flash device drivers” (`CYGPKG_IO_FLASH`) package is included in the eCos configuration.

The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the BCM943362WCD4 module.

A number of other aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including the GDB stub ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M3 core of the STM32 only supports six such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

The base BCM943362WCD4 module exposes the STM32F205RG JTAG/SWD signals on the module connectors TP6..TP10. A suitable hardware connection would be required to allow JTAG debugging. The BCM943362WCD4_EVB kit provides a standard 20-pin ARM JTAG header J8, but by default the module JTAG connection is configured to use the BCM9WCD1EVAL1 motherboard FT2232 connection presented via the USB J5 connector. Direct support for this USB interface is provided by the WICED-SDK supplied OpenOCD binary.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

Normally a notable disadvantage with JTAG debugging is that it does not allow thread-aware debugging, such as the ability to inspect different eCos threads or their stack backtraces, set thread-specific breakpoints, and so on. Fortunately the Ronetix PEEDI JTAG unit does support thread-aware debugging of eCos applications, however extra configuration steps are required. Consult the PEEDI documentation for more details as usage is beyond the scope of this document.

OpenOCD notes

The following OpenOCD documentation uses as an example the BCM943362WCD4_EVB J5 USB JTAG connection. An OpenOCD configuration that supports the `ft2232` interface and understands the `ft2232_layout BCM9WCD1EVAL1` configuration must be used, Such an **openocd** is pre-built and available in the WICED-SDK. For example WICED-SDK revision 3.1.2 the necessary host binaries can be found in the directory `WICED-SDK-3.1.2/tools/OpenOCD`.

An example OpenOCD configuration file `openocd.bcm943362wcd4_evb.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/bcm943362wcd4/`*`VERSION`*`/misc` relative to the root of your eCos installation.

This configuration file can be used with the WICED-SDK supplied OpenOCD on the host as follows:

```
$ ./Linux64/openocd-all-brcm-libftdi -f openocd.bcm943362wcd4_evb.cfg
Open On-Chip Debugger 0.8.0-dev-00139-g4505978-dirty (2013-08-26-15:55)

```

By default **openocd** provides a console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then, if required, you can define a “preload” gdb macro to emit any necessary commands to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Broadcom BCM943362WCD4 module hardware and should be read in conjunction with the specification for that device. The BCM943362WCD4 platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target module, and optionally, specifically supported motherboards.

Targetting the eCos platform `bcm943362wcd4` will configure eCos for a stand-alone BCM943362WCD4 module with no assumption made about the I/O connected to the module TP pins.

Targetting the `bcm943362wcd4_evb` platform will configure eCos for a BCM9WCD1EVAL1 motherboard based module, and provide access to the LEDs, switches, thermistor and SPI flash device available on that motherboard.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For the stand-alone application startup types, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/bcm943362wcd4_misc.c` in both the `hal_system_init` and `hal_platform_init` functions.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM
: This is located at address `0x20000000` of the memory space, and is 128KiB in size. The eCos VSR table always occupies the initial bytes at the base of this memory, followed by the optional virtual vector table depending on the eCos configuration. The top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of memory are reserved for the interrupt stack. The remainder of on-chip SRAM is available for use by applications.

Internal FLASH
: This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 1MiB in size. and `ROM` applications are by default configured to run from this memory.

On-Chip Peripherals
: These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the relevant STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for `CYGNUM_HAL_VSR_COUNT` entries is reserved to match the use of a STM32F2 processor.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, and is normally `0x20000184` for STM32F2 targets.

The CDL option CYGSEM_HAL_VIRTUAL_VECTOR_SUPPORT defines whether this virtual vector support is needed. If not defined then the table is zero sized.

hal_virtual_vector_table_end
This defines the location of the end of the (optional) virtual vector table.

hal_interrupt_stack
This defines the location of the interrupt stack. For all startup types this is allocated to the top of internal SRAM, at 0x20020000.

hal_startup_stack
This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack. The size of the interrupt stack is defined by the CDL option CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE.

Flash wait states

The BCM943362WCD4 platform HAL provides a configuration option to set the number of Flash read wait states to use: CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the STM32 Flash programming manual (PM0059) for appropriate values for different clock speeds or voltages. The default of 3 reflects a supply voltage of 3.3V and HCLK of 120MHz.

Diagnostic LEDs

The platform HAL header file at <cyg/hal/plf_io.h> defines the following convenience function to allow any LEDs to be set:

```
extern void hal_bcm943362wcd4_led(unsigned char c);
```

The low-order bits of the argument c correspond to individual LEDs.

The default BCM943362WCD4 module support does not provide LEDs, since the relevant off-module GPIO signals are not defined. However, when targetting the BCM9WCD1EVAL1 motherboard two LEDs are fitted for diagnostic purposes: D1 (red) and D2 (green). These LEDs are free for application use. The bcm943362wcd4_evb**manual** test provides a simple example of changing the LED state.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for the bcm943362wcd4_evb platform using the SRAM startup type and optimization flag -O2.

Example 308.1. bcm943362wcd4 Real-time characterization

```
             Startup, main thrd : stack used   360 size  1536
             Startup : Idlethread stack used    76 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    7.06 microseconds (7 raw clock ticks)

Testing parameters:
   Clock samples:            32

Name

Test Programs — Details

Test Programs

The BCM943362WCD4 platform HAL contains a test suitable for the `bcm943362wcd4_evb` platform, that allows various aspects of that board to be tested.

Manual Test

The **manual** test is only built by default when targetting a BCM9WCD1EVAL1 motherboard based BCM943362WCD4 module (e.g. the BCM943362WCD4_EVB development kit).

This program tests various aspects of the basic platform port. The basic test can be used to validate the LED and push-button GPIO operation. Depending on the eCos configuration further testing of the flash (detecting on-chip and motherboard SPI devices) and ADC device access is performed.

When flash support is configured the test will display the memory address ranges for the flash areas.

Note

Whereas the on-chip flash is directly addressable, the off-chip SPI flash is given a logical address for use through the flash API but it is not actually memory mapped.

When ADC support is configured the **manual** program tests the ADC driver for the STM32. The only device connected to the ADC on the board is the thermistor connected to ADC1 logical channel 3, named TH1 on the motherboard. In addition the test also report the values of the Temperature, Vrefint and Vbat inputs that are sourced on-chip.

Chapter 309. BCM943364WCD1 Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_BCM943364WCD1` — eCos Support for the BCM943364WCD1 WICED Module

Description

This documentation describes the platform-specific elements of the STM32F411 based BCM943364WCD1 WICED module support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support.

For this platform, the expected eCos development model is that programs may be downloaded and debugged via a hardware JTAG debugger. Nevertheless it is still possible to program a GDB stub image into the on-chip Flash and download and debug eCos applications with the GDB debugger via available UART pins.

Supported Hardware

The BCM943364WCD1 module consists primarily of a STM32F411RE CPU and a BCM43364 Wi-Fi CoB.

The base BCM943364WCD1 module exposes a set of I/O pins that are used to provide functionality based on the configuration of the STM32F4 host CPU on the module. This platform HAL optionally provides the ability to target the module as installed on the BCM943364WCD1_EVB development kit (a BCM943364WCD1 module installed on a BCM9WCD9EVAL1 motherboard).

Note

The BCM9WCD9EVAL1 motherboard is intended for evaluating 44-pin WICED modules.

The STM32F411RE has two main on-chip memory regions. The device has a SRAM region of 128KiB present at 0x20000000, and a 512KiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution).

The STM32 variant HAL includes support for the three on-chip serial devices which are documented in the variant HAL, however it is assumed that only USART1 is available.

Device drivers are also provided for the STM32 on-chip SPI interfaces, I²C interfaces, watchdog, RTC (wallclock) and Flash.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3j, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.32.2.

Name

Setup — Preparing the Broadcom BCM943364WCD1 for eCos Development

Overview

Given the limited available RAM memory, it is expected that the most common development method is to use JTAG for development, either by loading smaller applications into the on-chip SRAM, or by programming larger applications directly into on-chip Flash. In the first case, eCos applications should be configured for the `SRAM` startup type, and in the second case for `ROM` startup type.

Nevertheless, it is still possible to program a GDB stub ROM image into on-chip Flash and download and debug via a serial UART, if pins for the UART are available. In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This rate can be changed in the eCos configuration used for building the GDB stub ROM image.

HAL startup types

The following startup types may be selected for applications:

Configuration	Description
SRAM	Stand-alone programs running from on-chip SRAM, loaded via JTAG hardware debugger
ROM	Stand-alone programs running from on-chip FLASH
ROMAPP	Stand-alone programs running from an offset into the on-chip FLASH, that are started by a separate boot loader
RAM	Programs loading via a GDB stub ROM into on-chip RAM, which rely on a debug monitor

Further details are available later in this manual.

Programming ROM images

To program ROM startup applications into Flash, including the GDB stub ROM, a JTAG debugger that understands the STM32 flash may be used, such as the OpenOCD tool. The **openocd** GDB server can directly program flash based applications from the GDB **load** command.

For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the "bootup.elf" application into the on-chip flash:

```
$ arm-eabi-gdb install/bin/bootup.elf
GNU gdb (eCosCentric GNU tools 4.7.3g) 7.6.1
[ … GDB output elided … ]
(gdb) target remote localhost:3333
hal_reset_vsr () at path/hal_misc.c:171
(gdb) load
Loading section .rom_vectors, size 0x14 lma 0x8000000
Loading section .text, size 0x3adc lma 0x8000018
Loading section .rodata, size 0x6c0 lma 0x8003af8
Loading section .data, size 0x6dc lma 0x80041b8
Start address 0x8000018, load size 18572
Transfer rate: 14 KB/sec, 4643 bytes/write.
(gdb)
```

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Rebuilding the GDB stub

Should it prove necessary to rebuild a GDB stub ROM binary, this is done most conveniently at the command line. For the `bcm943364wcd1_evb` platform the steps needed are:

```
$ mkdir gdbstub_bcm943364wcd1_evb
$ cd gdbstub_bcm943364wcd1_evb
$ ecosconfig new bcm943364wcd1_evb stubs
[ … ecosconfig output elided … ]
$ ecosconfig tree
$ make
```

At the end of the build, the `install/bin` subdirectory should contain the file `gdb_module.bin`. This may be programmed to the board using the above procedure.

Name

Configuration — Platform-specific Configuration Options

Overview

The Broadcom BCM943364WCD1 module platform HAL package is loaded automatically when eCos is configured for the `bcm943364wcd1` or `bcm943364wcd1_evb` targets. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The Broadcom BCM943364WCD1 module platform HAL package supports four separate startup types:

SRAM

> This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from `hal_virtual_vector_table_end` and entered at that address. Memory below `hal_virtual_vector_table_end` is set aside for vector tables. eCos startup code will perform all necessary hardware initialization.

ROM

> This startup type can be used for finished applications which will be programmed into internal Flash ROM at location `0x08000000`. Data and BSS will be put into internal SRAM starting from `hal_virtual_vector_table_end`. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the `0x08000000` region. eCos startup code will perform all necessary hardware initialization.

ROMAPP

> This startup type can be used for finished applications which will be programmed into internal Flash ROM at the `CYGIMP_BOOTUP_RESERVED` configured offset. This is a variation of the `ROM` startup type for applications that are started by a smaller boot loader application. eCos startup code will perform all necessary hardware initialization.

RAM

> This is the startup type which is used if relying on a GDB stub ROM image programmed into internal Flash to download and run applications into SRAM via arm-eabi-gdb and a serial UART. RAM from `0x20000000` to `0x20001000` is reserved for the GDB stub, but then the RAM startup application may be loaded into memory from `0x20001000` and debugged using GDB. It is assumed that the hardware has already been initialized by the GDB stub ROM. By default the application will use the eCos virtual vectors mechanism to obtain services from the GDB stub ROM, including diagnostic output.

Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB stub ROM (or RedBoot).

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a `RAM` startup, and disabled otherwise. It can be manually disabled for a `RAM` startup, making the application self-contained, as a testing step before switching to `ROM` startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The BCM943364WCD1 module uses the STM32's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, is only expected to be available to be used on the USART1 port (counting the first UART as UART1).

As well as the polled HAL diagnostic interface, there is also a CYGPKG_IO_SERIAL_CORTEXM_STM32 package which contains all the code necessary to support interrupt-driven operation with greater functionality. All three UARTs can be supported by this driver. For the BCM943364WCD1 module however the available I/O pins impose a limit on the available functionality.

Note

It is not recommended to use this driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option (within the generic serial driver support package CYGPKG_IO_SERIAL) is enabled in the configuration. By default this will only enable support in the driver for the USART1 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports. Note that in this package, serial port numbering starts at 0, rather than 1. So for example, to enable the serial driver for ports USART1 and USART2, enable the configuration options “ST STM32 serial port 0 driver” (CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL0) and “ST STM32 serial port 1 driver” (CYGPKG_IO_SERIAL_CORTEXM_STM32_SERIAL1).

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (CYGPKG_DEVS_SPI_CORTEXM_STM32).

For the base BCM943364WCD1 module SPI bus 1 and bus 2 are configured for off-module SPI connections.

When targetting the BCM9WCD9EVAL1 based bcm943364wcd1_evb platform then the SPI1 flash memory device m25pxx_spi_device is enumerated.

To disable support for both the above SPI devices, the platform HAL contains an option “SPI devices” (CYGPKG_HAL_CORTEXM_STM32_BCM943364WCD1_SPI) which can be disabled. No other SPI devices are instantiated.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (CYGPKG_DEVS_FLASH_STM32) package. This driver is enabled automatically if the generic “Flash device drivers” (CYGPKG_IO_FLASH) package is included in the eCos configuration.

The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the BCM943364WCD1 module.

A number of other aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including the GDB stub ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M3 core of the STM32 only supports six such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

The base BCM943364WCD1 module exposes the STM32F411RE JTAG/SWD signals on the module connectors TP7..TP11. A suitable hardware connection would be required to allow JTAG debugging. The BCM943364WCD1_EVB kit provides a standard 20-pin ARM JTAG header J3, but by default the module JTAG connection is configured to use the BCM9WCD9EVAL1 motherboard FT2232 connection presented via the USB J4 connector. Direct support for this USB interface is provided by the WICED-SDK supplied OpenOCD binary.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

Normally a notable disadvantage with JTAG debugging is that it does not allow thread-aware debugging, such as the ability to inspect different eCos threads or their stack backtraces, set thread-specific breakpoints, and so on. Fortunately the Ronetix PEEDI JTAG unit does support thread-aware debugging of eCos applications, however extra configuration steps are required. Consult the PEEDI documentation for more details as usage is beyond the scope of this document.

OpenOCD notes

The following OpenOCD documentation uses as an example the BCM943364WCD1_EVB J4 USB JTAG connection. An OpenOCD configuration that supports the `ft2232` interface and understands the `ft2232_layout BCM9WCD1EVAL1` configuration must be used, Such an **openocd** is pre-built and available in the WICED-SDK. For example WICED-SDK revision 3.5.1 the necessary host binaries can be found in the directory `WICED-SDK-3.5.1/tools/OpenOCD`.

An example OpenOCD configuration file `openocd.bcm943364wcd1_evb.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/stm32/bcm943364wcd1/`*`VERSION`*`/misc` relative to the root of your eCos installation.

This configuration file can be used with the WICED-SDK supplied OpenOCD on the host as follows:

```
$ ./Linux64/openocd-all-brcm-libftdi -f openocd.bcm943364wcd1_evb.cfg
Open On-Chip Debugger 0.9.0-00029-g33ca6ac-dirty (2015-05-28-14:31)
Licensed under GNU GPL v2

```

By default **openocd** provides a console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

Normally **arm-eabi-gdb** is used to connect to the default GDB server port `3333` for debugging. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x00000000 in ?? ()
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then, if required, you can define a “preload” gdb macro to emit any necessary commands to OpenOCD. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Broadcom BCM943364WCD1 module hardware and should be read in conjunction with the specification for that device. The BCM943364WCD1 platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target module, and optionally, specifically supported motherboards.

Targetting the eCos platform `bcm943364wcd1` will configure eCos for a stand-alone BCM943364WCD1 module with no assumption made about the I/O connected to the module TP pins.

Targetting the `bcm943364wcd1_evb` platform will configure eCos for a BCM9WCD9EVAL1 motherboard based module, and provide access to the LEDs, switches, thermistor and SPI flash device available on that motherboard.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For the stand-alone application startup types, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/bcm943364wcd1_misc.c` in both the `hal_system_init` and `hal_platform_init` functions.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM
: This is located at address `0x20000000` of the memory space, and is 128KiB in size. The eCos VSR table always occupies the initial bytes at the base of this memory, followed by the optional virtual vector table depending on the eCos configuration. The top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of memory are reserved for the interrupt stack. The remainder of on-chip SRAM is available for use by applications.

Internal FLASH
: This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 512KiB in size. and `ROM` applications are by default configured to run from this memory.

On-Chip Peripherals
: These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the relevant STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for `CYGNUM_HAL_VSR_COUNT` entries is reserved to match the use of a STM32F2 processor.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, and is normally `0x20000198` for STM32F4 targets.

The CDL option `CYGSEM_HAL_VIRTUAL_VECTOR_SUPPORT` defines whether this virtual vector support is needed. If not defined then the table is zero sized.

hal_virtual_vector_table_end
: This defines the location of the end of the (optional) virtual vector table.

hal_interrupt_stack
: This defines the location of the interrupt stack. For all startup types this is allocated to the top of internal SRAM, at `0x20020000`.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack. The size of the interrupt stack is defined by the CDL option `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE`.

Flash wait states

The BCM943364WCD1 platform HAL provides a configuration option to set the number of Flash read wait states to use: `CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES`. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the STM32 Flash programming manual (PM0059) for appropriate values for different clock speeds or voltages. The default of `3` reflects a supply voltage of 3.3V and HCLK of 100MHz.

Diagnostic LEDs

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow any LEDs to be set:

```
extern void hal_bcm943364wcd1_led(unsigned char c);
```

The low-order bits of the argument `c` correspond to individual LEDs.

The default BCM943364WCD1 module support does not provide LEDs, since the relevant off-module GPIO signals are not defined. However, when targetting the BCM9WCD9EVAL1 motherboard two LEDs are fitted for diagnostic purposes: D4 (red) and D3 (green). These LEDs are free for application use. The `bcm943364wcd1_evb`**manual** test provides a simple example of changing the LED state.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for the `bcm943364wcd1_evb` platform using the `SRAM` startup type and optimization flag -O2.

Example 309.1. bcm943364wcd1 Real-time characterization

```
             Startup, main thrd : stack used   352 size  1536
             Startup : Idlethread stack used    84 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    8.50 microseconds (8 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   8
   Thread switches:         128

Name

Test Programs — Details

Test Programs

The BCM943364WCD1 platform HAL contains a test suitable for the `bcm943364wcd1_evb` platform, that allows various aspects of that board to be tested.

Manual Test

The **manual** test is only built by default when targetting a BCM9WCD9EVAL1 motherboard based BCM943364WCD1 module (e.g. the BCM943364WCD1_EVB development kit).

This program tests various aspects of the basic platform port. The basic test can be used to validate the LED and push-button GPIO operation. Depending on the eCos configuration further testing of the flash (detecting on-chip and motherboard SPI devices) and ADC device access is performed.

When flash support is configured the test will display the memory address ranges for the flash areas.

Note

Whereas the on-chip flash is directly addressable, the off-chip SPI flash is given a logical address for use through the flash API but it is not actually memory mapped.

When ADC support is configured the **manual** program tests the ADC driver for the STM32. The only device connected to the ADC on the board is the thermistor connected to ADC1 logical channel 3, named TH1 on the motherboard. In addition the test also report the values of the Temperature, Vrefint and Vbat inputs that are sourced on-chip.

Wi-Fi firmware

With a suitable eCos configuration the **manual** application can be used to initialise the off-chip SPI flash memory on the BCM9WCD9EVAL1 motherboard. The use of the off-chip flash will normally be required for this platform due to the limited on-chip flash space with which to hold both an application and the required radio firmware binary.

The following example uses the command-line **ecosconfig** tool, though, as always, the necessary configuration changes can be performed using the graphical **configtool** tool if desired. This configuration is just being used to build a `DIRECT` application containing a copy of the firmware binary, and to allow that image to be written to the off-chip flash memory. It is not envisaged that real-world applications for this platform will make use of the `DIRECT` mode due to the limited space remaining for applications.

Prior to creating the actual configuration some non-default options should be placed into a file suitable for importing. These are used to ensure the correct configuration for the firmware update build of the **manual** application. This example assumes the following has been placed into the file `tmp.ecm`.

```
cdl_option CYG_HAL_STARTUP { user_value ROM };
cdl_option CYGFUN_NET_WIFI_BROADCOM_WWD_RESOURCES_INDIRECT { user_value 0 };
cdl_option CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE { user_value "gdb_hwdebug_fileio" };
```

Once the configuration fragment file has been created then the application can be configured and built using the following command sequence:

```
$ ecosconfig new bcm943364wcd1_evb lwip_eth
$ ecosconfig add CYGPKG_IO CYGPKG_IO_FLASH CYGPKG_CRC
$ ecosconfig import tmp.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
$ make tests
```

The resulting `install/tests/hal/cortexm/stm32/bcm943364wcd1/current/tests/manual` application will then validate, and update appropriately if required, the off-chip firmware image. The firmware binary image included in the application is as defined by the selected WWD SDK. A successful run of the application will be similar to:

```
INFO:<Manual Test>
FLASH: 0x08000000-0x0807ffff, 4 x 0x4000 blocks, 1 x 0x10000 blocks, 3 x 0x20000 blocks
FLASH: 0xc0000000-0xc00fffff, 16 x 0x10000 blocks
INFO:<WWD configuration PLATFORM "BCM943364WCD1_EVB" SDK "3.5.2">
INFO:<WWD firmware image required and platform is INDIRECT capable>
INFO:<DIRECT F/W CRC 4585C974 mismatch against INDIRECT F/W CRC 48D488E3>
... Unlocking from 0xc0000000-0xc007ffff: ........
... Erase from 0xc0000000-0xc007ffff: ........
PASS:<Erased INDIRECT area C0001000-C0080000>
... Program from 0x080070dc-0x0805e5b0 to 0xc0001000: ......
PASS:<Programmed INDIRECT area>
... Locking from 0xc0000000-0xc007ffff: ........
PASS:<Current F/W image written to INDIRECT area with CRC 4585C974>
[ … rest of output elided … ]
```

Re-running the application will report that the off-chip image matches:

```
INFO:<Manual Test>
FLASH: 0x08000000-0x0807ffff, 4 x 0x4000 blocks, 1 x 0x10000 blocks, 3 x 0x20000 blocks
FLASH: 0xc0000000-0xc00fffff, 16 x 0x10000 blocks
INFO:<WWD configuration PLATFORM "BCM943364WCD1_EVB" SDK "3.5.2">

```

Subsequently, normal WWD Wi-Fi applications will use the `CYGFUN_NET_WIFI_BROADCOM_WWD_RESOURCES_INDIRECT` enabled support to allow all of the on-chip memory for application use; with the code loading the firmware binary from the off-chip storage.

Chapter 310. STM32L4R9-DISCO Platform HAL

Name

`CYGPKG_HAL_CORTEXM_STM32_STM32L4R9_DISCO` — eCos Support for the STM32L4R9-DISCO Board

Description

This documentation describes the platform-specific elements of the ST STM32L4R9I_DISCO board support within eCos. It should be read in conjunction with the STM32 variant HAL section, which covers the common functionality shared by all STM32 variants, including eCos HAL features and on-chip device support.

The board is equipped with an on-board ST-Link interface, which is typically used for eCos application development. There is also a TAG connector (CN8) available for a direct SWD debug connection.

Supported Hardware

The STM32L4R9AI has two main on-chip memory regions. The device has a SRAM region of 640KiB present at 0x20000000, and a 2MiB FLASH region present at 0x08000000 (which is aliased to 0x00000000 during normal execution). A 512Mbit MX25LM51245G Octo SPI flash device is available through the OCTOSPI controller. A 16Mbit PSRAM device provides an off-chip RAM area after the initialisaton of the system (the MFX I/O expander is used to configure the H/W appropriately).

The STM32 variant HAL includes support for the six on-chip serial devices. These consist of three USARTs, two UARTs and a LPUART. These are all supported by a common driver and are documented in the variant HAL. However, the STM32L4R9-DISCO motherboard only makes use of two of these. USART2 is routed to the on-board ST-Link and presented as a CDC-ACM device on the CN13 USB connector. USART3 is routed to the DSI with its hardware RTS/CTS flow control lines.

The STM32 variant HAL also includes support for the I²C buses. Support is provided for the on-board MFX I/O expander and audio codec I²C devices, with both being on bus 1. The descriptors are exported in the normal way via `<cyg/io/i2c.h>`, with the respective names `hal_st_mfx` and `hal_stm32l4r9_disco_cs42l51`.

Similarly the STM32 variant HAL includes support for the SPI buses. Though the board does not provide any SPI devices as standard.

Device drivers are also provided for the STM32 on-chip, ADC devices. The internal channels are available, with some I/O pins on the connectors available for analog input.

Additionally, support is provided for the on-chip watchdog, RTC (wallclock) and a Flash driver exists to permit management of the STM32's on-chip Flash and the off-chip Quad SPI NOR flash.

The STM32L4 processor and the STM32L4R9-DISCO board provide a wide variety of peripherals, but unless support is specifically indicated, it should be assumed that it is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 7.3.0c, **arm-eabi-gdb** version 8.1, and **binutils** version 2.23.2.

Name

Setup — Preparing the STM32L4R9-DISCO Board for eCos Development

Overview

The STM32L4R9-DISCO motherboard incorporates a ST-Link interface, which is used to provide hardware debug support for eCos application development. Applications can be loaded, run and debugged either via the command line GDB debugger **arm-eabi-gdb**, or via the Eclipse IDE. These host tools communicate with the target via a “GDB server” intermediary that supports a specific JTAG-based hardware debugger (e.g. **JLinkGDBServer** for the Segger J-Link, or **OpenOCD** for the J-Link and other hardware debuggers).

Normally for release applications the `ROM` startup type would be used, with the application programmed into the on-chip flash for execution when the board boots. It is still possible to use the hardware debugging support to debug such flash-based ROM applications, and this may be the desired approach if the application is too large for execution from on-chip SRAM, or where all of the SRAM is required for application run-time use.

If off-chip Non-Volatile Memory (NVM) is used to hold the main application then the board can boot from the internal flash using a suitable boot loader. For example, the eCosPro BootUp ROM loader, where the BootUp code can start the main application (after an optional update sequence).

If required, it is still possible to program a GDB stub or RedBoot `ROM` image into on-chip Flash and download and debug via a serial connection (using USART1). In that case, eCos applications are configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE as appropriate. However, the space available to applications with this approach is so limited as to make it essentially impractical.

Programming ROM images

The JTAG connection and suitable host software (e.g. The OpenOCD package **openocd** tool, or the Segger J-Link **JLinkGDBServer**) can be used to program the flash.

Both these GDB servers can directly program flash based applications from the GDB **load** command. For example, assuming that **openocd** is running on the same host as GDB, and is connected to the target board the following will program the “bootup.elf” application into the on-chip flash:

```
$ arm-eabi-gdb install/bin/bootup.elf
GNU gdb (eCosCentric GNU tools 7.3.0c) 8.1
[ … GDB output elided … ]
(gdb) target remote localhost:3333
hal_reset_vsr () at path/hal_misc.c:171
(gdb) load
Loading section .rom_vectors, size 0x14 lma 0x8000000
Loading section .text, size 0x3adc lma 0x8000018
Loading section .rodata, size 0x6c0 lma 0x8003af8
Loading section .data, size 0x6dc lma 0x80041b8
Start address 0x8000018, load size 18572
Transfer rate: 14 KB/sec, 4643 bytes/write.
(gdb)
```

If using **JLinkGDBServer**, the approach is identical, apart from using port 2231 to connect to the server.

Alternatively, the **openocd** telnet interface can be used to manually program the flash. By default the **openocd** session provides a comand-line via port `4444`. Consult the OpenOCD documentation for more details if a non-default **openocd** configuration is being used.

With a **telnet** connection established to the **openocd** any binary data can easily be written to the on-chip flash. e.g.

```
$ telnet localhost 4444
```

```
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
Open On-Chip Debugger
> flash write_image test.bin 0x08000000
wrote 32518 bytes from file test.bin in 1.073942s (29.569 KiB/s)
```

To create a binary for flash programming the **arm-eabi-objcopy** command is used. This converts the, ELF format, linked application into a raw binary. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The STM32L4R9-DISCO board platform HAL package `CYGPKG_HAL_CORTEXM_STM32_STM32L4R9_DISCO` is loaded automatically when eCos is configured for the `stm32l4r9_disco` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STM32L4R9-DISCO board platform HAL package supports four separate startup types:

ROM
: This startup type can be used for finished applications which will be programmed into internal flash at location 0x08000000. Data and BSS will be put into internal SRAM starting from 0x200002D8. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

ROMAPP
: This startup type can be used for finished applications which will be programmed into internal flash at location 0x08008000. Data and BSS will be put into internal SRAM starting from 0x200002D8. Internal SRAM below this address is reserved for vector tables. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x08000000 region. eCos startup code will perform all necessary hardware initialization.

  This startup type is identical to the ROM startup with the exception of the flash base address. It is used for applications that can be started or updated by BootUp.

SRAM
: This startup type can be used for finished applications which will be loaded into internal SRAM via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x200002D8 and entered at that address. eCos startup code will perform all necessary hardware initialization.

RAM
: When the board has RedBoot (or a GDB stub ROM) programmed into internal Flash at location 0x08000000 then the arm-eabi-gdb debugger can communicate with a suitably configured UART connection to load and debug applications. An application is loaded into memory from 0x20001000. It is assumed that the hardware has already been initialized by RedBoot. By default the application will *not* be stand-alone, and will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

  ### Warning

  RedBoot can have an adverse affect on the real-time performance of applications.

It should be noted that due to the MFX I/O expander needing to be used to configure the hardware for correct PSRAM operation there is no direct startup type for loading and executing applications from PSRAM. However, there is nothing to stop a suitable boot loader from initialising the hardware appropriately and application code subsequently being loaded into and executed from the PSRAM.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option CYGSEM_HAL_USE_ROM_MONITOR should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

Note

Though, as previously discussed, since the option of hardware debugging is available as standard on the STM32L4R9-DISCO platform, and space in the SRAM is limited, it is unlikely that the RAM startup type would be used for development.

SPI Driver

An SPI bus driver is available for the STM32 in the package “ST STM32 SPI driver” (CYGPKG_DEVS_SPI_CORTEXM_STM32).

No SPI devices are instantiated for this platform by default.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the STM32 SPI device driver.

I²C Driver

The STM32 variant HAL provides the main I²C hardware driver itself, configured at CYGPKG_HAL_STM32_I2C. However, the platform I²C support can also be configured separately at CYGPKG_HAL_CORTEXM_STM32_STM32L4R9_DISCO_I2C. This enables I²C bus 1. Some board H/W features are routed via the I²C MFXv3 I/O expander device, and as such, the support for bus 1 is enabled by default. An audio codec is also available on this bus and is instantiated with the name hal_stm32l4r9_disco_cs42l51. The instantiated device is available for applications via <cyg/io/i2c.h>.

ADC Driver

The STM32 processor variant HAL provides an ADC driver. The STM32L4R9-DISCO platform HAL enables the support for the device ADC1 and for configuration of the respective ADC device input channels.

Consult the generic ADC driver API documentation in the eCosPro Reference Manual for further details on ADC support in eCosPro, along with the configuration options in the STM32 ADC device driver.

Flash Driver

The STM32's on-chip Flash may be programmed and managed using the Flash driver located in the “STM32 Flash memory support” (CYGPKG_DEVS_FLASH_STM32) package. This driver is enabled automatically if the generic “Flash device drivers” (CYGPKG_IO_FLASH) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific STM32 variant present on the STM32L4R9-DISCO board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver for more details.

OCTOSPI Flash Driver

When OCTOSPI NOR flash support is enabled in the configuration with CYGHWR_HAL_CORTEXM_STM32_FLASH_OCTOSPI, then the cyg_stm32_octospi1_device device is exported and can be accessed via the standard flash API. The device is given a logical base address to match its physical base address of 0x90000000 (corresponding to FMC bank 4) when it is memory mapped (if CYGFUN_DEVS_FLASH_OCTOSPI1_CORTEXM_STM32_MEMMAPPED is enabled in the OCTOSPI driver, which is not the default). When memory mapping is disabled, using the eCos Flash API will still allow the device to be read/written at that logical base address.

Name

SWD support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M4 core of the STM32L4R9 only supports a limited number of such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

J-Link Support

The preferred debug device for this board is the on-board ST-Link debug interface probe. This also has the benefit fof routing USART2 as a standard USB CDC-ACM terminal.

Initialization scripts that support debugging the board via either the OpenOCD or J-Link GDB servers can be found in the directory `packages/hal/cortexm/stm32/stm32l4r9_disco/`*`VERSION`*`/misc` relative to the root of your eCos installation.

For **JLinkGDBServer**, the file `stm32l4r9_disco.jlink`, provides initialization for the board and should be used in the following command line:

```
    $ JLinkGDBServer -device STM32L4R9AI -xc stm32l4r9_disco.jlink
```

Similarly OpenOCD may be invoked with the following command line:

```
    $ openocd -f openocd.stm32l4r9_disco.cfg
```

Configuration of JTAG applications

JTAG/SWD applications can be loaded directly into SRAM or flash without requiring a ROM monitor. Loading can be done directly through the JTAG/SWD device, or through GDB where supported by the JTAG/SWD device.

In order to configure the application to support these modes, it is recommended to use the `SRAM`, `ROM` or `ROMAPP` startup types which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could be made by hand, but use of the aformentioned startup types will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel, by default USART2 on ST-Link USB CN13. An eCosCentric extension allows diagnostic output to appear on the GDB console, or on the Eclipse console. To enable this feature, you must set the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. If you are using the graphical configuration tool then you should then accept any suggested solutions to the subsequent configuration conflicts. Older eCos releases also required the gdb "set hwdebug on" command to be used to enable GDB or Eclipse console output, but this is no longer required with the latest tools.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STM32L4R9-DISCO board hardware, and should be read in conjunction with that specification. The STM32L4R9-DISCO platform HAL package complements the Cortex-M architectural HAL and the STM32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services.

For `ROM`, `ROMAPP` and `SRAM` startup types the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/stm32l4r9_disco_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. For all the STARTUP variations the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes of the on-chip SRAM are reserved for the interrupt stack. The remainder of the internal SRAM is available for use by applications. The key memory locations are as follows:

Internal SRAM

This is located at address `0x20000000` of the memory space, and is 640KiB in size. The eCos VSR table occupies the bottom 444 bytes of memory, with the virtual vector table starting at `0x200001BC` and extending to `0x200002D8`.

Internal FLASH

This is located at address `0x08000000` of the memory space and will be mapped to `0x00000000` at reset. This region is 2048KiB in size. `ROM` and `ROMAPP` applications are by default configured to run from this memory.

OCTOSPI NOR Flash

The OCTOSPI NOR flash is accessible through the flash API. It is partitioned between the alternate application image and test space for the JFFS2 flash file system. The alternate application image occupies the first 1Mbyte of the OCTOSPI flash. The JFFS2 test space currently occupies the next 256Kbytes. The space allocated for the alternate application image may be adjusted by changing `STM32L4_BOOTUP_ALTERNATIVE_OFFSET` and `STM32L4_BOOTUP_ALTERNATIVE_MAXLEN` in `plf_arch.h`. The JFFS2 test space is defined in `__STM32L4R9_DISCO_FLASHTEST_OCTOSPI` in `plf_io.h`. Applications would not normally use this to define their JFFS2 filesystem location, but use the device/offset/length placement device format in the filesystem `mount()` call.

On-Chip Peripherals

These are accessible at locations `0x40000000` and `0xE0000000` upwards. Descriptions of the contents can be found in the STM32 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table

This defines the location of the VSR table. This is set to `0x20000000` for all startup types, and space for 111 entries is reserved.

hal_virtual_vector_table

This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at `0x200002BC`.

hal_interrupt_stack This defines the location of the interrupt stack. This is allocated to the top of internal SRAM, from `0x200A0000` down.

hal_startup_stack This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Flash wait states

The STM32L4R9-DISCO platform HAL provides a configuration option to set the number of Flash read wait states to use: `CYGNUM_HAL_CORTEXM_STM32_FLASH_WAIT_STATES`. It is important to verify and if necessary update this value if changing the CPU clock (HCLK) frequency or CPU voltage. Consult the relevant STM32 datasheets and programming manuals for the STM32L476 parts for appropriate values for different clock speeds or voltages. The default of 5 reflects a supply voltage in Vcore range 1 and HCLK of 120MHz.

Real-time characterization

The **tm_basic** kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for `SRAM` startup with optimization flag -O2, since it provides the best performance as both code and data could remain on-chip.

Example 310.1. stm32l4r9_disco Real-time characterization

```

Name

Test Programs — Details

Test Programs

The STM32L4R9-DISCO platform HAL contains some test programs which allow various aspects of the board to be tested.

ADC Test

The **adc1** program tests the ADC driver for the STM32. The test reports the values of the Vrefint, Vbat and Vts inputs that are sourced on-chip. The option `CYGBLD_HAL_CORTEXM_STM32L4R9_DISCO_TESTS_ADC` must be enabled to run this test since it needs human interaction.

Name

BootUp Integration — Detail

BootUp

The BootUp support for the STM32L4R9-DISCO target is primarily implemented in the `stm32l4r9_disco_support.c` file. The majority of the functions provided by that source file are only included when the `CYGPKG_BOOTUP` package is being used to construct the actual BootUp ROM loader binary.

The BootUp code is designed to be very simple, and it is envisaged that once its implementation has been tested and validated, the binary will only need to be installed onto a device once. Its only purpose is to allow the safe updating and startup of the main application. If the BootUp code ever needs to be replaced then it is a “factory” operation, for example using JTAG to re-program the on-chip flash.

This platform specific documentation should be read in conjunction with the generic BootUp package.

The BootUp package provides a basic but fully functional implementation for the platform. This has been tested to ensure that the underlying mechanism is sound. It is envisaged that the developer will customize and further extend the platform side support to meet their specific application update requirements.

BootUp loaded applications

Applications started via the BootUp loader, since they cannot include the `CYGPKG_BOOTUP` package themselves, may need access to some related configuration state. The platform is responsible for providing such “common” information. For example, the CDL option `CYGIMP_BOOTUP_RESERVED` specifies the amount of on-chip flash set aside for BootUp. Applications can then ensure that they do not interfere with the BootUp loader if using the remaining on-chip flash for their own purposes.

Warning

Care must be taken to ensure that the target application configuration matches the BootUp configuration, since it is normally expected that the applications to be loaded will be independent of the initial BootUp build environment. This includes the fundamental on-chip flash space set aside for the BootUp ROM loader code (`CYGIMP_BOOTUP_RESERVED`). It is expected that such values, for a particular platform instance, will be *fixed* at a suitable point during development, and definitely before products are shipped. It is the responsibility of the developer to ensure a consistent configuration between the BootUp ROM loader and any applications that may be installed/started by that BootUp code.

On-Chip ROMAPP applications

BootUp provides an alternative mechanism that supports the safe update of on-chip flash resident (`CYG_HAL_STARTUP_ROMAPP`) applications.

Updates using this mechanism are initiated and directed solely by the application itself. The application is responsible for locating, acquiring and verifying a new update, and placing it into Non-Volatile Memory (NVM) storage. If BootUp detects a verified update in NVM, it installs the update into the on-chip flash, overwriting and replacing the existing application. The updated application is then executed.

The example implementation uses a simple scheme that checks a fixed-format contiguous structure near the start of the binary application image file. Other than the fields used to identify the structure, the BootUp code does not interpret the hal_stm32l4r9_disco_bootup_structure_t in any other way.

Depending on how the alternative (pending update) application is downloaded and installed in the NVM, it may be more relevant to have the `tail` marker at the very end of the binary image. The developer may wish to update the build/release process so that the actual binary length is held in the application description structure, since that could avoid the overhead of unnecessary flash reads and writes when processing updates. Similarly, instead of a simple binary number being used to differentiate application images, the choice may be made to use the 64-bit UTC timestamp the application was created, or a human-readable string as the unique identification for a release. It is the responsibility of the build/release engineer to ensure individual releases are uniquely identifiable.

It is *critical* that the main application, when storing a pending update, stores the `tail` marker as the last bytes written. It is the responsibility of the main application to verify the data written, prior to placing the `tail` marker. This ensures that a partial image is not treated as a valid update. For example the sequence undertaken by the main application would be:

Table 310.1. Pending update sequence

Operation	Details
Invalidate “previous” alternative image	At a minimum ensure an invalid signature `tail` marker is written. Erasing the flash is normally required anyway, and would invalidate any previous image.
Receive update application image and write to alternative image location	NOT writing the `tail` marker. The code that stores the application should leave a “hole” where the `tail` marker resides to ensure a partial image is not incorrectly treated as valid
Verify downloaded contents	e.g. CRC or binary comparison. Normally this would be done as individual application chunks are downloaded and written to the alternative storage
Write `tail` marker	This is the very last operation after validating that the alternative image has been stored correctly. If an error has occured during the download then not-writing the `tail` ensures that the BootUp loader will not interpret the data written as a pending update
Force system RESET to start update	e.g. using the `HAL_PLATFORM_RESET` macro

The BootUp loader code will only READ from the alternative image location. This ensures that if an in-progress update is interrupted (e.g. power-loss) then when the system restarts the BootUp code will restart the application update as required.

If the BootUp platform implementation for validating the alternative image is extended to include a CRC, or similar “slow” processing, it may be worth considering whether the main application on startup will always invalidate the `tail` marker after an update to avoid subsequent system resets having to re-validate the alternative image prior to discovering that it is the same as the current main application.

Note

We cannot have the SIGNATURE support purely conditional on the BOOTUP support; since non-BOOTUP applications need to be built leaving the space. For the moment this is only enforced for ROMAPP applications, since that is all that the simple BootUp update support implements.

Building BootUp

The `ROM` startup type is chosen for BootUp so that the loader uses the on-chip SRAM for its workspace.

Example eCos configuration templates for BootUp are provided in the `misc` directory of the release. The `bootup_ROM.ecm` configuration file can be used to configure the BootUp loader.

Building a BootUp ROM image is most conveniently done at the command line. The steps needed to rebuild the ROM version of BootUp on linux are:

```
$ mkdir bootup_rom
$ cd bootup_rom
$ ecosconfig new stm32l4r9_disco minimal
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm32l4r9_disco/current/misc/bootup_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The steps needed to rebuild the bundle based ROM version of BootUp on Windows within the Shell Environment are:

```
C:\Users\demo> mkdir bootup_rom
C:\Users\demo> cd bootup_rom
C:\Users\demo\bootup_rom> ecosconfig new stm32l4r9_disco minimal
[ … ecosconfig output elided … ]
C:\Users\demo\bootup_rom> ecosconfig import %ECOS_REPOSITORY%/hal/cortexm/stm32/stm32l4r9_disco/current/misc/bootup_ROM.ecm
C:\Users\demo\bootup_rom> ecosconfig resolve
C:\Users\demo\bootup_rom> ecosconfig tree
C:\Users\demo\bootup_rom> make
```

The resulting `install/bin/bootup.bin` binary can then be programmed into the on-chip flash from address `0x08000000`.

It is expected that the BootUp binary is installed onto the STM32L4S5VI on-chip flash either via JTAG or by utilising the on-chip `BootROM` USB based DFU process. This is a factory or in-field process requiring specific equipment/host-software.

Once BootUp is installed it is not normally expected to require updating. Its purpose is to bootstrap the main application, and provide a standard mechanism for installing the main application. The update mechanism does *NOT* provide a method for updating the BootUp loader itself. If in-field updates of the BootUp binary are necessary, this could be achieved via the STM32 on-chip `BootROM` USB based DFU process.

Altinit Test

This application is used to test BootUp support for updating a ROMAPP application from the QSPI flash. Since there is no Ethernet available on the board, this test uses the application already programmed in to the on-chip flash.

The test expects a ROMAPP application to be stored in the on-chip flash. It erases the alternate application in the QSPI flash, copies the ROMAPP application from on-chip flash into QSPI, and then invalidates the signature of the application in on-chip flash. When BootUp starts it will discover that the main application is invalid, copy the alternate application from the QSPI and then run it.

An example eCos configuration template for building the altinit application is provided in the `misc` directory. The steps needed to build this application are as follows:

```
$ mkdir altinit
$ cd altinit
$ ecosconfig new stm32l4r9_disco kernel
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/stm32/stm32l4r9_disco/current/misc/altinit_SRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
$ make -C hal/cortexm/stm32/stm32l4r9_disco/current tests
```

Following this, the **altinit** executable can be found in `install/tests/hal/cortexm/stm32/stm32l4r9_disco/current/tests/altinit`. Running this will produce the following output:

```
INFO:<STM32L4_BOOTUP_ALTERNATIVE_OFFSET 00008000>
INFO:<STM32L4_BOOTUP_ALTERNATIVE_MAXLEN 000F8000>
INFO:<CYGNUM_BOOTUP_SIGNATURE_OFFSET 8>
INFO:<CYGNUM_BOOTUP_SIGNATURE_LENGTH 16>
INFO:<Erasing MX25L128 area for alternative image>
INFO:<Copy main image to alt>
INFO:<Set signature in alt image>
INFO:<Invalidate main image>
INFO:<Update done>
```

The erase and copy operations here may take a some time, do not reset the board until the program is finished.

Chapter 311. STM32L4R9-EVAL Platform HAL

This documentation is still under development.

Chapter 312. NXP i.MX RT10XX Variant HAL

Name

`CYGPKG_HAL_CORTEXM_IMX` — eCos Support for the NXP i.MX RT10XX Microprocessor Family

Description

The NXP i.MX RT10XX series of Cortex-M microcontrollers is supported by eCos with an eCos processor variant (VAR) HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for the on-chip flash, serial, I²C, SPI, Ethernet, CAN, PWM and watchdog devices. In addition it provides common functionality and definitions that RT10XX based platform ports may require, as well as definitions useful to application developers. Throughout this document this processor family will just be referred to as *i.MX* or *IMX*, without any numerical designations.

This documentation covers the i.MX functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the IMX variant HAL provides. The areas that are specific to platform HALs and not the IMX variant HAL include:

- memory map and related configuration and setup
- Clock parameters
- Pin multiplexing and GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED/LCD control

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

The IMX family contains many on-chip peripherals.

On-chip memory

The IMX parts include on-chip SRAM (`OCRAM`). The SRAM can vary in size from as little as 4KiB to 1MiB. Support is also available for external FLASH and SDRAM.

Typically, an eCos platform HAL port will expect a standalone application image to be programmed into boot memory, and the board would boot this image from reset.

Note

The i.MX RT ROM bootloader will only load and execute SRAM (OCRAM) or memory-mapped flash applications. If your final application is linked for SRAM then creating a bootable image as described in the relevant platform specific documentation is sufficient. For applications that are linked to execute from external memory (e.g. SDRAM) then the first stage of booting an application will be via execution of a second-level boot loader application started by the ROM bootloader. For eCos this second-level is normally BootUp (`CYGPKG_BOOTUP`) or RedBoot (`CYGPKG_REDBOOT`), though it can just as well be a custom application if required.

The i.MX RT ROM bootloader will parse a table describing the initial I/O setup and memory destination for the application image (copying the image if required). This table is known as the DCD (Device Configuration Data).

For embedded development it is normally expected that H/W debugging (JTAG/SWD) via a suitable adapter is used to aid application development of standalone applications. For standalone applications (no dependency on a ROM monitor) there is **no** application binary difference whether the application is started from the i.MX RT ROM bootloader process or loaded via a H/W debugger interface; with the exception that the H/W debugger may need to perform the same actions as the DCD table prior to loading an executable to ensure the MCU setup is the same as execution via the ROM bootloader.

An alternative to H/W debugging using an external adapter is for RedBoot to be installed as the application started by the IMX boot process. RedBoot provides GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels. If RedBoot is present it may also be used to manage the external flash memory. For RedBoot based production purposes, applications are programmed into external FLASH and may be self-booting. Applications may also be loaded into memory using a RedBoot startup script. RedBoot has a memory and performance impact on applications if they are configured to use RedBoot provided functionality. The use of the simple BootUp world instead of RedBoot means that there is no performance or memory impact on the final **standalone** application started by the boot process.

Cache Handling

The RT10XX variants contain an instruction and data cache controller defined as part of the Cortex-M architectural specification. Support for this controller is supplied by the architecture HAL.

The variant HAL provides a mechanism for setting aside a, configurable size, block of `OCRAM` as uncached for device driver and DMA usage.

OCOTP (On-Chip One-Time-Programmable) fuses

The HAL provides for basic `OCOTP` operations. Details are supplied later.

Serial I/O

The IMX variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_NXP_LPUART` which provides support for the IMX on-chip serial devices. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor or RedBoot for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

The HAL defines CDL interfaces, `CYGINT_HAL_CORTEXM_IMX_UART1` to `CYGINT_HAL_CORTEXM_IMX_UART8` for each of the available UARTs. The platform HAL CDL should contain an **implements** directive for each such UART that is available for use on the board. This will enable use of the UART for diagnostic use.

Interrupts

The IMX HAL relies on the architectural HAL to provide support for the interrupts directly routed to the NVIC. The `cyg/hal/var_intr.h` header defines the vector mapping for these.

Pin Multiplexing and GPIO

The variant HAL provides support for packaging the pin, GPIO and daisy chain configurations of an external line into 32-bit descriptors that can then be used with macros to configure the pin and set and read its value. Details are supplied later.

Ethernet

eCos includes a device driver for the on-chip `ENET` Ethernet controllers. This is located in the package `CYGPKG_DEVS_ETH_FREESCALE_ENET` (“Freescale ENET ethernet driver”).

This variant HAL provides some common support for `ENET` interfaces via the initialisation helper function `CYGHWR_FREESCALE_ENET_PLATFORM_INIT(base)` and the IEEE MAC acquisition function `CYGHWR_FREESCALE_ENET_PLATFORM_MAC(base, p_enaddr)`.

Note

The `CYGHWR_FREESCALE_ENET_PLATFORM_MAC()` will attempt to use the `OCOTP` fuses set aside for holding MAC addresses, but from the factory these are unset. In which case for the first `ENET` controller the code will fall back to providing a MAC address based on the `OCOTP` unique ID field.

It is the responsibility of the developer to implement any factory production steps required to fuse a unique MAC address into the relevant `OCOTP` locations as required.

CAN

eCos includes a device driver for the on-chip `FlexCAN` controllers. This is located in the package `CYGPKG_DEVS_CAN_NXP_FLEXCAN` (“NXP FlexCAN driver”).

Watchdog

eCos includes device drivers for the on-chip watchdog in the IMX family. This is located in the package `CYGPKG_DEVICES_WALLCLOCK_NXP` ("NXP wallclock driver").

Clock Control

The platform HAL must provide the input oscillator frequency (`CYGHWR_HAL_CORTEXM_IMX_OSC_MAIN`) in its CDL file. Under normal circumstances this is set to 24MHz.

The actual values of the clock frequencies, is stored in a global structure, `hal_imx_clock`, which contains the PLL frequencies, PFDs and root clocks. The clock supplied to the SysTick timer is also assigned to `hal_cortexm_systick_clock`. These variables are set by examining the actual hardware register so they reflect settings made by any bootloader or JTAG adaptor.

Note that when changing or configuring any of these clock settings, you should consult the relevant processor datasheet as there may be both upper and lower constraints on the frequencies of some clock signals, including intermediate clocks. There are also some clocks where, while there is no strict constraint, clock stability is improved if values are chosen wisely. Finally, be aware that increasing clock speeds using this package may have an effect on platform specific properties, such as memory timings which may have to be adjusted accordingly.

`CYGHWR_HAL_IMX_GPIO_INTMASK (desc, enable);`

`CYGHWR_HAL_IMX_GPIO_INTCLR (desc);`

Description

The IMX HAL provides a number of macros to support the encoding of various hardware configuration options into a 32-bit descriptor. This is useful to drivers and other packages that need to configure the hardware.

PAD Multiplexing

Many of the IO pads on the chip can be connected to a variety of different devices and have a variety of properties that need to be configured. A standard pad descriptor is created by the `CYGHWR_HAL_IMX_PAD()` macro. For the `SNVS` pads connected to `GPIO5` the `CYGHWR_HAL_IMX_SNVS_PAD()` is used instead. The `pad` argument defines the pad to be configured, and follows the hardware naming convention, for example `AD_B0(12)` or `SD_B1(3)`. The `mode` argument is the terminal part of a `CYGHWR_HAL_IMX_PAD_MODE_XXXX` macro; this may be one supplied in the HAL, or one constructed by the driver or application. This macro is defined as a combination of the `CYGHWR_HAL_IMX_PAD_MODE_` definitions in `cyg/hal/var_io.h`, which correspond to the definitions in the hardware pad MUX and CTL registers.

The macro `CYGHWR_HAL_IMX_PAD_SET()` is used to configure a pad according to the descriptor.

The following example shows how the LPUART pads are configured.

```
#define CYGHWR_HAL_IMX_PAD_MODE_LPUART_PAD(__alt)       \
        CYGHWR_HAL_IMX_PAD_MODE_MUX(__alt)      |       \
        CYGHWR_HAL_IMX_PAD_MODE_PUE             |       \
        CYGHWR_HAL_IMX_PAD_MODE_PKE             |       \
        CYGHWR_HAL_IMX_PAD_MODE_PUS_47K_PU      |       \
        CYGHWR_HAL_IMX_PAD_MODE_DSE(6)          |       \
        CYGHWR_HAL_IMX_PAD_MODE_SPEED_MED2

#define CYGHWR_HAL_IMX_LPUART1_TX       CYGHWR_HAL_IMX_PAD( AD_B0(12), LPUART_PAD(2) )
#define CYGHWR_HAL_IMX_LPUART1_RX       CYGHWR_HAL_IMX_PAD( AD_B0(13), LPUART_PAD(2) )
```

PAD Daisy Chaining

Some device IO lines can connect to multiple pads, the daisy chain registers select which pad is to be used for the device. A daisy chain descriptor is created by the CYGHWR_HAL_IMX_DAISY macro. The reg argument selects which daisy chain device line is to be programmed, and the val argument defines the pad selection. Both of these arguments are fragments of macros defined in cyg/hal/var_io.h. Only registers and values currently used are defined there, new ones can be added there or defined in the driver or application.

The CYGHWR_HAL_IMX_DAISY_SET macro is called to program the configuration from a descriptor into the hardware.

The following example shows some daisy chain descriptor definitions.

```
#  define CYGHWR_HAL_NXP_LPUART3_TXD_DAISY CYGHWR_HAL_IMX_DAISY(LPUART3_TX, AD_B1_06_ALT2)

#  define CYGHWR_HAL_NXP_LPUART3_RXD_DAISY CYGHWR_HAL_IMX_DAISY(LPUART3_RX, AD_B1_07_ALT2)

#  define CYGHWR_HAL_NXP_LPUART3_CTS_DAISY CYGHWR_HAL_IMX_DAISY(LPUART3_CTS_B, AD_B1_04_ALT2)
#  define CYGHWR_HAL_NXP_LPUART3_RTS_DAISY CYGHWR_HAL_IMX_DAISY_NONE
```

Clock Gating Control

Most device clocks are controlled by a gate that needs to be switched on or off. The HAL provides macros which may be used to enable or disable peripheral clocks. Effectively this indicates whether the peripheral is powered on (enabled) or powered down (disabled), and so may be used to ensure unused peripherals are turned off to save power. The macro CYGHWR_HAL_IMX_CLOCK_GATE() defines a clock gate descriptor. The reg argument gives the CCGR register to be used and the gate argument selects the clock gate bit in that register. Clock gate descriptors are defined in cyg/hal/var_io.h and new values will be added there as needed.

The macros CYGHWR_HAL_IMX_CLOCK_ENABLE() and CYGHWR_HAL_IMX_CLOCK_DISABLE() enable and disable the clock described by the descriptor. At present clocks are either fully on or fully off, the option to switch clocks off in WAIT mode is not implemented.

It is important to remember that before a peripheral can be used, it must be enabled. It is safe to re-enable a peripheral that is already enabled, although usually a device driver will only do so once in its initialization. eCos will automatically initialize some peripheral blocks where it needs to use the associated peripherals, and in eCos-supplied device drivers which are included in the eCos configuration. However this should not be relied on - it is always safest to enable the peripheral clocks anyway just in case.

GPIO

A descriptor is created by the CYGHWR_HAL_IMX_GPIO() macro. The ctlr argument selects the GPIO controller while the pin argument selects the GPIO pin in the controller. The mode argument configures the pin within the GPIO controller.

For basic I/O the supplied mode is either IN or OUT. For input pins an interrupt configuration mode can us used instead (with IN implied). At present the options LOW_LEVEL, HIGH_LEVEL, RISING_EDGE, FALLING_EDGE and BOTH_EDGES are available to define which input transitions/states will generate an interrupt event.

For example, the descriptor for GPIO output control of GPIO1 pin 9 could be declared as follows:

```
#define OUTPUT_EXAMPLE CYGHWR_HAL_IMX_GPIO(1, 9, OUT)
```

Correspondingly, a descriptor for polled input of GPIO5 pin 0 can simply be declared using IN for the mode field:

```
#define INPUT_EXAMPLE CYGHWR_HAL_IMX_GPIO(5, 0, IN)
```

For polled **or** interrupt driven input the relevant interrupt detection can be specifiued as the mode field. e,g:

```
#define INPUT_EXAMPLE CYGHWR_HAL_IMX_GPIO(5, 0, BOTH_EDGES)
```

In addition to GPIO configuration, the matching pad will need to be configured using a PAD descriptor as detailed above in PAD Multiplexing.

Prior to a pin being accessed for GPIO then the pin **and** its corresponding pad will need to be configured at run-time. With appropriate descriptor values defined this is done via the SET calls. For example, using the manifests from above:

```
   // One-time initialisation of output pin:
   CYGHWR_HAL_IMX_PAD_SET(OUTPUT_PAD);
   CYGHWR_HAL_IMX_GPIO_SET(OUTPUT_EXAMPLE);

   // One-time initialisation of input pin:
   CYGHWR_HAL_IMX_PAD_SET(INPUT_PAD)
   CYGHWR_HAL_IMX_GPIO_SET(INPUT_EXAMPLE);
```

Subsequent to the setting of the I/O configuration the GPIO pin can then be accessed as configured.

If a GPIO pin has been configured as an output then its value may be set using CYGHWR_HAL_IMX_GPIO_OUT(). For example:

```
   CYGHWR_HAL_IMX_GPIO_OUT(OUTPUT_EXAMPLE, 0); // set LOW
   some_app_processing();
   CYGHWR_HAL_IMX_GPIO_OUT(OUTPUT_EXAMPLE, 1); // set HIGH
```

Similarly the current value of an input pin can be read using CYGHWR_HAL_IMX_GPIO_IN(). For example:

```
   int bstat;
   CYGHWR_HAL_IMX_GPIO_IN(INPUT_EXAMPLE, &bstat);
```

Note

Normally the variant HAL will manage the masking and acknowledgment of interrupts via the standard kernel interrupt support API, and so the application level code does not normally need to access the low-level INTMASK and INTCLR functions directly since they will be called by the kernel as appropriate.

For completeness the low-level helpers exposed to the standard interrupt support are documented here.

The CYGHWR_HAL_IMX_GPIO_INTMASK() parameter enable controls the masking/unmasking of the interrupt associated with the pin descriptor. A non-zero value will enable the source, with 0 disabling the source.

If required, the current active “interrupt asserted” state of a pin can be interrogated using CYGHWR_HAL_IMX_GPIO_INTSTAT().

The CYGHWR_HAL_IMX_GPIO_INTCLR function can be used to acknowledge an active interrupt.

Since most of the individual GPIO pin interrupt sources are multiplexed through the Cortex-M NVIC the variant HAL provides support for demultiplexing the combined GPIO interrupts to individual logical vectors. The CDL option CYGSEM_HAL_CORTEXM_IMX_GPIO_INT_DEMUX controls whether the demux feature is implemented. It is enabled by default when the CYGPKG_KERNEL is configured. This feature avoids application code having to manage their own demux support when interrupt support is required for multiple pins on a specific GPIO controller.

For example, the physical GPIO2 pin 5 is actually multiplexed via the hardware CYGNUM_HAL_INTERRUPT_GPIO2_COMBO_0_15 interrupt vector. If the HAL demux support is enabled then that specific pin source can be supported individually via the CYGNUM_HAL_INTERRUPT_GPIO2_INT5 logical vector manifest, with the other 15 sources multiplexed onto the underlying NVIC interrupt also available via their own logical vector numbers.

Name

OCOTP Support on IMX Processors — Details

Synopsis

#include <cyg/hal/hal_io.h>

cyg_bool success = **cyg_imx_ocotp_timing**();

cyg_bool success = **cyg_imx_ocotp_read**(*addr*, *p_value*);

cyg_bool success = **cyg_imx_ocotp_write**(*addr*, *value*, *key*);

cyg_imx_ocotp_reload();

Description

The IMX HAL provides a number of functions to support interaction with the `OCOTP` (On-Chip One-Time-Programmable) fuses.

OCOTP Initialisation

Prior to accessing the `OCOTP` the function `cyg_imx_ocotp_timing()` should be used to configure the required timing setup. If the function returns `false` then an error has occurred and the `OCOTP` API should not be used.

OCOTP Reading

The `addr` is constructed using the `CYGHWR_HAL_IMX_HW_OCOTP_ADDR(bank, word)` macro to convert a bank# and word# into a register offset.

The passed `p_value` parameter is then filled with the `OCOTP` fuse value corresponding to the passed `addr`.

OCOTP Writing

Note

Due to the fact that `OCOTP` updates can affect how the CPU operates from boot, the writing of fuses (setting from `0` to `1`) is **disabled** by default.

If `OCOTP` write support is required then the CDL option `CYGHWR_HAL_CORTEXM_IMX_OCOTP_WRITE` should be explicitly enabled.

When the `OCOTP` write support is configured then the function `cyg_imx_ocotp_write()` can be used to set a specific `value` for the specified fuse location. The `key` parameter is an extra safety measure since the write will only be performed if `key` is `CYGHWR_HAL_IMX_HW_OCOTP_WRITE_KEY`. This is to minimise the chance for errant execution of the write function due to some application flaw resulting in erroneous `OCOTP` updates. The source code is constructed so that the 32-bit key value does **not** appear in the binary. Application users of the `OCOTP` write support should ideally implement similar functionality. e.g.

```
static const cyg_uint32 keyth = (0xDEAD0000 | (CYGHWR_HAL_IMX_HW_OCOTP_WRITE_KEY >> 16));
static const cyg_uint32 keybh = (0xC0DE0000 | (CYGHWR_HAL_IMX_HW_OCOTP_WRITE_KEY & 0xFFFF));

cyg_uint32 bitshigh;
cyg_uint32 bitslow;

HAL_READ_UINT32(&keyth, bitshigh);
HAL_READ_UINT32(&keybh, bitslow);
```

```
cyg_uint32 writekey = (((bitshigh & 0xFFFF) << 16) | (bitslow & 0xFFFF));

if (cyg_imx_ocotp_write(CYGHWR_HAL_IMX_HW_OCOTP_ADDR(bank, word), bitmask, writekey)) {
  // success // OCOTP updated
} else {
  // failure
}
```

After updating the fuses the `cyg_imx_ocotp_reload()` **should** be called to reload the shadow registers. This ensures other code, that may directly access the shadow state, will see the updated fuse state.

Name

BootUp second level boot loader — Bootstrap

BootUp

BootUp (CYGPKG_BOOTUP) is a lightweight second-level boot loader package, which can be extended with VAR and PLF specific features as required (e.g. firmware updates, secure boot, etc.).

The BootUp support for the i.MX RT targets is primarily implemented in the imx_support.c file. The functions are normally only included when the CYGPKG_BOOTUP package is being used to construct the actual BootUp loader binary.

The BootUp code is designed to be very simple, and it is envisaged that once an implementation has been defined the binary will only need to be installed onto a device once.

Alternative

An alternative to using BootUp to start applications is to use a SRAM (OCRAM) based RedBoot to manage the flash space, and to use the RedBoot features to load and start the main application.

The benefit of RedBoot is the ability for command-line interaction with the management of the stored application. The downside of RedBoot is the code+data space overhead and potential for run-time performance costs when using (via the virtual vector interface) RedBoot features or debugging an application via RedBoot. The BootUp package offers a light weight solution without impacting the memory space or performance of the final application, and is better suited to a H/W debugger development environment.

Boot details

Currently, its only purpose is to allow the startup of the main application when linked for external memory (e.g. SDRAM) since the i.MX RT ROM Bootloader will only load and execute applications to SRAM (OCRAM). If an SRAM based application is to be booted then the BootUp intermediate (second-level) code is not needed since the CPU can directly load and start the SRAM application from the bootable NVM.

This platform specific documentation should be read in conjunction with the generic BootUp package documentation.

The BootUp package provides a basic but fully functional implementation for the platform. It is envisaged that the developer will customize and further extend the platform side support to meet their specific application identification and update requirements.

The BootUp binary iself can be installed on *any* i.MX RT bootable media, and is not restricted to being placed into FlexSPI flash.

On execution BootUp will copy the configured final application from its Non-Volatile-Memory (NVM) location to its destination address and start the application. The configuration option CYGIMP_BOOTUP_IMX_SOURCE selects where the second-level BootUp code will look for the final application image. The available options depend on the configured target CPU, and whether the variant/platform specific BootUp has support for the specific storage medium.

The following diagrams give an overview of the first-level (on-chip) ROM Bootloader and second-level (SRAM) boot sequence. Blocks shown in green indicate running code. The blue arrows indicate a memory copy operation. The red arrows indicate a switch in execution. The BootUp application image stored in the bootable NVM is expected to be a valid image prefixed with FCFB, BootData, DCD and IVT information as required for the on-chip ROM Bootloader. This example is for the final application binary to be executed from SDRAM.

Figure 312.1. On-chip ROM Bootloader executes

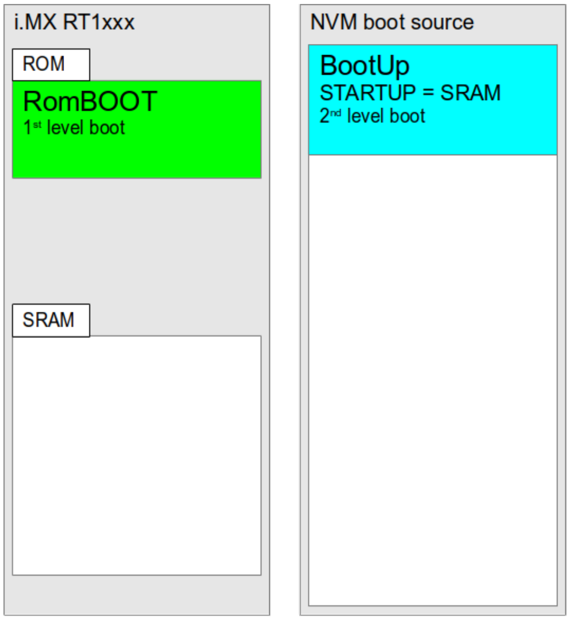

Figure 312.2. On-chip ROM Bootloader copies second-level boot code from NVM to on-chip SRAM

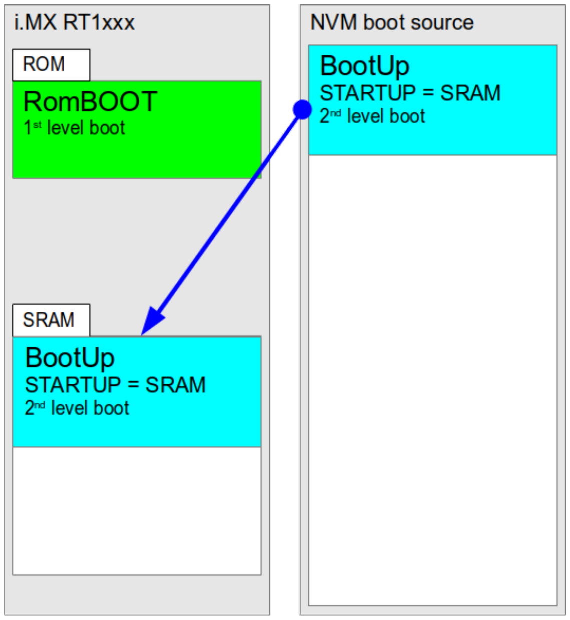

Figure 312.3. SRAM loaded second-level boot code is executed

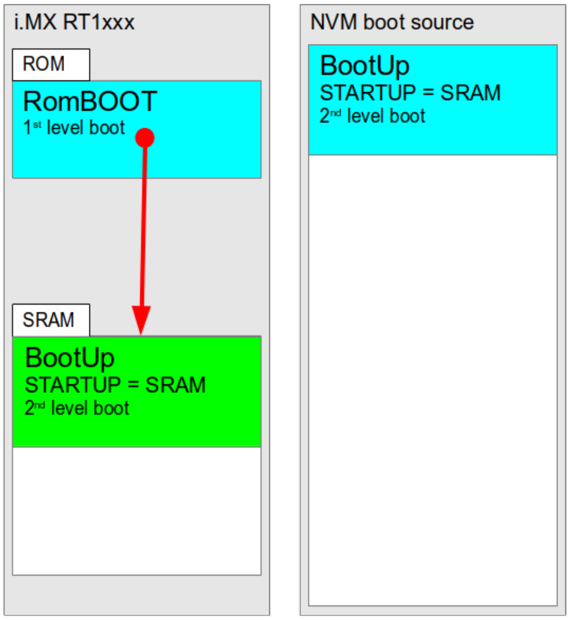

Figure 312.4. Final application is located in NVM

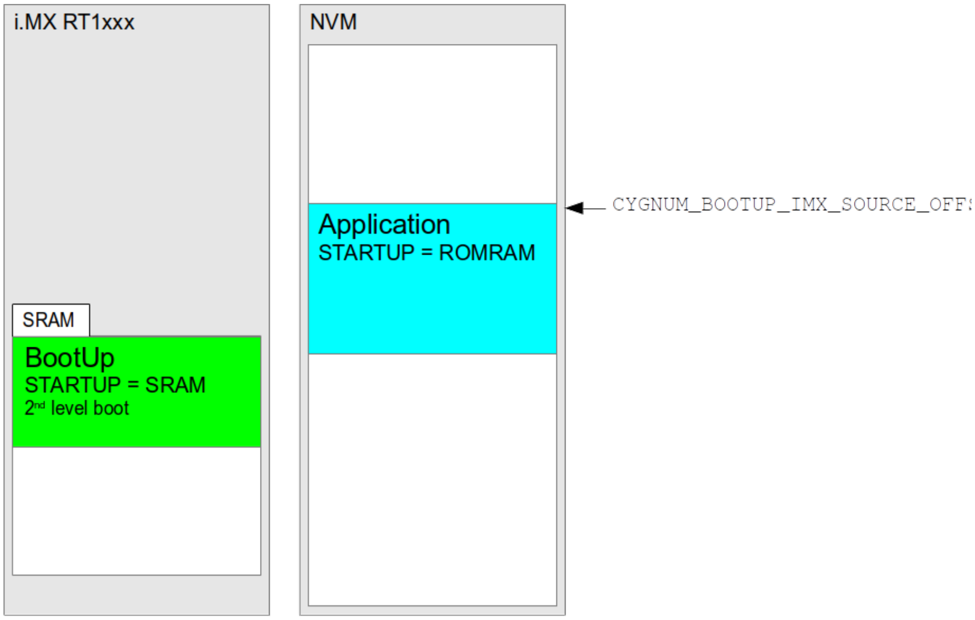

Figure 312.5. Second-level boot copies application from NVM to SDRAM

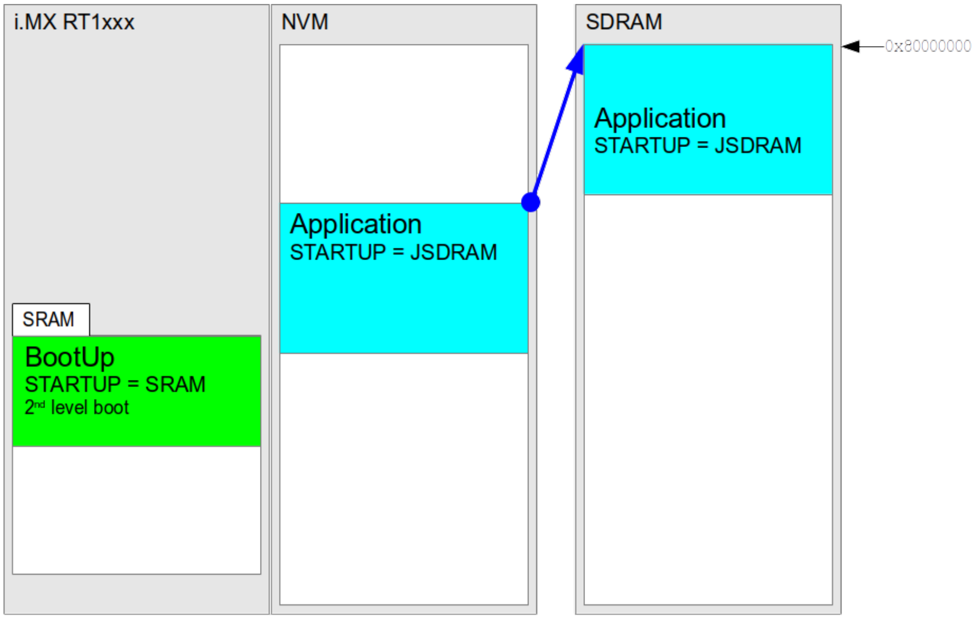

Figure 312.6. Application is started

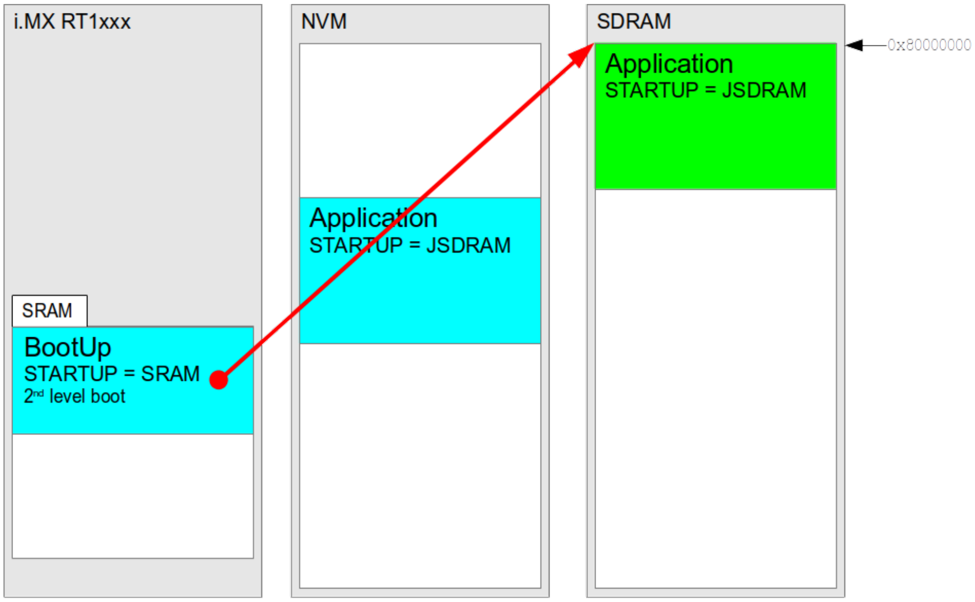

The example above shows an application with the platform startup type `JSDRAM`, but the application could also be the special-case `RBRAM` startup type for a RAM based RedBoot image, or some other platform specific SDRAM or other external-memory startup type as required.

Building BootUp

Building a BootUp loader image is most conveniently done at the command line. The steps needed to rebuild the `SRAM` version of BootUp are:

```
$ mkdir bootup_SRAM
$ cd bootup_SRAM
$ ecosconfig new TARGET minimal
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/packages/hal/cortexm/imx/var/current/misc/bootup_SRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

Where *TARGET* is replaced with the required i.MX target platform name, e.g. mimxrt1064_evk, mimxrt1050_evk, etc.

The resulting install/bin/bootup.bin binary can then be packaged into a bootable image (see platform specific documentation), with that bootable image subsequently programmed into a suitable non-volatile memory as supported by the i.MX RT on-chip ROM Bootloader. To be clear, the BootUp binary itself needs to be wrapped with the descriptors required by the i.MX RT ROM Bootloader **but** the binary started by BootUp is just the unmodified final application binary.

The example bootup_SRAM.ecm is configured to expect to find the application stored in the selected FlexSPI flash from the address offset CYGNUM_BOOTUP_IMX_SOURCE_OFFSET.

The option CYGIMP_BOOTUP_IMX_SOURCE selects the NVM location used by BootUp. Currently this is limited to the FlexSPI flash interface(s), and will default to the controller instance used by the ROM Bootloader to match the device where the second-level boot loader is stored.

For convenience, prebuilt wrapped BootUp images named qspi_bootup.bin are provided with eCosPro releases in the loaders/*target* subdirectory of your eCosPro installation alongside the unwrapped BootUp images as well as various RedBoot images.

Application Signature

The BootUp loader will only copy and start execution of binaries with a suitable “signature” block. For the i.MX targets the location of the descriptor block is fixed at the offset of 8-bytes within the binary image (CYGNUM_BOOTUP_SIGNATURE_OFFSET).

The binary image descriptor provides “magic” identifier values used to detect a complete signature block, and the descriptor holds the necessary information required by BootUp. e.g. a length field specifying the number of bytes in the binary image.

If the binary image at offset CYGNUM_BOOTUP_IMX_SOURCE_OFFSET is not valid then BootUp will enter the hal_imx_badapp() function. The VAR HAL provides a default implementation which is a simple infinite loop, but the weak VAR HAL definition can be overridden by a PLF specific implementation if required.

Chapter 313. NXP MIMXRT1xxx-EVK Platform HAL

Name

CYGPKG_HAL_CORTEXM_MIMXRT1XXX_EVK — eCos Support for the IMXRT1050-EVKB and MIMXRT1064-EVK boards

Description

This document covers the configuration and usage of eCos on the NXP MIMXRT10XX-EVK evaluation kits. This includes the RT1052 and RT1064 on which this support has been tested. Boards containing other devices in the RT10XX family should be supportable with minimal effort.

For typical eCos development it is expected that programs will be downloaded and debugged via a hardware debugger (JTAG/SWD) attached to either the standard ARM 20-pin JTAG connector or via the on-board CMSIS-DAP USB socket. Use of a hardware debugging interface avoids the requirement for (and cost overheads of) a debug monitor application to be present on the platform.

Note

As shipped the EVK boards are configured for H/W debugging via the onboard CMSIS-DAP interface. If the standard ARM 20-pin 2.54mm IDC J21 connector is to be used the jumpers may need to be re-configured. For example, the MIMXRT1064-EVK requires jumpers J47..J50 to be disconnected. The relevant NXP schematic or board documentation should be referenced to correctly configure the target board if using an external H/W debugger connected via J21.

The Startup section below gives an overview of the various STARTUP types that can be configured. The selected STARTUP type defines where the final application binary will be linked to execute from, as well as control some run-time features of the final application (e.g. standalone or dependant on a ROM monitor, etc.).

Supported Hardware

The variant HAL includes support for the on-chip serial devices which are documented in the variant HAL. LPUART1 is connected to the CMSIS socket where it is available as a CDC/ACM interface. There is no support for hardware flow control in this device. LPUART1 is configured as the default diagnostics console.

Device drivers provide support for the I²C interfaces, which are instantiated by the platform (PLF) HAL. These have been tested using external I²C devices.

Device drivers provide support for the SPI interfaces, which are instantiated by the platform HAL. These have been tested using external SPI devices.

Support is available for the FlexSPI controller(s) with attached QSPI device(s). In the case of the MIMXRT1064-EVK board this support is provided for the SiP QSPI device as well as the external ISSI IS25WP064D QSPI device. For the IMXRT1050-EVKB the FlexSPI support requires board modifications to use the on-board QSPI ISSI IS25WP064D device in place of the default HyperFlash device.

Normally the first few blocks of the bootable QSPI NOR flash are set aside for a bootable application image (e.g. standalone SRAM application, 2nd-level boot loader, or a (RBSRAM) RedBoot debug monitor image). The bootable application image requires specific descriptor structures to be prefixed to allow the i.MX RT ROM Bootloader to start the application, as documented in the flashimg_rt10 section. When using RedBoot (either a directly booted RBSRAM build, or a RBRAM build loaded via BootUp or a RBSRAM RedBoot), the last couple of blocks of the flash device are used to hold the RedBoot **fconfig** and FIS information. The remaining blocks are free for use by application code. When not using RedBoot all of the flash beyond the i.MX RT ROM Bootloader required (DCD+image) is available for application use.

Warning

The IMXRT1050-EVKB and MIMXRT1064-EVK boards ship with J1 configured to power the board via the CMSIS-DAP debug connector. Unfortunately, depending on the host connection, that connection is insufficient to power the

USB and CAN tranceivers, and the Ethernet PHY, such that USB, CAN and Ethernet are **unlikely** to operate correctly when the board is powered via that debug USB connection.

It is **important** to power the board via an external PSU via J2, with the J1 pins 1-2 connected as appropriate if CAN, USB or Ethernet are to be used.

Support for USB host and peripheral mode is provided by EHCI drivers. Host mass storage and CDC-ACM class drivers are present. The peripheral port is configured by default to provide a CDC-ACM device.

Support for Ethernet and CAN (**not** CAN-FD) is provided by configuring the respective device drivers.

Note

The `IMXRT1050-EVKB` and `MIMXRT1064-EVK` boards seen to date do **not** have the CAN connector J11 populated. So a suitable connector will need to be soldered to provide access to the on-board CAN transceiver.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 7.3.0e, **arm-eabi-gdb** version 8.1, and **binutils** version 2.30.

`flashimg_rt10`

The i.MX RT ROM Bootloader will only bootstrap applications prefixed with headers describing the application to be started. A suitable bootable image can be created using the `flashimg_rt10` tool to prefix the eCos executable binary with the required descriptors.

The tool will by default create an image suitable to be booted from an SDcard.

To create a QSPI boot image from a binary image the `--qspi` command-line option should be used:

```
$ flashimg_rt10 --qspi image.bin qspi_boot.bin
```

Note

Only binaries linked to execute from the On-Chip SRAM are supported as bootable applications.

Application Boot Location Examples

For the `mimxrt1050_evk` and `mimxrt1064_evk` targets the code executed at boot can be loaded from flash using the ROM Bootloader FlexSPI NOR flash support. Refer to the NXP H/W board documentation and relevant i.MX RT Processor Reference Manual for details on the available boot-from-reset configurations.

The following section just highlights where images are stored in the FlexSPI NOR for some, common, example startup configurations.

Note

The following examples are **not** exhaustive. For example, a custom second-level bootloader can be used to start an application. These are just common examples.

For FlexSPI configured boots the `mimxrt1050_evk` target only has the FlexSPI1 flash mapped from address `0x60000000`. However, the FlexSPI boot option for the `mimxrt1064_evk` can only boot from the FlexSPI2 (SiP) flash mapped from address

`0x70000000`, but any second-level boot loader or application started has access to the external FlexSPI1 flash mapped from `0x60000000`.

If an application binary is linked for SDRAM execution then it needs to be loaded via a second-level boot loader. Only the second-level bootloader (as started by the i.MX RT ROM Bootloader) needs to be created using the `flashimg_rt10` tool. The final application does not need to be converted. When using BootUp as the second-level boot loader the SDRAM application stored in NVM will be a simple, raw, binary located at a **fixed** location. When using RedBoot as the second-level loader the application image stored in the NVM will be the larger ELF image, with FIS controlling where the image is located.

In the following figures **BLUE** is used to indicate an image at its storage location, with **GREEN** indicating an application at its final execution location. For applications that can be loaded via a RedBoot debug session **YELLOW** is used.

Direct standalone application startup

If the final application loads and executes from On-Chip SRAM, or is itself a second-level boot loader executing from SRAM then the suitable wrapped (QSPI bootable) image is placed from offset `0` of the respective bootable flash device.

The following figures highlight the RT1064 and RT1052 locations.

Figure 313.1. Standalone `mimxrt1064_evk` SRAM application

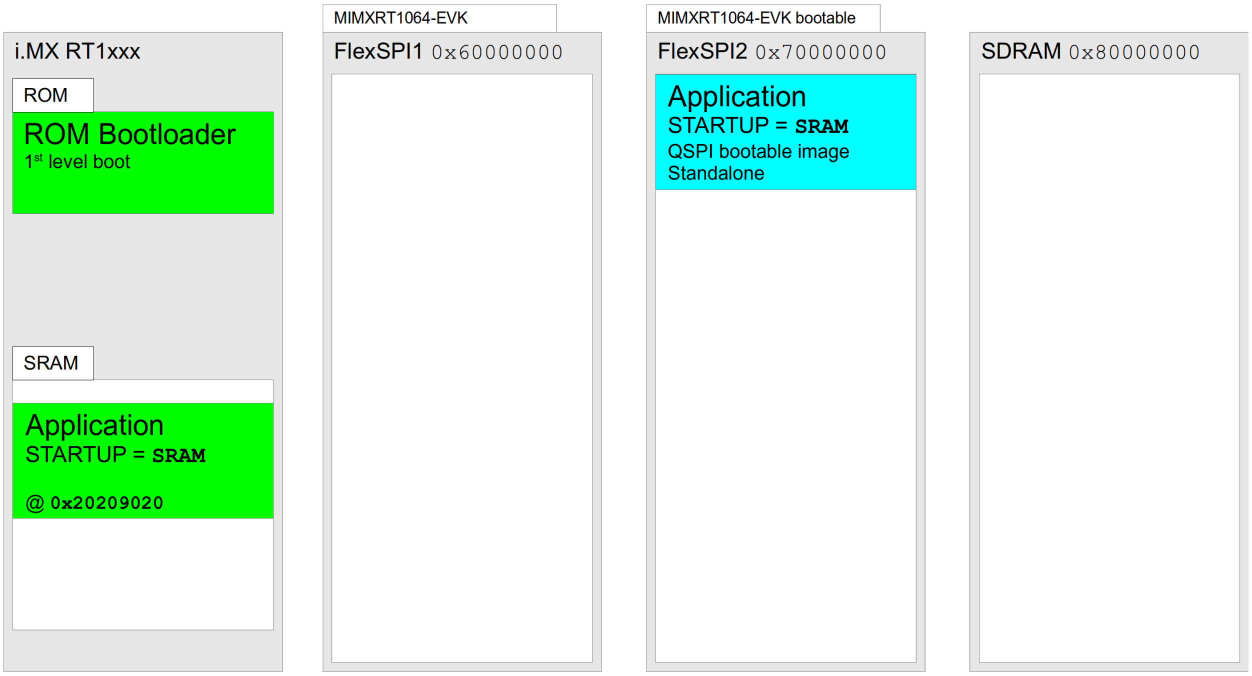

Figure 313.2. Standalone `mimxrt1050_evk` `SRAM` application

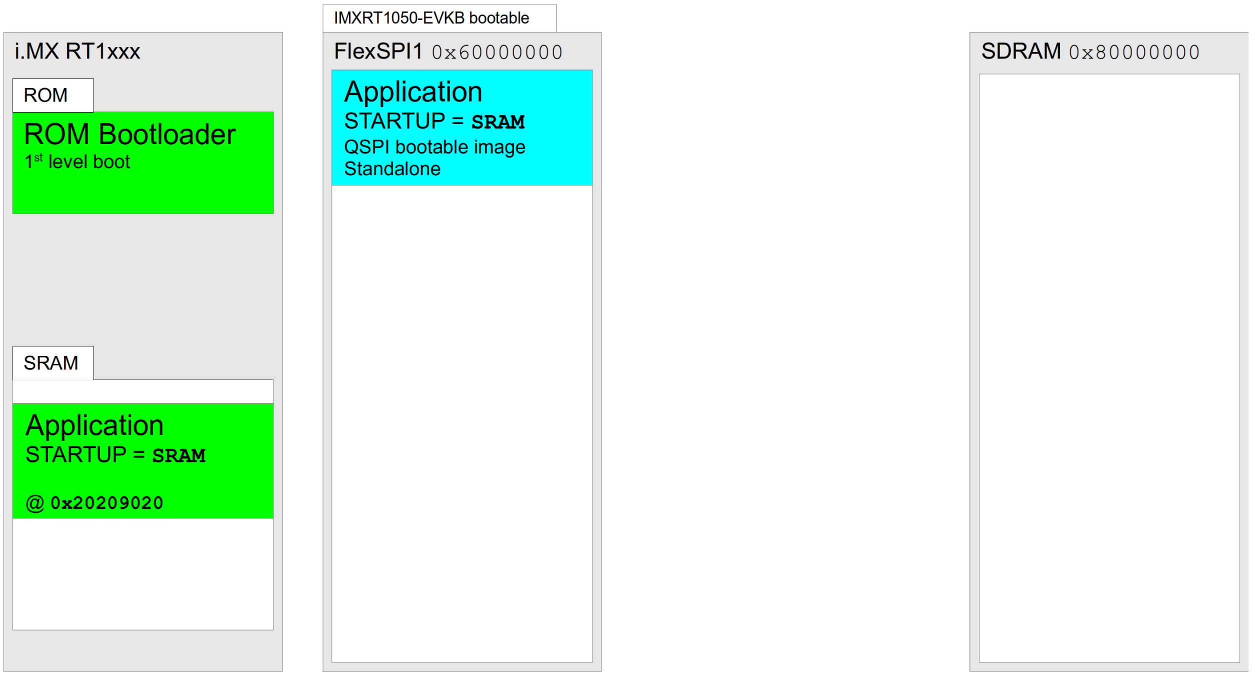


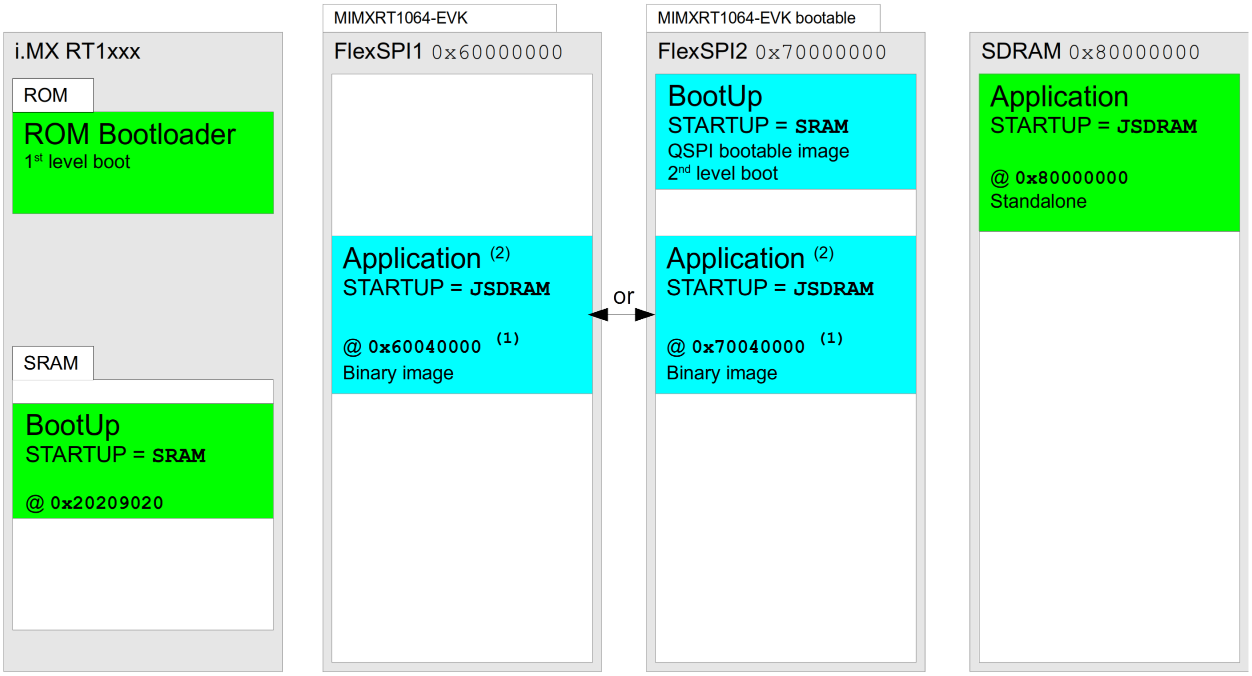
Since the RedBoot specific `RBSRAM` is just a variation of a SRAM application, for the figures above we can replace the `SRAM` Application with a `RBSRAM` RedBoot QSPI bootable image. Examples of which are shown below.

BootUp used to start application

For systems where a standalone, external-SDRAM, application is to be started at boot then the BootUp second-level boot loader can be used.

Normally the final application would be a `JSDRAM` startup application as shown for the RT1064 and RT1050 platforms respectively.

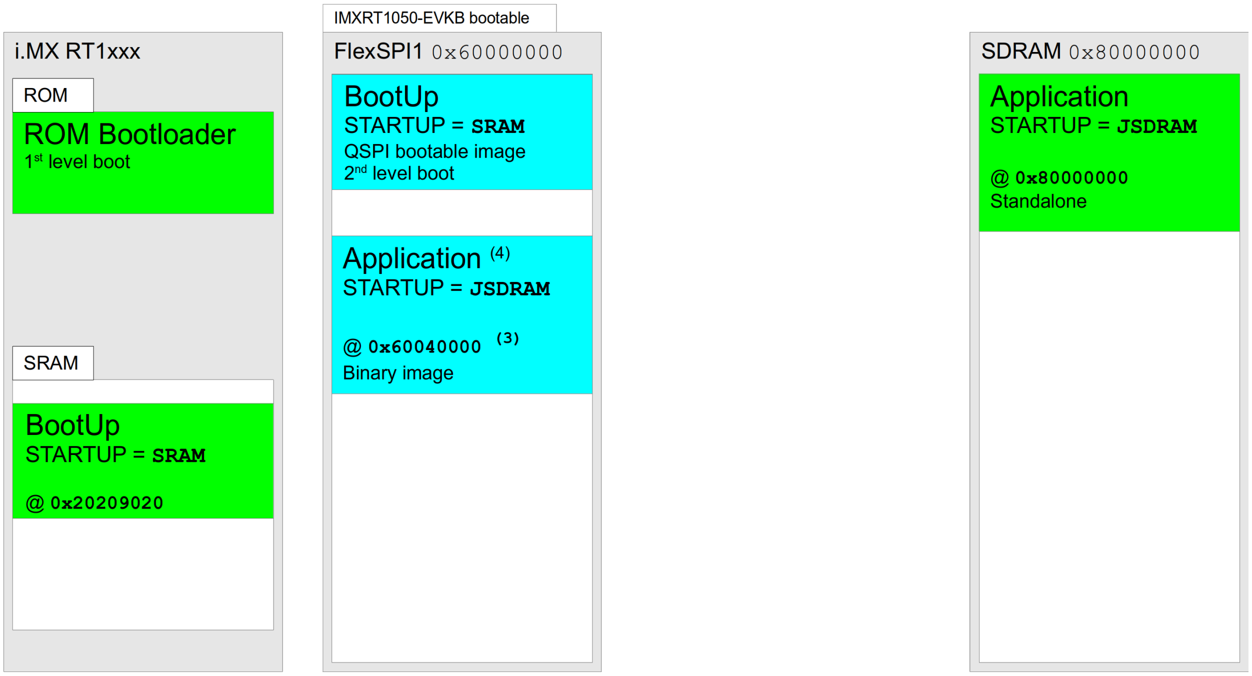
Figure 313.3. Standalone `mimxrt1064_evk` `JSDRAM` application



(1) address shown is the result of adding the default `CYGNUM_BOOTUP_IMX_SOURCE_OFFSET` offset onto the relevant FlexSPI# flash base

(2) default `CYGIMP_BOOTUP_IMX_SOURCE` is FlexSPI2, but BootUp can use FlexSPI1 if required

Figure 313.4. Standalone `mimxrt1050_evk` `JSDRAM` application

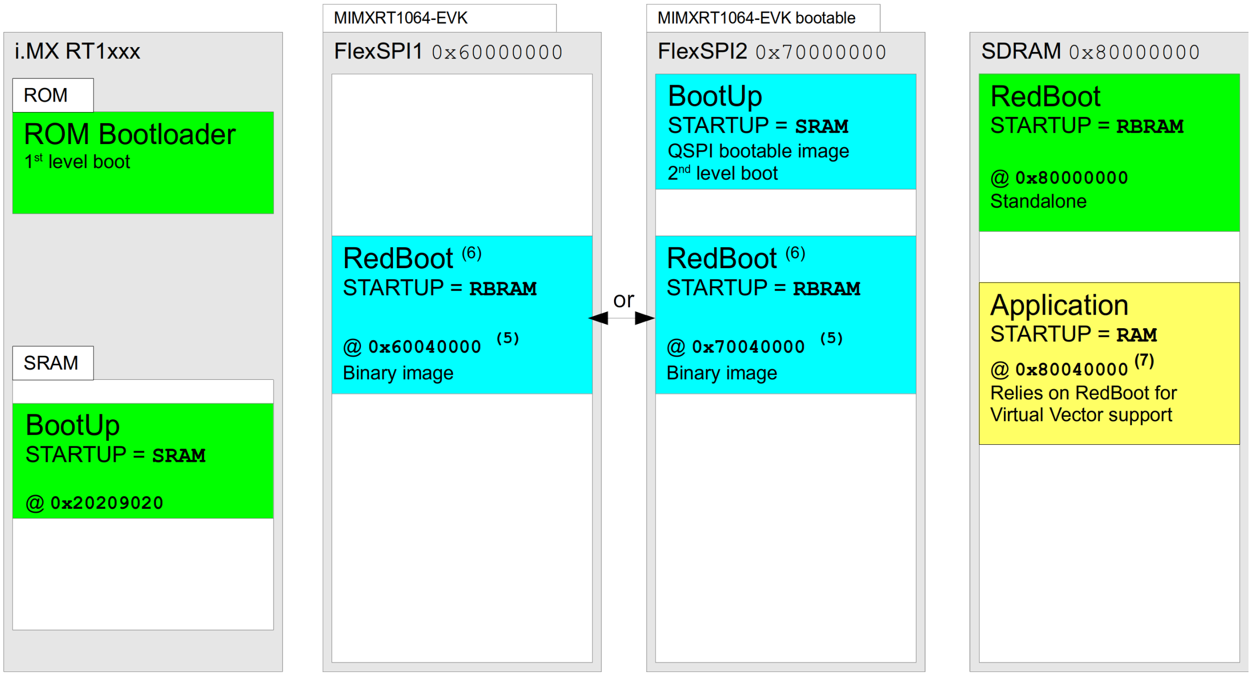


(3) address shown is the result of adding the default `CYGNUM_BOOTUP_IMX_SOURCE_OFFSET` offset onto the FlexSPI1 base address

(4) CYGIMP_BOOTUP_IMX_SOURCE is FlexSPI1

However, if a SDRAM based RedBoot is required (RBRAM startup) then BootUp can be used to load and start the SDRAM RedBoot, which can then subsequently be used to load RAM startup applications that make use of RedBoot functionality via the virtual vector support. The following figures highlight that the SDRAM configured RedBoot requires a second-level boot loader to copy and start the RedBoot instance from SDRAM:

Figure 313.5. Standalone mimxrt1064_evk RBRAM application

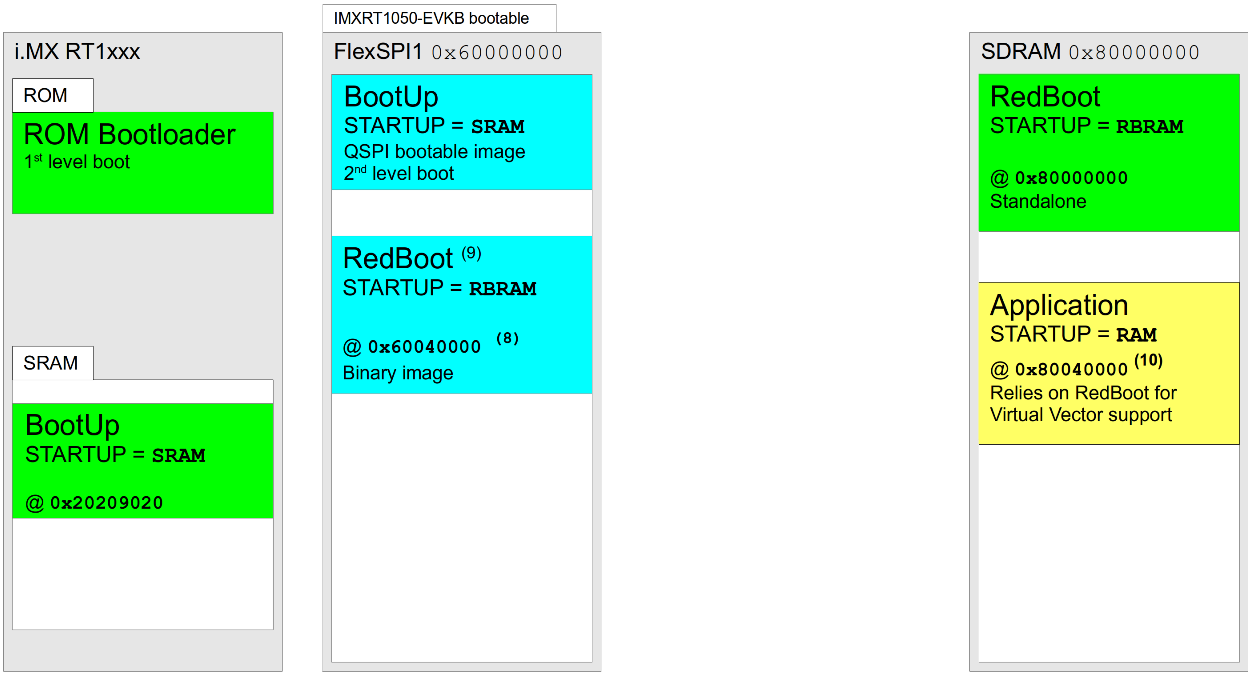


(5) address shown is the result of adding the default CYGNUM_BOOTUP_IMX_SOURCE_OFFSET offset onto the relevant FlexSPI# flash base

(6) default CYGIMP_BOOTUP_IMX_SOURCE is FlexSPI2, but BootUp can use FlexSPI1 if required

(7) default CYGMEM_REGION_redboot_SIZE offset into SDRAM defined in the “mlt_mimxrt1xxx_evk.h” header with app loaded by RedBoot from FIS or via GDB stubs

Figure 313.6. Standalone `mimxrt1050_evk` `RBRAM` application



(8) address shown is the result of adding the default `CYGNUM_BOOTUP_IMX_SOURCE_OFFSET` offset onto the FlexSPI1 flash base

(9) `CYGIMP_BOOTUP_IMX_SOURCE` is FlexSPI1

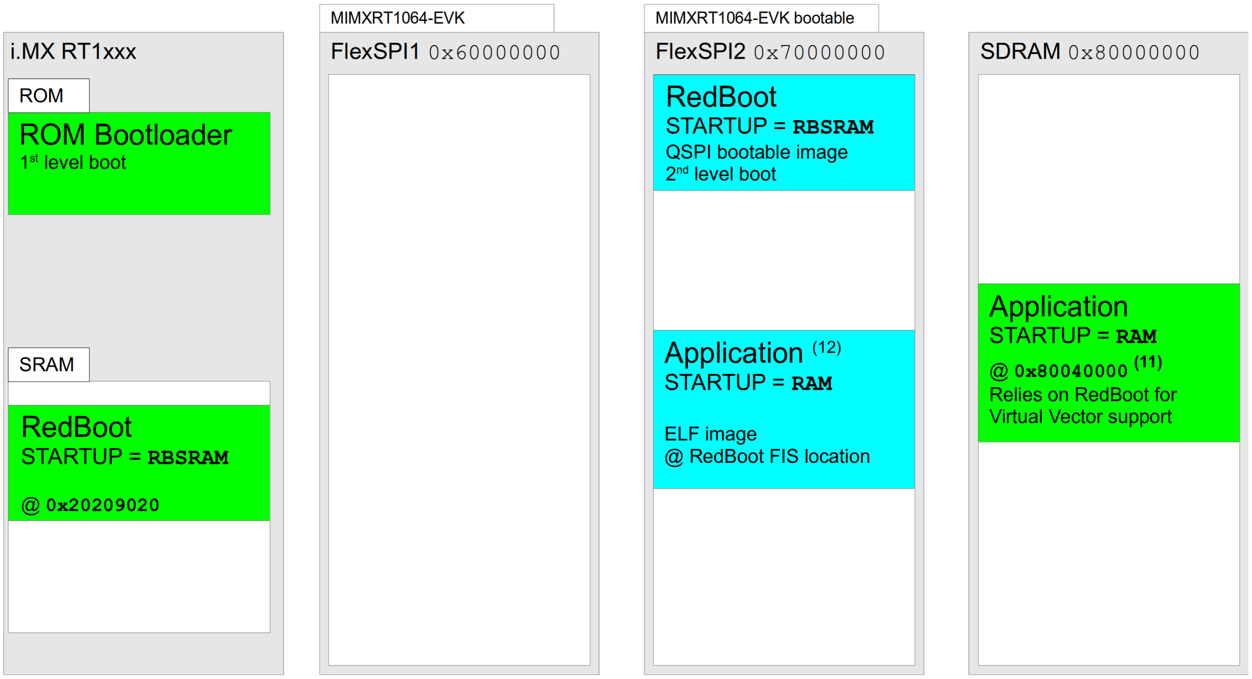
(10) default `CYGMEM_REGION_redboot_SIZE` offset into SDRAM defined in the `"mlt_mimxrt1xxx_evk.h"` header with app loaded by RedBoot from FIS or via GDB stubs

RedBoot used to start application

When RedBoot is being used to load an application, the storage location of the ELF image held in flash is controlled by the RedBoot FIS support. The following figure shows a SRAM based RedBoot setup, but the same FIS held ELF image is also applicable to external-SDRAM (`RBRAM`) RedBoot instances.

Only the RT1064 platform is shown in the figures below, but as per the standalone SRAM examples above, for the RT1052 based target the bootable second-level loader image and stored application image will be held in the FlexSPI1 flash memory.

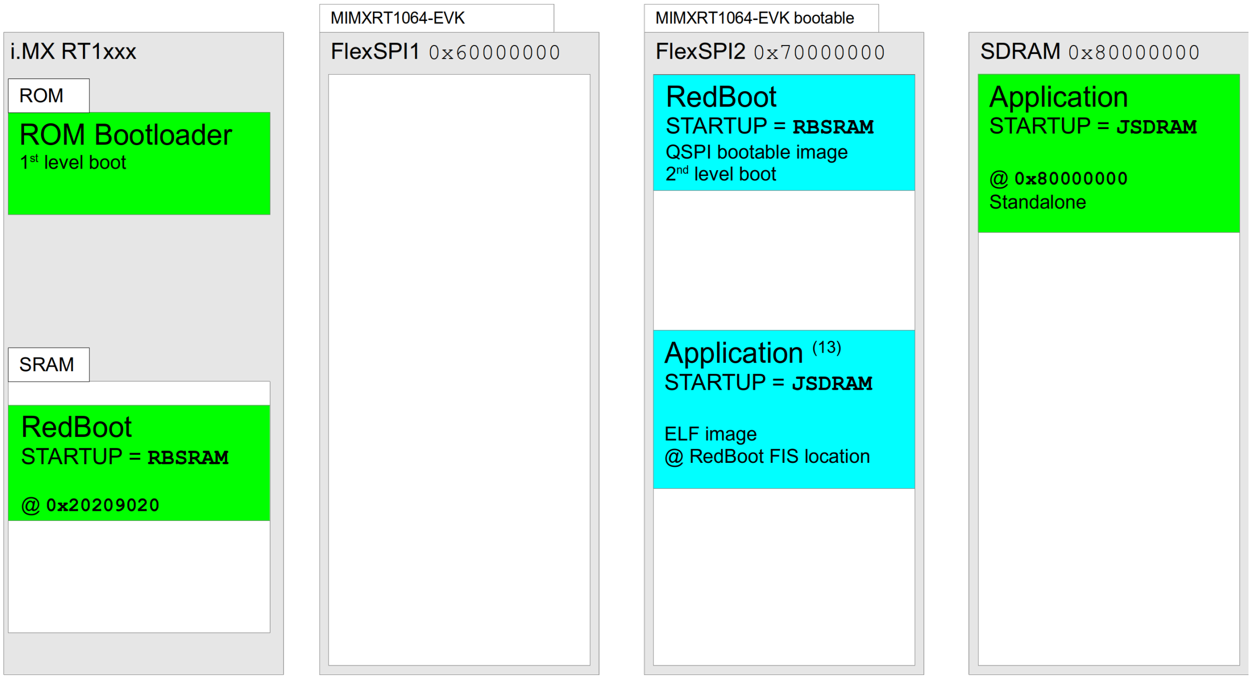
Figure 313.7. `mimxrt1064_evk` SRAM RedBoot and `RAM` application



(11) address shown is the result of adding the default `CYGMEM_REGION_redboot_SIZE` offset onto the SDRAM base address, where that offset manifest is defined in the “`mlt_mimxrt1xxx_evk.h`” header, and the app subsequently loaded by RedBoot from FIS or via GDB stubs

(12) figure shows RedBoot managed application stored in flash, but app can also be loaded via the GDB stubs debug connection

Figure 313.8. `mimxrt1064_evk` SRAM RedBoot and `JSDRAM` application



(13) figure shows RedBoot managed application stored in flash, but app can also be loaded via the GDB stubs debug connection

Name

Setup — Preparing the MIMXRT1xxx-EVK Board for eCos Development

Overview

In a development environment the EVK board may be programmed via a JTAG/SWD interface or via RedBoot loaded from boot memory.

When debugging via JTAG, you may need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. If you are debugging via SWD this should not be necessary. When using hardware debug we **recommend** that the board SW7 DIP switches (1234) are used to select SD card boot (ON OFF ON OFF). Without an SD card installed, this will have the useful side effect of causing the processor to pause in the ROM loader. It avoids potential issues caused by any pre-installed firmware re-configuring the SoC as part of the ROM Bootloader process.

For debugging, applications are loaded and then executed on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. The following describes setting up to use OpenOCD with GDB.

OpenOCD

Note

As mentioned in the Overview section, if there is unknown firmware already installed in the bootable QSPI then it is worth ensuring that it does not interfere with the H/W debug session by changing the SW7 bootstrap selection to disable QSPI execution, until a known eCos application has been installed in the bootable flash.

To debug via OpenOCD the `etc/openocd.cfg` from the build install directory should be used. Running OpenOCD on a host connected to the board via a suitable cable should produce something similar to the following:

```
$ openocd -f openocd.cfg
Open On-Chip Debugger 0.11.0-2 (eCosCentric 2021-06-15)
Licensed under GNU GPL v2
For bug reports, read
  http://openocd.org/doc/doxygen/bugs.html
Info : auto-selecting first available session transport "swd". To override use 'transport select <transport>'.
Info : Listening on port 6666 for tcl connections
Info : Listening on port 4444 for telnet connections
Info : CMSIS-DAP: SWD  Supported
Info : CMSIS-DAP: FW Version = 1.10
Info : CMSIS-DAP: Interface Initialised (SWD)
Info : SWCLK/TCK = 0 SWDIO/TMS = 1 TDI = 0 TDO = 0 nTRST = 0 nRESET = 1

Info : SWD DPIDR 0x0bd11477
Info : imxrt1050.cpu: hardware has 8 breakpoints, 4 watchpoints
Info : starting gdb server for imxrt1050.cpu on 3333
Info : Listening on port 3333 for gdb connections
```

When subsequently connecting via GDB, the output similar to the following will be seen from the OpenOCD session:

```
Info : accepting 'gdb' connection on tcp/3333

Initialising CPU...
target halted due to debug-request, current mode: Thread
xPSR: 0x21000000 pc: 0x2020e3a8 psp: 0x2023f728
force hard breakpoints
Note: Breakpoints limited to 8 hardware breakpoints
Disable Caches
Initialising SDRAM
```

```
semihosting is enabled
```

As can be see from the “Initialising SDRAM” above, the default CDL behaviour is to install the SDRAM initialising OpenOCD configuration script. This ensures that applications configured for the `JSDRAM` or `RBRAM` startup types can be loaded directly via GDB and OpenOCD for debugging, without requiring staging via a second-level boot loader.

See OpenOCD scripts for notes regarding the OpenOCD scripts.

PEEDI

For the Ronetix PEEDI, the `peedi.mimxrt1064_evk.cfg` or `peedi.imxrt1050_evkb.cfg` file respectively should be used to setup and configure the `MIMXRT1064-EVK` and `IMXRT1050-EVKB` hardware to an appropriate state to load programs. These files only perform basic initialization by default, leaving application code to initialize PLLs and other clocks. However, these files do include an initialization section to configure SDRAM.

The configuration files also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_Cortex-M_SWD]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

Note

Normally, when shipped, the EVK platforms are configured to use the on-board CMSIS-DAP H/W debug interface via the micro-USB connector. If an external H/W debugger is being attached via the standard ARM 20-pin 2.54mm IDC debug connector (labelled `J21` on RevA1 boards) then the corresponding H/W debug signal jumpers need to be adjusted accordingly. Please refer to the schematic or board documentation. For example, on the RevA1 `MIMXRT1064-EVK` board jumpers `J47` through `J50` control access to the external H/W debug signals.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 9000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:9000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the configuration file, and halts the target. This behaviour is repeated with the PEEDI **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal and run from the contents of the flash.

Consult the PEEDI documentation for information on other features.

H/W Debugging

Currently the standalone startup types, where H/W debug can be used, default to outputting all diagnostics information via LPUART1. The default communications parameters are 115200 baud, no parity, 1 stop bit. It is recommended that LPUART1 be accessed via the virtual CDC-ACM communication device presented by the CMSIS-DAP port.

It is possible to arrange for diagnostics to be output via the H/W debug GDB connection and appear on the gdb console. This requires the configuration option `CYGFUN_HAL_GDB_FILEIO` in the common HAL package to be enabled. This has two sub-options, `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` and `CYGSEM_HAL_DIAG_VIA_GDB_FILEIO_IMMEDIATE`, that are enabled by default when `CYGFUN_HAL_GDB_FILEIO` is enabled and both should remain enabled. In this case, when **arm-eabi-gdb** is attached to the PEEDI, the following gdb command must be issued:

```
(gdb) set hwdebug on
```

Eclipse users can do this by creating a GDB command file with the contents:

```
define preload
  set hwdebug on
end
```

This will be referenced from their Eclipse debug launch configuration. Using GDB command files is described in more detail in the "Eclipse/CDT for eCos application development" manual.

OpenOCD scripts

The OpenOCD `.cfg` files supplied in the platform package `misc` directory assume that the debug session is being used to load/start a new application. If the developer wants to attach a H/W debug session to a running system (debugging a live system) then a `noinit` configuration file that connects but does not modify the hardware state should be used instead.

For historical reasons the scripts are prefixed with `openocd.mimxrt1050-evk`, but are also used for the i.MX RT1064 targets (e.g. `mimxrt1064_evk`). Similarly, internally the OpenOCD configuration scripts use the `imxrt1050` name to identity CPU information messages generated by OpenOCD. The OpenOCD naming can be ignored.

A full overview of all of OpenOCD is beyond the scope of this document, and the developer is referred to the 3rd-party OpenOCD website for detailed documentation.

Installing RedBoot

RedBoot allows for S/W based debugging of applications over the LPUART1 diagnostic channel, or an Ethernet connection, via the GDB stubs support built into RedBoot. RedBoot is normally used to load+debug applications when a H/W debugger interface is **not** available. Since the IMX EVK boards provide an on-board CMSIS-DAP then RedBoot is not strictly required for debugging since a H/W debugger is always present. However, RedBoot also provides some functionality that may be required for the target use case (e.g. RBL (`CYGPKG_RBL`)).

Warning

The default RedBoot configuration enables Ethernet support to allow debug sessions over Ethernet. See the Supported Hardware warning about powering the board from an external PSU if RedBoot-with-Ethernet is being installed.

The following RedBoot installation process uses a H/W debug session with a `RBSRAM` RedBoot image to provide the flash access support for updating the bootable QSPI device. This approach of using a on-chip SRAM based RedBoot to provide flash write capability is applicable to any binary data that the developer wishes to install in flash (and in the case of the MIMXRT1064-EVK target the SiP QSPI as well as the external QSPI). For example, the SRAM based RedBoot can be used to write the BootUp bootable QSPI image as well as the binary (`JSDRAM`) application that BootUp will start.

Prebuilt RedBoot binaries are provided in the `loaders/mimxrt1xxx_evk` subdirectory of the eCosPro release installation. The `host` directory within this subdirectory includes the `openocd.cfg` OpenOCD configuration file used to load and execute RedBoot such that the QSPI flash boot image can be programmed into the bootable FlexSPI QSPI flash memory of the i.MX RT10XX boards.

Notes:

1. The IMXRT1050-EVKB hardware **must** be modified from its default (as shipped) HyperFlash configuration to enable QSPI access. This is documented in the relevant "MIMXRT1050-EVK Board Hardware User Guide". It involves removing and moving some 0 Ω resistors on the underside of the board. The MIMXRT1064-EVK requires no such modification since the external QSPI is already the default, and the RT1064 boots from the internal SiP flash anyway.

2. Detailed instructions for rebuilding and programming your own version of RedBoot may be found in the section called “Rebuilding and Installing RedBoot” below.

In one shell window, start OpenOCD as described in the section called “OpenOCD” above, replacing `openocd.cfg` with the OpenOCD configuration file `loaders/mimxrt1xxx_evk/host/openocd.cfg` provided within the eCosPro installation directory.

Within a second shell window, open a suitable terminal application and connect to the CDC-ACM device provided by the CMSIS-DAP debug USB interface.

Within a third shell window, as illustrated in the figure below, change to the `loaders/mimxrt1xxx_evk` subdirectory of the eCosPro release installation, run cksum to note the checksum and size of the QSPI boot image, and load the (`RBSRAM`) RedBoot ELF prebuilt image into the target using OpenOCD and GDB.

Figure 313.9. Checksum of QSPI image and Execution of RedBoot

```
$ cd eCos-4.x.y/loaders/mimxrt1050_evk
$ cksum qspi_boot.bin
2434204827 111164 qspi_boot.bin
$ arm-eabi-gdb redboot_RBSRAM.elf
GNU gdb (eCosCentric GNU tools 7.3.0e) 8.1
Copyright (C) 2018 Free Software Foundation, Inc.
... elided ...
Reading symbols from redboot_RBSRAM.elf...done.
(gdb) tar extended-rem localhost:3333
Remote debugging using localhost:3333
0x2020c330 in hal_delay_us (us=100) at .../packages/hal/cortexm/arch/current/src/hal_misc.c:609
(gdb) load
Loading section .rom_vectors, size 0x8 lma 0x20209020
Loading section .text, size 0xc080 lma 0x20209028
Loading section .rodata, size 0x36f8 lma 0x202150a8
Loading section .data, size 0x634 lma 0x202187a0
Start address 0x20209028, load size 64948
Transfer rate: 42 KB/sec, 9278 bytes/write.
(gdb) cont
Continuing.
```

From the cksum result above you can see the checksum and size of the QSPI boot image which are `2434204827` and `111164` respectively. On the second shell window running the terminal application, RedBoot output similar to the following should appear.

Figure 313.10. RedBoot Output

```
RedBoot(tm) bootstrap and debug environment [RBSRAM]
eCosCentric certified release, version 4.6.6 - built 15:15:21, Mar 17 2022

Platform: NXP MIMXRT1050-EVK (Cortex-M7)
RAM: 0x20200000-0x2023f000 [0x20220b40-0x2023b000 available]
     0x20240000-0x20280000 [0x20240000-0x20280000 available]
     0x80000000-0x82000000 [0x80000000-0x82000000 available]
FLASH: 0x60000000-0x607fffff, 2048 x 0x1000 blocks
RedBoot>
```

The naming and RAM and FLASH areas reported will depend on the target board.

RedBoot is now running on the NXP EVK and may be interacted with through the terminal application. The RedBoot output shows the available RAM that can be used as a temporary load buffer for the RedBoot QSPI boot image. In the example above the spaces

0x20240000-0x20280000 and 0x80000000-0x82000000 are available. The flash can now be initialised using RedBoot with the following flash initialisation issued at the **RedBoot>** prompt within the terminal application.

Note

Change your responses below accordingly if using DHCP/BOOTP or provide your own IP addresses and netmask for the gateway, server and local address of NXP EVK.

Figure 313.11. Initialise Flash

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.1.1
Local IP address: 192.168.1.5
Local IP address mask: 255.255.255.0
Default server IP address: 192.168.1.2
Console baud rate: 115200
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Default network device: enet0_eth
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x607fe000-0x607fefff: .
... Program from 0x20231000-0x20232000 to 0x607fe000: .
RedBoot>
```

Once the flash is initialised perform the following actions, as illustrated in Figure 313.12, “Loading RedBoot QSPI boot image into memory”:

1. Temporarily interrupt RedBoot execution by using **ctrl-C** within the third shell window (in which GDB is executing), returning to the **(gdb)** prompt.
2. Load the prepared QSPI boot image into available SRAM using the **restore** command. In this example location 0x20240000 was used.
3. Resume execution of RedBoot.

The steps above are just a simple mechanism to use the GDB debug connection to load an arbitrary binary from the host machine into the target board memory.

Figure 313.12. Loading RedBoot QSPI boot image into memory

```
...
(gdb) cont
Continuing.
^C
Program received signal SIGINT, Interrupt.
0x2020c330 in hal_delay_us (us=76) at .../packages/hal/cortexm/arch/current/src/hal_misc.c:609
(gdb) restore qspi_boot.bin binary 0x20240000
Restoring binary file qspi_boot.bin into memory (0x20240000 to 0x202524ac)
(gdb) cont
Continuing.
```

Within the RedBoot terminal, confirm the image has been loaded correctly into memory by performing a checksum of the memory region into which the QSPI boot image was loaded by GDB and compare these results with the results from the cksum application as illustrated in Figure 313.9, “Checksum of QSPI image and Execution of RedBoot”. The RedBoot cksum command requires the base address of the memory region (0x20240000 as used above) as well as the size of the region (111164 in our example).

Figure 313.13. RedBoot cksum of memory image

```
RedBoot> cksum -b 0x20240000 -l 111164
POSIX cksum = 2434204827 111164 (0x9117049b 0x000124ac)
```

As you can see the checksum values `2434204827` from both sources match. Instruct RedBoot to program the bootable QSPI flash with the image in memory as shown below.

Note

For the IMXRT1050-EVKB external QSPI the bootable flash base address is `0x60000000`. For the MIMXRT1064-EVK SiP flash the base address is `0x70000000`.

Figure 313.14. Program RedBoot into QSPI from memory image

```
RedBoot> fis write -f 0x60000000 -b 0x20240000 -l 111164
* CAUTION * about to program FLASH
            at 0x60000000..0x60012fff from 0x20240000 - continue (y/n)? y
... Erase from 0x60000000-0x60012fff: ...................
... Program from 0x20240000-0x20253000 to 0x60000000: ...................
```

At this point RedBoot has been programmed into the QSPI flash. The GDB session as well as OpenOCD must now be terminated using the **`ctrl-C`** keystroke combination in each window to interrupt and terminate the application. Assuming the SW7 is set to `OFF`, `OFF`, `ON`, `OFF` for QSPI boot selection then on the next hardware reset the system will boot (the `RBSRAM`) RedBoot from the QSPI copy automatically. The output illustrated in Figure 313.10, "RedBoot Output" will again be seen in the window executing the terminal application and normal interaction with RedBoot may again occur.

Finally, terminate the terminal application to release the CDC-ACM interface and enable both GDB and Eclipse to make use of the interface to download and debug user applications.

Rebuilding and Installing RedBoot

The following process is actually applicable to any standalone application that needs to be programmed into the FlexSPI QSPI flash memory and started from CPU reset, not just the special `RBSRAM` RedBoot startup type. For example, a different second-level boot loader or the final standalone (`SRAM`) application. The `RBSRAM` is for RedBoot configurations that execute from SRAM and can be directly started by the i.MX RT ROM bootloader, with `RBRAM` being used for RedBoot configurations that execute from SDRAM and are started via a second-level boot loader (e.g. BootUp, a `RBSRAM` RedBoot or a customer specific boot loader application). See the section called "Startup" for an overview of the different application startup types.

See the Notes: from the previous section with regards to IMXRT1050-EVKB QSPI support.

RedBoot can be configured to reside+execute from SRAM (OCRAM) or the external SDRAM. A `RBSRAM` RedBoot application should be configured and built using the `redboot_RBSRAM.ecm` file provided in the `packages/hal/cortexm/imx/mimxrt1xxx_evk/current/misc` subdirectory of the eCosPro installation. Correspondingly a SDRAM resident RedBoot application should be configured and built using the `redboot_RBRAM.ecm` configuration fragment.

However, since the decision to keep a single `RAM` startup type for applications loaded into SDRAM and executed under RedBoot regardless of whether a SRAM or SDRAM RedBoot is active means that the RedBoot SRAM allocation is **always** set aside. This means that there is **no** substantive benefit from an SDRAM based RedBoot currently. So the following example just documents the `RBSRAM` case.

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the SRAM version of RedBoot are:

```
$ mkdir redboot_rbsram
$ cd redboot_rbsram
$ ecosconfig new mimxrt1050_evk redboot
[ … ecosconfig output elided … ]
```

```
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/imx/mimxrt1xxx_evk/VERSION/misc/redboot_RBSRAM.ecm
$ ecosconfig tree
$ make
```

The standard make build process will create a binary version of the RedBoot application alongside the ELF version used for debugging. The `install/bin` subdirectory should contain the file `redboot.bin` which will be used when building the boot image. The example above targets the `mimxrt1050_evk` platform, but the same process can be used by replacing with the `mimxrt1064_evk` platform name.

Create a QSPI boot image from this `RBSRAM` RedBoot binary as follows:

```
$ flashimg_rt10 --qspi install/bin/redboot.bin install/bin/qspi_boot.bin
```

Notes:

1. Prebuilt host executables of the **flashimg_rt10** are located in the `loaders/mimxrt1050_evk/host` subdirectory of the eCosPro installation directory. Ensure these executables are either in the host's PATH or provide the full or relative path to the executable relevant to your host's operating system when executing the above command.

2. The **--qspi** parameter is **required** to ensure the correct layout and contents of boot ROM descriptor structures to allow the application to be booted from the QSPI device.

3. If using the prebuilt RedBoot images provided in the release, the filenames `redboot_RBSRAM.elf`, `redboot_RBSRAM.bin` and its flashimg_rt10 derivative `qspi_boot.bin` within the `loaders/mimxrt1050_evk` subdirectory should be referenced in place of the files `install/bin/redboot.elf`, `install/bin/redboot.bin` and `install/bin/qspi_boot.bin` respectively in the examples below.

The simplest approach for installing the boot image is to use the onboard CMSIS-DAP debug interface and GDB to load the boot image into memory and use the `RBSRAM` RedBoot itself to initialise the flash. See the OpenOCD section for an overview of starting the necessary GDB server, and the Installing RedBoot section for an example of using RedBoot to flash an image.

Further application installation examples

The following are just examples of some possible use cases that may helpful in providing an overview for developers.

SRAM application

Since SRAM resident applications, configured with the `SRAM` startup type, do not need a second-stage boot loader they can be packaged as a bootable image and flashed to the start of the respective flash memory directly.

The `RBSRAM` (SRAM resident) RedBoot is just a special-case of an SRAM application since it needs to ensure SRAM and SDRAM are shared between itself and the non-standalone `RAM` startup applications that it hosts. Aside: The `RBSRAM` RedBoot can be used to start a standalone (e.g. `JSDRAM`) application and so can just act as a second-stage boot loader if required where the executed application makes no use of RedBoot functionality after it has been started, **but** note that such standalone applications can then not be debugged via the RedBoot GDB stubs connection.

To boot **any** application built from a `SRAM` startup type configuration you first need to extract the binary image from the generated ELF file. e.g. replacing *`app.elf`* and the destination binary name as appropriate:

```
$ arm-eabi-objcopy -O binary app.elf app.bin
```

Then, as described in the flashimg_rt10 section, you convert that raw binary into a bootable image:

```
$ flashimg_rt10 --qspi app.bin qspi_boot.bin
```

The resulting image can then be written to the relevant bootable flash device as demonstrated in the Installing RedBoot section, with the filenames replaced accordingly.

BootUp started application

When the user wants to start an external SDRAM based application at boot a SRAM based second-level boot loader like BootUp is required. BootUp provides a simpler, quicker, smaller implementation than RedBoot. It can be extended with customer or platform features as required; but the basic implementation simply copies the application from its stored NVM (Non-Volatile Memory) location to SDRAM and executes it.

As documented in the VAR BootUp section the command-line BootUp build creates the `bootup.bin` image. So the `arm-eabi-objcopy` step as documented above for SRAM applications is already done. However the `flashimg_rt10` step should still be performed to create a bootable image. The resulting QSPI bootable image should be written to the start of the flash.

For the actual application, created from a `JSDRAM` configured build, just like the SRAM approach, the generated ELF file should be converted to a binary for flashing.

```
$ arm-eabi-objcopy -O binary sdramapp.elf sdramapp.bin
```

That binary needs no further processing, and should be written as-is to the relevant flash memory at offset `CYGNUM_BOOTUP_IMX_SOURCE_OFFSET`. The use of a H/W debug session and a `RBSRAM` RedBoot provides a mechanism for writing arbitrary images to flash.

On subsequent target resets, the system ROM Bootloader will execute the BootUp code, which in turn will find, load and start the SDRAM application.

For subsequent updates of the main SDRAM based application only the application binary from offset `CYGNUM_BOOTUP_IMX_SOURCE_OFFSET` onwards need be replaced. The BootUp installation itself is normally just a one-time process.

As previously noted, the SDRAM based `RBRAM` is just a special-case startup type used when building a SDRAM resident RedBoot. If using the `RBRAM` RedBoot then its binary should be written to the flash from offset `CYGNUM_BOOTUP_IMX_SOURCE_OFFSET`.

RedBoot started application

For details of using RedBoot to start the final SDRAM based application refer to the Executing Programs from RedBoot documentation.

Name

Configuration — Platform-specific Configuration Options

Overview

The MIMXRT1xxx-EVK board platform HAL package is loaded automatically when eCos is configured for a suitable target, e.g. `mimxrt1050_evk` or `mimxrt1064_evk`. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The MIMXRT1xxx-EVK board platform HAL package supports six separate startup types:

JTAG

> This is the default startup type. It is used to build applications that are loaded via a H/W debug interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20209000 and entered at 0x20209008. eCos startup code will perform all necessary hardware initialization.
>
> Even though this startup type is the default, it is not normally expected to be used in the field. It is normally used for testing and development on uninitialised boards.

SRAM

> This startup type is currently essentially equivalent to the JTAG startup type in memory layout and usage. This startup is intended to be used for standalone applications, either loaded from an external memory device such as an SD card or FlexSPI flash at boot time, or via a H/W debug interface.
>
> The program expects to be loaded from 0x20209020, and the eCos startup code will perform all necessary hardware initialisation. The difference in load address from the JTAG startup is to allow space for the boot ROM configuration structures required when the application is packaged into a boot image using the `flashimg_rt10` tool.
>
> This startup type should be configured for standalone applications to execute from SRAM. All of the SRAM is available for application use, and the external SDRAM is unassigned and not managed by eCos, but is available for application use.

JSDRAM

> This startup is intended to be used for standalone applications, either loaded from an external memory device such as an SD card or FlexSPI flash at boot time via a second-level boot loader, or via a H/W debug interface into external SDRAM.
>
> The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x80000000 and entered at 0x80000018 (based on the current application signature block size). eCos startup code will perform all necessary hardware initialization. JSDRAM applications can only be loaded once the SDRAM has been initialised, either when loaded from a boot location in conjunction with a valid IVT+DCD via a second-level boot loader, or when loaded via a suitable H/W debug session directly.
>
> This startup type should be configured for standalone applications to execute from SDRAM. All of the SDRAM and SRAM is available for application use.

RBRAM

> This is a special case startup type intended for SDRAM based RedBoot applications. It is essentially equivalent to the `JSDRAM` startup type, but with a section from the start of SRAM and SDRAM allocated to RedBoot for its code+data storage. The remaining SRAM and SDRAM is set aside for applications loaded/executed via the RedBoot instance. As mentioned, this startup is intended to be used for the standalone RedBoot, either loaded at boot from a memory device such as the FlexSPI flash via a second-level boot loader, or via a H/W debug interface.

The program expects to be loaded from 0x80000000, and the eCos startup code will perform all necessary hardware initialisation.

RBSRAM

This is a special case startup type intended for SRAM based RedBoot applications. It is essentially equivalent to the `SRAM` startup type, but with the bottom of the SRAM allocated to RedBoot, along with an (unused) section at the start of SDRAM, for the RedBoot code+data requirements. The remaining SRAM and SDRAM are set aside for applications loaded/executed via the RedBoot instance. As mentioned, this startup is intended to be used for the standalone RedBoot, either loaded at boot from a memory device such as the FlexSPI flash, or via a H/W debug interface.

The program expects to be loaded from 0x20209020, and the eCos startup code will perform all necessary hardware initialisation. The difference in load address from the `JTAG` startup is to allow space for the boot ROM configuration structures required when the application is packaged into a boot image. e.g. as by the **flashimg_rt10** tool.

RAM

This startup type is for applications that are loaded via RedBoot into external SDRAM. They rely on services supplied by RedBoot. RAM applications can only be loaded via RedBoot.

Note

Due to the `RBSRAM` startup type RedBoot code+data occupying SRAM, only the upper section of SRAM is available for `RAM` applications.

Similarly due to the `RBRAM` startup type RedBoot code+data occupying the start of SDRAM, the available SDRAM for `RAM` applications starts from the offset `CYGMEM_REGION_redboot_SIZE`.

The decision to set aside the SRAM and SDRAM space for RedBoot in both `RBRAM` **and** `RBSRAM` RedBoot configurations was taken to allow the `RAM` startup applications to be loaded irrespective of whether RedBoot is executing from SRAM or SDRAM.

As highlighted in the VAR On-chip memory section, the i.MX RT ROM bootloader cannot directly boot external-SDRAM applications. If the final application is a `JSDRAM` standalone application, or a `RBRAM` RedBoot, then a second-level boot loader is required. The BootUp (`CYGPKG_BOOTUP`) application is a lightweight second-level loader implementation, with the VAR BootUp section providing an overview. Alternatively a `RBSRAM` RedBoot could be used to boot the final `RBRAM` RedBoot if really required, but since the SRAM cost of both RedBoot configurations are the same it is expected that if RedBoot is required then a `RBSRAM` version is used (as can be directly booted by the i.MX RT ROM bootloader). The only benefit for a SDRAM based RedBoot would be **if** the `RBRAM` **and** `RAM` startup types were modified to not make use of the SRAM, but that would preclude using `RAM` startup applications under a `RBSRAM` RedBoot.

UART Serial Driver

The MIMXRT1050-EVK board uses the RT10XX internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, is only expected to be available to be used on the LPUART1 port.

As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_NXP_LPUART` package which contains all the code necessary to support interrupt-driven operation with greater functionality.

It is not recommended to use the interrupt-driven serial driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration. By default this will only enable support in the driver for the LPUART1 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports.

SPI Driver

An SPI bus driver is available in the package "NXP LPSPI Support" (CYGPKG_DEVS_SPI_NXP_LPSPI).

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the NXP SPI device driver.

I²C Driver

Support for NXP I²C busses is provided by the "NXP LPI2C Support" package (CYGPKG_DEVS_I2C_NXP_LPI2C). The variant HAL causes two buses to be instantiated. These have been tested using external I²C devices.

Flash Driver

The external FlexSPI Flash, and in the case of RT1064 boards the FlexSPI2 attached SiP Flash. may be programmed and managed using the Flash driver located in the "NXP FlexSPI Support" (CYGPKG_DEVS_FLASH_NXP_FLEXSPI) package. This driver is enabled automatically if the generic "Flash device drivers" (CYGPKG_IO_FLASH) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific flash variant present on the IMXRT1050-EVKB and MIMXRT1064-EVK boards.

Ethernet Driver

The EVK boards use the internal ENET Ethernet device attached to an external Micrel KSZ8081RNB PHY. The CYGPKG_DEVS_ETH_FREESCALE_ENET package, in conjunction with the VAR HAL, contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the board. The driver is not active until the generic Ethernet support package, CYGPKG_IO_ETH_DRIVERS, is included in the configuration.

This PLF HAL provides support for enforcing the start-of-day PHY pin strapping for correct operation.

CAN Driver

The iMX RT1xxx devices have multiple FlexCAN interfaces. Device support is via the NXP FlexCAN CAN Driver package.

The EVK boards have a single CAN connector (unpopulated by default) on J11 that is configured as FlexCAN2 for RT1052 boards, and FlexCAN3 for RT1064 boards.

Consult the generic Chapter 90, *CAN Support* documentation for further details on use of the CAN API, CAN configuration and device drivers.

Watchdog Driver

The board uses the RT10XX Watchdog timer 1. The CYGPKG_DEVICES_WATCHDOG_ARM_IMX package contains all the code necessary to support this device. Within that package the CYGNUM_DEVS_WATCHDOG_ARM_IMX_DESIRED_TIMEOUT_MS configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, CYGPKG_IO_WATCHDOG, is included in the configuration.

PWM Driver

Support for the NXP FlexPWM devices is provided by the "NXP PWM Support" package (CYGPKG_DEVS_PWM_NXP) which needs to be used in conjunction with the CYGPKG_IO_PWM generic PWM package. Refer to the documentation for that package for usage details.

The RT10XX contains four FlexPWM devices, each of which contains four independent submodules. Each submodule has two semi-independent output lines that can be routed to a variety of pads. Each submodule is presented as a separate PWM device and have names such as "pwm1.0" for FlexPWM 1 submodule 0 or "pwm3.2" for FlexPWM 3 submodule 2. The output lines are mapped on to channel 0 for output A and channel 1 for output B. These outputs are semi-independent in that they must share a period, but may have different duty cycles.

USB Support

Support for both Host and Peripheral mode operation is provided by the USB protocol stack plus EHCI host and peripheral drivers (`CYGPKG_DEVS_USB_EHCI` and `CYGPKG_DEVS_USB_PCD_EHCI`).

Host mode is supported for USB2 which is connected to the USB_HOST microab receptacle. Class support is available for mass storage devices, and CDC-ACM serial.

Peripheral mode is supported for USB1 which is connected to the USB_OTG microab receptacle. Note that OTG mode is not supported. By default this peripheral port is configured as a CDC-ACM device.

USB configuration is handled by the "RT10XX USB controller configuration" package (`CYGPKG_DEVS_USB_RT10XX`). Here both the host and peripheral drivers are instantiated along with the CDC-ACM peripheral serial device if configured.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the IMXRT1050-EVKB and MIMXRT1064-EVK board hardware, and should be read in conjunction with that specification. The MIMXRT1xxx-EVK platform HAL package complements the Cortex-M architectural HAL and the i.MX variant HAL. It provides functionality which is specific to the target boards.

Startup

For the `SRAM`, `JTAG`, `JSDRAM`, `RBRAM` and `RBSRAM` startups, the HAL will perform initialization, programming the various internal registers including the PLL, peripheral clocks and pin multiplexing. The details of the early hardware startup may be found in the `src/imx_misc.c` in both `hal_system_init()` and `hal_platform_init()`.

Note

Some of the initial I/O run-time configuration is performed by the iMX boot ROM parsing the IVT+DCD binary structures that describe a bootable image. The relevant i.MX RTxxx PRM (Processor Reference Manual) documentation should be consulted for a detailed overview if required.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory areas are as follows:

Internal SRAM

This is located at address 0x20200000 of the memory space, and is 512KiB in size for RT105x CPUs and 1MiB in size for the RT1064. The eCos VSR table occupies the bottom 704 bytes, with the virtual vector table starting at 0x200002C0 and extending to 0x200003C0. Depending on the startup type the top of SRAM may have `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes reserved for the interrupt stack, as well as an uncached area for driver/DMA use. The remainder of internal SRAM is available for use by applications.

External SDRAM

This is located at address 0x800000000 of the memory space. This region is 32MiB in size. Standalone `JSDRAM` or RedBoot loaded `RAM` applications are by default configured to run from this memory. This memory is only available after either A) an application has been loaded from a boot device, since it is initialized by the DCD that is part of the boot image or B) configured by the H/W debugger connection script.

For example, if RedBoot is installed as the bootable application then the DCD prefixed to the RedBoot application configures the SDRAM as needed.

On-Chip Peripherals

These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the i.MX RT10XX User Manual.

Flash

For the RT1052 and RT1064 the external (off-chip) QSPI flash is mapped from address 0x60000000. For the RT1052 this external flash is the bootable flash device.

For the RT1064 the “external” (SiP) QSPI attached to FlexSPI2 is mapped from address 0x70000000. For the RT1064 this SiP flash is the bootable flash device.

Linker Scripts

The platform linker script defines the following symbols:

hal_vsr_table
This defines the location of the VSR table. This is set to 0x20200000 for all startup types, and space for 176 entries is reserved.

hal_virtual_vector_table
This defines the location of the virtual vector table used to communicate between a ROM monitor and an eCos application. If required this is allocated right after the VSR table, at 0x202002C0.

hal_interrupt_stack
This defines the location of the interrupt stack. This is allocated to the top of application available SRAM or SDRAM depending on the startup type.

hal_startup_stack
This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for JTAG startup on a MIMXRT1050-EVK board.

Example 313.1. MIMXRT1050-EVK Real-time characterization

```
Configured
Testing parameters:
   Clock samples:            32
   Threads:                  25
   Thread switches:         128
   Mutexes:                1165
   Mailboxes:               340
   Semaphores:             2040
   Scheduler operations:    128
   Counters:                680
   Flags:                  1360
   Alarms:                  582
   Stack Size:             1088

             Startup, main thrd : stack used   356 size  2048
             Startup : Idlethread stack used    76 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    7.84 microseconds (7 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  25
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32
   Stack Size:             1088

PASS:<Basic timing OK>
EXIT:<done>
```

Platform specific tests

A single platform specific test is available.

platform

The `platform` test is a simple validity check application. It tests application access to some basic functionality, as well as providing some diagnostic information on system settings.

The test source is set up for automated testing (e.g. as used in the eCosCentric test farm). However, the `__MANUAL` manifest can be manually enabled to provide some extra testing requiring user interaction. Currently `__MANUAL` controls access to a simple polled and interrupt-driven GPIO `SW8` (USER_BUTTON) test. That specific test case implements an example of using the demultiplexed GPIO interrupt support.

Part LXXIX. H8300 Architecture

Table of Contents

Chapter 314. H8/300 Architectural Support

Name

Overview — eCos Support for the H8/300 Family of Processors

Description

The H8/300 family includes the H8/300H and H8S processors. These processors execute a largely common instruction set and have the following common features:

- Eight general purpose 32-bit registers, ER0 to ER7,which may also be addressed as 16 16-bit and 16 8-bit registers. Register ER7 is also used as the stack pointer. In addition there is a 24-bit program counter, an 8-bit condition code register, and on the H8S an 8 bit extended control register.
- A linear address space, limited to 24-bits, matching the size of the PC. Hence the processor can address 16 megabytes of memory.
- No separate address space for I/O operations. Instead devices are accessed just like memory via the main address and data buses.
- A variable-length instruction set with a variety of different addressing modes.
- The H8/300H has a simple single-level interrupt system while the H8S can support an 8-level prioritized system via the extended control register.
- The H8S has support for single instruction tracing.

The architectural HAL provides support for those features which are common to all members of the H8/300 families, and for certain features which are present on some but not all members. A typical eCos configuration will also contain a variant HAL package with support code for a family of processors, possibly a processor HAL package with support for one specific processor, and a platform HAL which contains the code needed for a specific hardware platform. For example the variant or processor HAL may define the exact interrupt controller hardware that is available, and the platform HAL will define the external interrupt vector connections.

Name

Options — Configuring the H8/300 Architectural Package

Loading and Unloading the Package

The H8/300 architectural HAL package CYGPKG_HAL_H8300 should be loaded automatically when eCos is configured for H8/300-based target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Stacks

By default the architectural HAL provides a single block of memory to act as both the startup stack and the interrupt stack. The variant, processor or platform HAL may override this. For example if there are several banks of RAM with different performance characteristics it may be desirable to place the interrupt stack in fast RAM rather than in ordinary RAM.

The assembler startup code sets the stack pointer to the startup stack before switching to C code. This stack is used for all HAL initialization, running any C++ static constructors defined either by eCos or by the application, and the cyg_start entry point. In configurations containing the eCos kernel cyg_start will enable interrupts, activate the scheduler and threads will then run on their own stacks. In non-kernel single-threaded applications the whole system continues to run on the startup stack.

When an interrupt occurs the default behaviour is to switch to a separate interrupt stack. This behaviour is controlled by the common HAL configuration option CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK. It reduces the stack requirements of all threads in the system, at the cost of some extra instructions during interrupt handling. In kernel configurations the startup stack is no longer used once the scheduler starts running so its memory can be reused for the interrupt stack. To handle the possibility of nested interrupts the interrupt handling code will detect if it is already on the interrupt stack, so in non-kernel configurations it is also safe to use the same area of memory for both startup and interrupt stacks. This leads to the following scenarios:

1. If interrupt stacks are enabled via CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK and the interrupt stack is not provided by the variant, processor or platform HAL then a single block of memory will be used for both startup and interrupt stacks. The size of this block is determined by the common HAL configuration option CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE, with a default value CYGNUM_HAL_DEFAULT_INTERRUPT_STACK_SIZE provided by the H8300 architectural HAL.
2. If the use of an interrupt stack is disabled then the H8/300 architectural HAL will provide just the startup stack, unless this is done by the variant, processor or platform HAL. The size of the startup stack is still controlled by CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK.
3. Otherwise the interrupt and/or startup stacks are provided by other packages and it is up to those packages to provide configuration options for setting the sizes.

SCI Baud Rate

The architecture HAL provides a polled driver for the SCI serial device that is common to all H8/300 implementations. This is used by RedBoot for user interaction and by eCos applications for diagnostic output. Configuration of the device is handled in the variant HAL, but the baud rate is set in the architecture HAL using the CYGNUM_HAL_H8300_SCI_BAUD_RATE option.

Interrupt Vector Hook

The H8/300 architecture does not provide any mechanism for determining the source of an interrupt or exception other than the address of the routine to which control is vectored. Since eCos uses common code for most vectors, and demultiplexes the source later, this makes handling difficult. To overcome this, all interrupt and exception vectors are pointers to entries in a table of single instruction JSR instructions which all call the common handling code. The stacked return address can then be used to synthesize a vector number that is used by the common handling code.

By default this JSR hook table is stored in on-chip RAM (it is actually placed by the platform specific .ldi file). This placement makes this vectoring fast and of minimal impact on performance. It also allows individual vectors to be replaced if desired -- although this functionality is also provided in a more convenient form by the standard eCos VSR table that is also placed in on-chip RAM. If the option CYGSEM_HAL_H8300_VECTOR_HOOK is disabled, then the hook table will be stored in ROM, which will free space in the on-chip RAM but will increase interrupt processing time and remove the ability to revector exceptions at this level (but won't affect the VSR table).

If the option CYGSEM_HAL_H8300_SAVE_STUB_VECTOR is enabled then the vector hook table will be saved by an eCos application before being replaced with its own table. This is theoretically to permit RedBoot to coexist with eCos. In practice the common VSR table mechanism handles this in a more portable manner.

Other Options

The H8/300 architectural HAL package does not define any other configuration options that can be manipulated by the user.

Name

HAL Port — Implementation Details

Description

This documentation explains how the eCos HAL specification has been mapped onto H8/300 hardware, and should be read in conjunction with that specification. It also describes how variant, processor and platform HALs can modify the default behaviour.

eCos support for any given target will involve either three or four HAL packages: the architectural HAL, the platform HAL, the variant HAL, and optionally a processor HAL. This package, the architectural HAL, provides code and definitions that are applicable to all H8/300 processors. The platform HAL provides support for one specific board, or possibly for a number of almost-identical boards. The processor HAL, if present, serves mainly to provide details of on-chip peripherals including the interrupt controller. The variant HAL provides functionality that is common to a group of processors, for example all H8S processors have very similar UARTs and hence can share HAL diagnostic code. There is no fixed specification of what should go into the variant HAL versus the processor HAL. For simplicity the description below only refers to variant HALs, but the work may actually happen in a processor HAL instead.

As a design goal lower-level HALs can always override functionality that is normally provided higher up. For example the architectural HAL will provide the required eCos `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` macros, but these can be provided lower down instead. In some areas such as handling context switching the architectural HAL will usually provide the basic functionality but it may be extended by lower HALs. The architecture HAL consequently contains a large number of macros at both C and assembler level that variant HALs are expected to supply functionality for.

The architectural HAL provides header files `cyg/hal/hal_arch.h`, `cyg/hal/hal_intr.h`, `cyg/hal/hal_cache.h`, `cyg/hal/hal_io.h` and `cyg/hal/arch.inc`. These automatically include an equivalent header file from the variant HAL, for example `cyg/hal/var_arch.h`. The variant HAL header will in turn include processor and platform-specific headers. This means that application developers and other packages can simply include the architectural HAL headers without needing to know about variants or platforms. It also allows the variant and platform HALs to override architectural settings.

Data Types

For eCos purposes all H8/300 processors are big-endian and 32-bit, so the default data types in `cyg/infra/cyg_type.h` are used. Some variants have external bus widths less than 32-bit, but this does not affect the architectural HAL.

Startup and Exception Vectors

The conventional bootstrap mechanism involves a table of exception vectors at the base of memory. The first two words of this table are reset entry points for power-on reset and manual reset. In a typical embedded system the hardware is arranged such that non-volatile flash memory is found at location 0x0 so it is the start of flash that contains the exception vectors and the boot code. The table of exception vectors is used subsequently for interrupt handling and for hardware exceptions.

The exact hardware details, the various startup types, the steps needed for low-level hardware initialization, and so on are not known to the architectural HAL. Hence although the architectural HAL does provide the basic framework for startup, much of the work is done via macros provided by lower-level HAL packages and those macros are likely to depend on various configuration options. Rather than try to enumerate all the various combinations here it is better to look at the actual code in `vectors.S` and in appropriate variant, processor or platform HALs. `vectors.S` is responsible for any low-level initialization that needs to happen. This includes setting up a standard C environment with the stack pointer set to the startup stack in working RAM, making sure all statically initialized global variables have the correct values, and that all uninitialized global variables are zeroed. Once the C environment has been set up the code jumps to `cyg_start()` which completes the initialization and jumps to the application entry point.

Interrupt Handling

The H8/300 architecture reserves a vector table area of memory for exception vectors. These are used for internal and external interrupts, exceptions, software traps, and special operations such as reset handling. Some of the vectors have well-defined uses.

However when it comes to interrupt handling the details will depend on the processor variant and on the platform, and the appropriate package documentation should be consulted for full details.

The default behaviour is for all exceptions and interrupts to be vectored from the hardware vector table via the JSR hook table to a piece of trampoline code. This saves the CPU state on the stack and decodes the hook table return address into a simple vector number. This is then used to index the VSR table and fetch the address of the Vector Service Routine for that exception. This is then called with the vector number in ER1.

The standard eCos macros HAL_VSR_GET and HAL_VSR_SET just manipulate one of the entries in the VSR table. Hence it is possible to replace the default handlers for exceptions and traps in addition to interrupt handlers. hal_intr.h provides #define's for the more common exception vectors, and additional ones can be provided by the platform or variant. It is the responsibility of the platform or variant HAL to initialize the table, and to provide the HAL_VSR_SET_TO_ECOS_HANDLER macro since that requires knowledge of the default table entries.

At the architecture level there is no fixed mapping between VSR and ISR vectors. Instead that is left to the variant or platform HAL. The architectural HAL does provide default implementations of HAL_INTERRUPT_ATTACH, HAL_INTERRUPT_DETACH and HAL_INTERRUPT_IN_USE since these just involve updating a static table.

By default the interrupt state control macros HAL_DISABLE_INTERRUPTS, HAL_RESTORE_INTERRUPTS, HAL_ENABLE_INTERRUPTS and HAL_QUERY_INTERRUPTS are implemented by the variant HAL for the different processor variants, and involve updating either the condition code or extended control registers.

HAL_DISABLE_INTERRUPTS has no effect on non-maskable interrupts. This causes a problem because parts of the system assume that all normal interrupt sources are affected by this macro. If the target hardware can raise non-maskable interrupts then it is the responsibility of application code to install a suitable VSR and handle non-maskable interrupts entirely within the application, bypassing the usual eCos ISR and DSR mechanisms.

The architectural HAL does not provide any support for the interrupt controller management macros like HAL_INTERRUPT_MASK. These can only be implemented on a per-variant, per-processor or per-platform basis.

Exception Handling

Synchronous exception handling is done in much the same way as interrupt handling.

The details of exception handling vary from one variant to the next depending on the interrupt control mode. The architectural HAL makes no attempt to cope with these differences, and it is the responsibility of the variants to provide more advanced support. Otherwise if an exception needs to be handled in a very specific way then it is up to the application to install a suitable VSR and handle the exception directly.

Stacks and Stack Sizes

cyg/hal/hal_arch.h defines values for minimal and recommended thread stack sizes, CYGNUM_HAL_STACK_SIZE_MINIMUM and CYGNUM_HAL_STACK_SIZE_TYPICAL. These values are specific to the current configuration, and are affected mainly by options related to interrupt handling.

By default eCos uses a separate interrupt stack, although this can be disabled through the configuration option CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK. When an interrupt or exception occurs eCos will save the context on the current stack and then switch to the interrupt stack before calling the appropriate ISR interrupt handler. This means that thread stacks can be significantly smaller because there is no need to worry about interrupt handling overheads, just the thread context. However switching the stack does require some extra work and hence increases the interrupt latency. Disabling the interrupt stack removes this processing overhead but requires larger stack sizes. It depends on the application whether or not this is a sensible trade off.

By default eCos does not allow nested interrupts, but this can be controlled via the configuration option CYGSEM_HAL_COMMON_INTERRUPTS_ALLOW_NESTING. Supporting nested interrupts requires larger thread stacks, especially if the separate interrupt stack is also disabled. It may also require additional support from the variant and platform HALs. Note that at present this support is not complete in any variant, so interrupt nesting is currently disabled.

The H8/300 is somewhat register-poor, and although the calling conventions are register-oriented, a lot of use is made of stack space. In particular register contents must be spilled to the stack frequently, and the return address is pushed rather than ending up in a link register. To allow for this the recommended minimum stack sizes are a little bit larger than for some other architectures. Variant HALs cannot directly affect these stack sizes.

Usually the H8/300 architectural HAL will provide a single block of memory which acts as both the startup and interrupt stack, and there are configuration options to control the size of this block.

Thread Contexts and Setjmp/Longjmp

A typical thread context consists of the following:

1. The integer context. This consists of the data registers `ER0` to `ER6`. The stack pointer register `ER7` does not have to be always saved explicitly since it is implicit in the pointer to the saved context.

   The caller-save registers are `ER0` to `ER2`, and the condition code register. The remaining registers are callee-save. The result is passed back via `ER0`.

2. The condition code register, the program counter, and extended status register `EXR` on H8S. These are special because when an interrupt occurs the hardware automatically pushes these onto the stack, but exactly what gets pushed depends on the variant.

`setjmp` and `longjmp` only deal with the callee-save registers. The variant HAL package can override the default implementations if necessary.

When porting to a new H8/300 variant, the variant HAL must define a number of assembler-level macros to customize the behaviour of the architecture HAL to the variant. These are too numerous to specify in detail here and the reader is directed to look at the existing HAL ports for examples.

Bit Indexing

For performance reasons the `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` macros are implemented using functions containing inline assembler. A variant HAL can override the default definitions if, for example, the variant has special instructions to perform these operations.

Idle Thread Processing

The default `HAL_IDLE_THREAD_ACTION` implementation is a no-op. A variant HAL may override this, for example to put the processor into sleep mode. Alternative implementations should consider exactly how this macro gets used in eCos kernel code.

Clock Support

The architectural HAL cannot provide the required clock support because it does not know what timer hardware may be available on the target hardware. Instead this is left to either the variant or platform HAL, depending on whether the processor has a suitable on-chip timer or whether an off-chip timer has to be used.

HAL I/O

The H8/300 architecture does not have a separate I/O bus. Instead all hardware is assumed to be memory-mapped. Further it is assumed that all peripherals on the memory bus are wired appropriately for a big-endian processor and that there is no need for any byte swapping. Hence the various HAL macros for performing I/O simply involve pointers to volatile memory.

The variant, processor and platform equivalents of the `cyg/hal/hal_io.h` header will typically also provide details of some or all of the peripherals, for example register offsets and the meaning of various bits in those registers.

Diagnostic Support

The architecture HAL provides an implementation of the SCI serial device that is common to all H8/300 microcontrollers. However, it is the responsibility of the the variant or platform HAL to provide the register definitions and to instantiate the devices by calling `cyg_hal_plf_sci_init()`.

SMP Support

The H8/300 port does not have SMP support.

Debug Support

The H8300 architectural HAL package provides basic support only for gdb stubs. There is no support for more advanced debug features like hardware watchpoints. Trace-based single step is supported on the H8S variant.

Other Functionality

The H8/300 architectural HAL only implements the functionality provided by the eCos HAL specification and does not export any extra functionality.

Part LXXX. i386 Architecture

Table of Contents

Chapter 315. I386 PC Support

Name

eCos Support for the i386 PC — Overview

Description

This document covers the eCos support for all i386 based PCs. This configuration of eCos should run on all i386/486/Pentium motherboards and PC compatible embedded devices.

For typical eCos development, a RedBoot image is programmed onto a disk device and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

eCos runs the i386 CPU in 32-bit protected mode. The segment registers are initialized to provide a flat 32-bit address space and the MMU is not enabled. Coherence between the cache and device memory is handled entirely by the hardware.

There is a serial driver `CYGPKG_IO_SERIAL_GENERIC_16X5X` which supports the 16X5X UARTs used by the PC. The `CYGPKG_IO_SERIAL_I386_PC` package provides customization of this generic driver to the PC hardware. These devices can be used by RedBoot for communication with the host. If any of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver packages are loaded automatically when configuring for the PC target.

Supported Ethernet devices include the Intel i82559, Intel i82544, National Semiconductor DP83816 and RealTek RTL8139. Each of these devices is supported by a generic device driver plus a package that customizes it to the PC hardware environment.

eCos manages the standard PC priority interrupt controller. PIT timer 0 is used to implement the eCos system clock and the microsecond delay function. eCos assumes that the PCI bus will be configured by the BIOS.

Tools

The i386 port is intended to work with GNU tools configured for an i386-elf target. The original port was undertaken using i386-elf-gcc version 3.2.1, i386-elf-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing a PC for eCos Development

Overview

In a typical development environment, the PC boots into the RedBoot monitor from a floppy disk. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **i386-elf-gdb**. Preparing for development therefore involves writing a suitable RedBoot image onto a floppy disk.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
FLOPPY	RedBoot booted from a floppy disk and running in the bottom 640k of RAM	`redboot_FLOPPY.ecm`	`redboot_FLOPPY.bin`
GRUB	RedBoot loaded by the GRUB bootloader into memory above 0x00100000	`redboot_GRUB.ecm`	`redboot_GRUB.bin`
ROM	RedBoot booted directly from ROM (experimental and unsupported)	`redboot_ROM.ecm`	`redboot_ROM.bin`
FLOPPY_SMP	RedBoot booted from a floppy disk and running in the bottom 640k of RAM. This version supports dual processor systems.	`redboot_FLOPPY_SMP.ecm`	`redboot_FLOPPY_SMP.bin`
GRUB_SMP	RedBoot loaded by the GRUB bootloader into memory above 0x00100000. This version supports dual processor systems.	`redboot_GRUB_SMP.ecm`	`redboot_GRUB_SMP.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. RedBoot also supports ethernet communication and flash management.

Initial Installation

Floppy Installation

RedBoot takes the form of a self-booting image that must be written onto a formatted floppy disk. The process will erase any file system or data that already exists on that disk, so proceed with caution.

For Red Hat Linux users, writing the RedBoot image to floppy disk this can be achieved using the following command:

```
$ dd conv=sync if=install/bin/redboot.bin of=/dev/fd0H1440
```

For Windows users with recent versions of Cygwin, the raw floppy device should be accessible as `/dev/fd0`. Users with older versions of Cygwin may need to mount the floppy drive explicitly using the command:

```
$ mount -f -b //./a: /dev/fd0
```

To actually install the boot image on the floppy under Cygwin, use the command:

```
$ dd conv=sync if=install/bin/redboot.bin of=/dev/fd0
```

Insert this floppy in the A: drive of the PC to be used as a target and ensure that the BIOS is configured to boot from A: by default. On reset, the PC will boot from the floppy and the target will be ready for GDB debug sessions via either serial line, or the ethernet interface if it is installed.

NOTE

Unreliable floppy media may cause the write to silently fail. This can be determined if the RedBoot image does not correctly boot. In such cases, the floppy should be (unconditionally) reformatted using the **fdformat** command on Linux, or **format a: /u** on DOS/Windows.

VMWare Installation

The PC platform HAL may also be run under VMWare (Player, Server, etc). This can provide an initial development environment using simulated i386 PC hardware. The setup is similar to a floppy installation. However no IDE devices should be included in the guest definition due to issues with VMWare. The AMD Lance ethernet device is also recommended as the mechanism to communicate to the simulated PC hardware. The remainder of this sub-section describes how to set up a suitable virtual machine under VMWare that will be bootstrapped by RedBoot and allow for debugging of i386 PC applications either over the network or using serial communications.

First create a RedBoot floppy bootstrap image with the AMD Lance ethernet device included:

```
% ecosconfig new pc_vmWare redboot
% ecosconfig import $ECOS_REPOSITORY/hal/i386/pc/VERSION/misc/redboot_FLOPPY.ecm
% ecosconfig tree
% make
```

Create a VMWare virtual machine definition with no SCSI or IDE interfaces, 1MB memory, a single serial interface to a file, NAT Network adaptor and a floppy. Copy the `redboot.bin` you created above into place on the VMWare host and point the floppy image to this file. Example `.vmx` and `.vmxf` files for this configuration may be found in the `misc` subdirectory of the PC hal (`$ECOS_REPOSITORY/packages/hal/i386/pc/`). You may use other types of Network connections or serial ports as required.

To configure the Network connection to be an AMD Lance ethernet, you must edit the `.vmx` if you created your own VM definition and set `ethernet0.virtualDev` to `vlance`.

Note

The example `.vmx` file is intended for a Windows VMWare host so the setting `serial0.fileName` also must be adjusted accordingly.

If you intend to develop on a different host from the VMWare host, you may also wish to set up a NAT port forward from the VMWare host to the PC running RedBoot. An example Linux `nat.conf` NAT configuration file may also be found in the `misc` directory. For Windows, the Virtual Network Editor is recommended.

When the VM is powered on in this configuration, you will be able to download and debug executables through either the network connection or through the virtualised serial port using RedBoot.

GRUB Installation

If RedBoot is built with the GRUB startup type, it is configured to be loaded by the GRUB bootloader.

GRUB is an open source boot loader that supports many different operating systems. It is available from http://www.gnu.org/software/grub. The latest version of GRUB should be downloaded from there and installed. GRUB is now the default bootloader for most Linux distributions and therefore is already installed in many systems.

To install GRUB on a floppy disk from Linux you need to execute the following commands, with a fresh floppy diskette in the main drive:

```
$ mformat a:
$ mount /mnt/floppy
$ grub-install --root-directory=/mnt/floppy '(fd0)'
Probing devices to guess BIOS drives. This may take a long time.
Installation finished. No error reported.
This is the contents of the device map /mnt/floppy/boot/grub/device.map.
Check if this is correct or not. If any of the lines is incorrect,
fix it and re-run the script `grub-install'.

(fd0) /dev/fd0
$ cp $ECOS_REPOSITORY/packages/hal/i386/pc/current/misc/redboot_menu.lst /mnt/floppy/boot/grub/menu.lst
$ umount /mnt/floppy
```

The file `redboot_menu.lst` is a GRUB menu configuration file. It contains a menu item to load RedBoot from the floppy diskette. Alternatively you can use the command-line interface of GRUB to input commands yourself.

To install RedBoot on the diskette, execute the following command:

```
$ mcopy redboot_GRUB.img a:/boot/redboot
```

Insert this floppy in the A: drive of the PC to be used as a target and ensure that the BIOS is configured to boot from A: by default. On reset, the PC will boot from the floppy into GRUB which will display its Boot Menu. If left for 30 seconds it will boot into RedBoot automatically. However, typing a return on the keyboard will cause it to boot RedBoot immediately.

To install GRUB on a hard disk, refer to the GRUB documentation. Be warned, however, that if you get this wrong it may compromise any existing bootloader that exists on the hard disk and may make any other operating systems unbootable. Practice on floppy disks or sacrificial hard disks first. On machines already running a GRUB-booted Linux you can just add your own menu items to the `/boot/grub/menu.lst` file that already exists.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is achieved most conveniently at the command line. The steps needed to rebuild the the FLOPPY version of RedBoot for the PC are:

```
$ mkdir redboot_pc_floppy
$ cd redboot_pc_floppy
$ ecosconfig new TARGET redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/i386/pc/VERSION/misc/redboot_FLOPPY.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

When following the above instructions, the user should adopt one of i386 PC target names detailed in the following section to build RedBoot with support for a specific ethernet adapter. At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

The steps needed to rebuild the the GRUB version of RedBoot for the PC are:

```
$ mkdir redboot_pc_grub
$ cd redboot_pc_grub
$ ecosconfig new pc redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/i386/pc/current/misc/redboot_GRUB.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.img.`.

Name

Configuration — Platform-specific Configuration Options

Overview

The PC platform HAL package is loaded automatically when eCos is configured for a `pc` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The PC platform HAL package accommodates four separate startup types:

RAM

> This is the startup type which is normally used during application development. The board has RedBoot running in low memory and boots into that initially. i386-elf-gdb is then used to load a RAM startup application into memory above 0x00200000 and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

FLOPPY

> This startup type can be used for finished applications which will be loaded from a floppy disk by the BIOS. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. Such applications are limited to running only within the bottom 640k of RAM.

GRUB

> This startup type can be used for finished applications which can be loaded using the GRUB boot loader. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. These applications are loaded above the 0x00100000 boundary and therefore have all of the upper RAM area available.
>
> The load address for GRUB applications is 0x00108000 while that for RAM applications is 0x00200000. This allows a GRUB-loaded RedBoot to occupy the first 1MB of upper memory and while allowing RAM applications to be loaded beyond the second 1MB boundary, avoiding any potential clashes.

ROM

> This startup type can be used for eCos applications booting directly from ROM. The ROM startup code for the i386 PC target is experimental at present and ROM startup is therefore unsupported in this release.

Floppy Startup Installation

If an application is built with a startup type of FLOPPY, then it is configured to be a self-booting image that must be written onto a formatted floppy disk. This will erase any existing file system or data that is already on the disk, so proceed with caution.

To write an application to floppy disk, it must first be converted to a pure binary format. This is done with the following command:

```
$ i386-elf-objcopy -O binary app.elf app.bin
```

Here `app.elf` is the final linked application executable, in ELF format (it may not have a `.elf` extension). The file `app.bin` is the resulting pure binary file. This must be written to the floppy disk with the following command:

```
$ dd conv=sync if=app.bin of=/dev/fd0
```

Insert this floppy in the A: drive of the PC to be used as a target and ensure that the BIOS is configured to boot from A: by default. On reset, the PC will boot from the floppy and the eCos application will load itself and execute immediately.

NOTE

Unreliable floppy media may cause the write to silently fail. This can be determined if the application image does not correctly boot. In such cases, the floppy should be (unconditionally) reformatted using the **fdformat** command on Linux, or **format a: /u** on DOS/Windows. If this fails, try a different disk.

GRUB Bootloader Support (version 0.97)

If an application is built with the GRUB startup type, it is configured to be loaded by the GRUB bootloader.

GRUB is an open source boot loader that supports many different operating systems. It is available from http://www.gnu.org/software/grub. The latest version of GRUB should be downloaded from there and installed. GRUB is now the default bootloader for Linux and therefore is already installed in many installations.

To install GRUB on a floppy disk from Linux you need to execute the following commands:

```
$ mformat a:
$ mount /mnt/floppy
$ grub-install --root-directory=/mnt/floppy '(fd0)'
Probing devices to guess BIOS drives. This may take a long time.
Installation finished. No error reported.
This is the contents of the device map /mnt/floppy/boot/grub/device.map.
Check if this is correct or not. If any of the lines is incorrect,
fix it and re-run the script `grub-install'.

(fd0) /dev/fd0
$ cp $ECOS_REPOSITORY/packages/hal/i386/pc/VERSION/misc/menu.lst /mnt/floppy/boot/grub
$ umount /mnt/floppy
```

The file `menu.lst` is an example GRUB menu configuration file. It contains menu items to load some of the standard eCos tests from floppy or from partition zero of the first hard disk. You should, of course, customize this file to load your own application. Alternatively you can use the command-line interface of GRUB to input commands yourself.

Applications can be installed, or updated simply by copying them to the floppy disk at the location expected by the `menu.lst` file. For booting from floppy disks it is recommended that the executable be stripped of all debug and symbol table information before copying. This reduces the size of the file and can make booting faster.

To install GRUB on a hard disk, refer to the GRUB documentation. Be warned, however, that if you get this wrong it may compromise any existing bootloader that exists on the hard disk and may make any other operating systems unbootable. Practice on floppy disks or sacrificial hard disks first. On machines already running a GRUB-booted Linux you can just add your own menu items to the `/boot/grub/menu.lst` file that already exists.

NOTE

Certain distributions of Linux, including Red Hat Linux, supply a version of GRUB which references a configuration file named `grub.conf` rather than `menu.lst`.

GRUB 2 Bootloader Support (version 1.98)

If an application is built with the GRUB startup type, it is configured to be loaded by the GRUB bootloader.

GRUB 2 is an open source boot loader that supports many different operating systems. GRUB 2 is the sucessor to the legacy GRUB boot loader. It has been rewritten and requires a new configuration file that is different from the legacy GRUB loader. It is available from http://www.gnu.org/software/grub. The latest version of GRUB should be downloaded from there and installed. Cygwin users will need to install the GRand Unified Bootloader package on their system.

To install GRUB 2 on a disk drive from Cygwin you will first need to format your disk. Begin by launching a windows Command Prompt with ADMINISTRATOR priviledges. This example assumes that your destination drive is E and the filesystem type is FAT32.

```
$ format e: /fs:fat32 /q

The type of the file system is FAT32.
WARNING, ALL DATA ON NON-REMOVABLE DISK
DRIVE E: WILL BE LOST!
Proceed with Format (Y/N)? y
QuickFormatting 512M
Initializing the File Allocation Table (FAT)...
Volume label (11 characters, ENTER for none)?
Format complete.
```

When your drive is finished formatting, Cygwin will automatically mount the drive under /cygdrive/e. Next, launch a bash shell. Cygwin users should run their shell as ADMINISTRATOR otherwise the grub-install program will fail. To install GRUB we need to know the device name for your disk. A second disk drive is usually called /dev/sdb. The C: drive is usually called /dev/sda. Determine your device name by reading the /proc/partitions file. This example uses /dev/sdb as input to the GRUB install program.

```
$ cat /proc/partitions
major minor  #blocks  name
    8     0 156290904 sda
    8     1    102400 sda1
    8     2 156185600 sda2
    8    16 156290904 sdb
    8    17    524288 sdb1

$ grub-install --root-directory=/cygdrive/e /dev/sdb
Installation finished. No error reported.

$ cp $ECOS_REPOSITORY/packages/hal/i386/pc/current/misc/grub.cfg /cygdrive/e/boot/grub

$ cp redboot.elf /cygdrive/e/boot
```

After installing GRUB 2, we need to a copy a configuration file for grub to use. The file `grub.cfg` is an example configuration file that loads redboot.elf. You should, of course, customize this file to load your own application. Alternatively you can use the command-line interface of GRUB to input commands yourself. Applications can be installed or updated simply by copying them to the location expected by the `grub.cfg` file. In this example the /boot directory is used.

When installing GRUB on a hard disk, refer to the GRUB documentation. Be warned, however, that if you get this wrong it may compromise any existing bootloader that exists on the hard disk and may make any other operating systems unbootable. Practice on a spare disk or sacrificial hard disks first.

Debugging FLOPPY and GRUB Applications

When RedBoot loads an application it also provides debugging services in the form of GDB remote protocol stubs. When an application is loaded stand-alone from a floppy disk, or by GRUB, these services are not present. To allow these application to be debugged, it is possible to include GDB stubs into the application.

To do this, set the "Support for GDB stubs" (`CYGDBG_HAL_DEBUG_GDB_INCLUDE_STUBS`) configuration option. Following this any application built will allow GDB to connect to the debug serial port (by default serial device 0, also known as COM1) whenever the application takes an exception, or if a Control-C is typed to the debug port. Ethernet debugging is not supported.

The option "Enable initial breakpoint" (`CYGDBG_HAL_DEBUG_GDB_INITIAL_BREAK`) causes the HAL to take a breakpoint immediately before calling cyg_start(). This gives the developer a chance to set any breakpoints or inspect the system state before it proceeds. The configuration sets this option by default if GDB stubs are included, and this is not a RedBoot build. To make the application execute immediately either disable this option, or disable `CYGDBG_HAL_DEBUG_GDB_INCLUDE_STUBS`.

RedBoot and Virtual Vectors

If the application is intended to act as a monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to FLOPPY or GRUB startup.

If the application does not rely on a monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Ethernet Drivers

eCos is designed to support typical embedded development and production boards. These usually have a fixed set of hardware devices which are either on-chip or are soldered to the board. The PC target is unusual in that is does not have a fixed ethernet device, instead a variety PCI ethernet cards may be installed in the PCI card slots.

eCos supports different ethernet cards by defining a separate target configuration for each supported device. An instance of eCos or RedBoot configured to use one device will not work with a different ethernet device installed. The following table lists the targets and driver packages for the supported devices.

Device	Target	Driver Packages	Cards
Intel i82559	pc_i82559	CYGPKG_DEVS_ETH_INTEL_I82559, CYGPKG_DEVS_ETH_I386_PC_I82559	Intel Pro 10/100
RealTek RTL8139	pc_rltk8139	CYGPKG_DEVS_ETH_RLTK_8139, CYGPKG_DEVS_ETH_I386_PC_RLTK8139	D-Link DFE-538TX
National Semiconductor DP83816	pc_dp83816	CYGPKG_DEVS_ETH_NS_DP83816, CYGPKG_DEVS_ETH_I386_PC_DP83816	Netgear FA311
Intel i82544	pc_i82544	CYGPKG_DEVS_ETH_INTEL_I82544, CYGPKG_DEVS_ETH_I386_PC_I82544	Intel Pro 1000
AMD Lance PCNet32	pc_vmWare	CYGPKG_DEVS_ETH_AMD_LANCEPCI, CYGPKG_DEVS_ETH_I386_PC_LANCEPCI	VMWare vlance

Entries in the cards column are examples only. There are for example many cards that contain the RealTek RTL8139 or a compatible device. Also be aware that manufacturers may change the device on a particular card to a totally different one without changing the model number.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are no i386 specific flags that need to be specified for a PC platform.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the PC hardware, and should be read in conjunction with that specification. The PC platform HAL package complements the i386 architectural HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize the on-chip peripherals that are used by eCos. There is an exception for RAM startup applications which depend on a monitor for certain services.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Low RAM

This is the original 640KB of PC RAM between 0x00000000 and 0x000a0000. For FLOPPY startup this is all the RAM that is available since the BIOS operations used to load the executable off the diskette can only write to this memory region.

The lower few K bytes of this region are allocated to special uses as follows:

Base	Size	Purpose
0x00000000	0x1000	The BIOS stores various system parameters in this area, and it is left untouched in case these values are of use.
0x00001000	0x800	The Interrupt Descriptor Table (IDT). Space for a full sized 256 entry table is left, although a full size table is not normally created.
0x00001800	0x400	The Vector Service Routine (VSR) table. There is space here for 256 entries, matching the IDT, although not all will be used.
0x00001c00	0x400	The Virtual Vector Table. This is used to pass control between RedBoot and the application for access to services and debugging.
0x00002000	0x1000	This area is used in SMP configurations to start up and synchronize the slave CPUs. It is unused in non-SMP configurations.
0x00003000	0xbd000	Any FLOPPY startup application will load itself at 0x00003000 and use RAM up to the 0x000a0000 boundary. In RAM and GRUB startup configurations this area is unused.

Reserved Region

The region between 0x000a0000 and 0x00100000 is reserved for ROMs, devices and display memory. The only thing of real interest here is the character display buffer at 0x000B8000.

Main Memory

The region above 0x00100000 is the main memory area. This is where RAM and GRUB startup applications are loaded. The upper limit of this region depends on the amount of RAM fitted and is determined at runtime by querying the BIOS.

PCI Devices

The exact memory region used to map PCI devices is largely dependent on the BIOS, but is usually placed above the 0xD0000000 boundary. Drivers for PCI devices will usually determine the location of any device memory regions by querying the device configuration.

IO Ports

The i386 architecture defines a separate address space for IO device registers. These are accessed by the IO instructions. All the standard PC devices are available in this space, and any PCI devices that define IO ports will also be allocated here by the BIOS. In eCos these ports are accessed using the `HAL_READ_XXX()` and `HAL_WRITE_XXX()` macros defined in the `hal_io.h` header.

SMP Support

The i386 HAL contains support for Symmetric Multi-Processing (SMP). The HAL expects the machine to be running under a multiprocessor-aware BIOS and expects to find an MP configuration table from which to configure itself. The HAL also switches over to using the per-CPU APICs and the shared IOAPIC for interrupt control in preference to the standard PIC.

SMP support in eCos is enabled by setting the `CYGPKG_KERNEL_SMP_SUPPORT` configuration option. This will cause the HAL-level support to be enabled. If applications are to be run under RedBoot then an SMP-aware RedBoot must be used. The `FLOPPY_SMP` and `GRUB_SMP` configurations of RedBoot supply this.

Other Issues

The PC platform HAL does not affect the implementation of other parts of the eCos HAL specification. The generic i386 variant HAL, and the I386 architectural HAL documentation should be consulted for further details.

Chapter 316. STPC Atlas Support

Name

CYGPKG_HAL_I386_STPC_ATLAS — eCos Support for the STPC Atlas Processor

Description

The STPC Atlas is an x86 core PC compatible system-on-chip intended for embedded applications. The central processor is largely 486-compatible and can run at up to 133MHz. The chip includes an integrated SDRAM controller, a VGA/SVGA graphics controller with TFT panel support, two serial ports, a parallel port, keyboard, mouse and USB host interfaces, support for PCI, PCMCIA and ISA buses as well as a local bus, and interrupt controller, timers, and DMA engines as per the standard PC architecture.

The STPC Atlas variant HAL package CYGPKG_HAL_I386_STPC_ATLAS provides support for all platforms based around this chip. It complements the I386 architectural HAL CYGPKG_HAL_I386. An eCos configuration for an STPC Atlas-based platform should also include a platform HAL package to support board-level details like the nature of the external memory chips.

Configuration

The STPC Atlas variant HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The package does not contain any configuration options.

The HAL Port

This section describes how the STPC Atlas variant HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and platform HAL documentation.

HAL I/O

The cyg/hal/var_io.h header provides definitions for the on-chip peripherals. This header file is automatically included by the architectural cyg/hal/hal_io.h so other packages and application code will usually only include the latter. It is also necessary to include cyg/hal/hal_intr.h. The definitions largely follow the STPC documentation, so for example the ISA Port_B register has a definition HAL_STPC_ATLAS_Port_B, and there also definitions HAL_STPC_ATLAS_Port_B_PE and HAL_STPC_ATLAS_Port_B_SE for the PE and SE bits.

STPC Atlas registers can be accessed in a variety of ways. Some of them can be accessed directly via the x86 in and out instructions, and the eCos macros HAL_READ_UINT8, HAL_WRITE_UINT8, etc. can be used for these. However there are also memory-mapped registers, registers accessed indirectly via the IDX and DATA registers, local bus registers, PCI registers, and so on. In an attempt to reduce confusion various suffixes are used, and in some cases utility macros are provided to access the registers:

Type	Suffix	Size	Access using
Normal I/O port	None	8, 16 or 32	HAL_READ_UINT8, HAL_WRITE_UINT8 etc.
Indexed via 0x22/0x23	_IDX	8 bits	HAL_STPC_ATLAS_READ_IDX and HAL_STPC_ATLAS_WRITE_IDX
Host bus	_HB	32 bits	HAL_STPC_ATLAS_READ_HB and HAL_STPC_ATLAS_WRITE_HB
Local bus	_LB	16 bits	HAL_STPC_ATLAS_READ_LB and HAL_STPC_ATLAS_WRITE_LB
PC	_PCI	32 bits	HAL_STPC_ATLAS_READ_PCI and HAL_STPC_ATLAS_WRITE_PCI

Type	Suffix	Size	Access using
PCMCIA	_PCMCIA	8 bits	HAL_STPC_ATLAS_READ_PCMCIA and HAL_STPC_ATLAS_WRITE_PCMCIA
Memory	_MEM	32 bits	as C pointers

Accessing IDX, HB, LB, PCI and PCMCIA registers involves non-atomic sequences of operations so to avoid concurrency problems the associated macros briefly disable interrupts. If this is known to be unnecessary, for example because the relevant code runs during system initialization before interrupts are enabled, then INTS_UNSAFE variants of the macros such as HAL_STPC_ATLAS_READ_IDX_INTS_UNSAFE can be used instead.

Interrupts

The STPC Atlas variant HAL provides default implementations of the HAL macros related to the interrupt controller: HAL_INTERRUPT_ACKNOWLEDGE, HAL_INTERRUPT_MASK, HAL_INTERRUPT_UNMASK, HAL_INTERRUPT_CONFIGURE and HAL_INTERRUPT_SET_LEVEL. The platform HAL can override these definitions if platform-specific macros are more appropriate. It is up to the platform HAL to define the interrupt vector numbers. The SET_LEVEL macro is a no-op so there is no support for prioritizing interrupts.

Clock and Profiling Support

The STPC Atlas variant HAL provides default definitions of the clock-related macros HAL_CLOCK_INITIALIZE, HAL_CLOCK_RESET, HAL_CLOCK_READ and HAL_CLOCK_LATENCY. The implementation uses the processor's PIT0 timer since that is the only on-chip timer which can generate interrupts. The platform HAL determines the default clock frequency, and can override any of these definitions if required. If the variant HAL clock macros should be used then the platform HAL should implement the CDL interface CYGINT_HAL_I386_STPC_ATLAS_STANDARD_CLOCK.

When the variant HAL's clock macros are enabled the package will also provide profiling timer support.

Idle Thread Processing

The variant HAL defines a macro HAL_IDLE_THREAD_ACTION which gets invoked automatically by the kernel's idle thread. This macro executes a hlt instruction, suspending the CPU until the next interrupt and thus reducing power consumption. The platform HAL can override this definition if necessary.

Other Functionality

The variant HAL defines a HAL_PLATFORM_RESET macro which resets the processor using functionality provided by the STPC Atlas' keyboard/mouse controller. It also provides a HAL_DELAY_US macro which works in terms of a simple busy loop, so it does not depend on PIT0 having been started.

The implementation of other parts of the HAL specification is unaffected, and no additional functionality is provided.

Part LXXXI. M68000 / ColdFire Architecture

Table of Contents

Chapter 317. M68000 / ColdFire Architectural Support

Name

Overview — eCos Support for the M68K Family of Processors

Description

The original Motorola 68000 processor was released in 1979, and featured the following:

- Eight general purpose 32-bit data registers, %D0 to %D7. Seven 32-bit address registers %A0 to %A6, with %A7 dedicated as the stack pointer. A 16-bit status register.
- A linear address space, limited to 24-bits because the chip package only had 24 address pins. Hence the processor could address 16 megabytes of memory.
- No separate address space for I/O operations. Instead devices are accessed just like memory via the main address and data buses.
- 16-bit external data bus, even though the data registers were 32 bits wide.
- A CISC variable-length instruction set with no less than 14 different addressing modes (although of course the terms RISC and CISC were not yet in common use).
- Separate supervisor and user modes. The processor actually has two distinct stack pointer registers %A7, and the mode determines which one gets used.
- An interrupt subsystem with support for vectored and prioritized interrupts.

The 68000 processor was used in several microcomputers of its time, including the original Apple Macintosh, the Commodore Amiga, and the Atari ST. Over the years numerous variants have been developed. The core instruction set has remained essentially unchanged. Some of the variants have additional instructions. The development of MMUs led to changes in exception handling. In more recent variants, notably the Freescale ColdFire family, some infrequently used instructions and addressing modes have been removed.

- The 68008 reduced the widths of the external data and address buses to 8 bits and 20 bits respectively, giving the processor slow access to only one megabyte.
- The 68010 (1982) added virtual memory support.
- In the 68020 (1984) both the address and data buses were made 32-bits wide. A 256-byte instruction cache was added, as were some new instructions and addressing modes.
- The 68030 (1987) included an on-chip mmu and a 256-byte data cache.
- The 68040 (1991) added hardware floating point (previous processors relied on an external coprocessor or on software emulation). It also had larger caches and an improved mmu.
- The 68060 (1994) involved an internally very different superscalar implementation of the architecture, but few changes at the interface level. It also contained support for power management.
- There have been numerous 683xx variants for embedded use, with on-chip peripherals like UARTs and timers. The cpu core of these variants is also known as cpu32.
- The MCFxxxx ColdFire series (1995) resembles a stripped-down 68060, with some instructions and addressing modes removed to allow for a much smaller and more efficient implementation. Various hardware units such as the and FPU and MMU have become optional.

eCos only provides support for some of these variants, although it should be possible to add support for additional variants with few or no changes to the architectural HAL package.

The architectural HAL provides support for those features which are common to all members of the 68000 and ColdFire families, and for certain features which are present on some but not all members. A typical eCos configuration will also contain: a variant HAL package with support code for a family of processors, for example MCFxxxx; possibly a processor HAL package with support for one specific processor, for example the MCF5272; and a platform HAL which contains the code needed for a specific hardware platform such as the m5272c3.

Name

Options — Configuring the M68K Architectural Package

Loading and Unloading the Package

The M68K architectural HAL package `CYGPKG_HAL_M68K` should be loaded automatically when eCos is configured for M68K-based target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. `CYGPKG_HAL_M68K` serves primarily as a container for lower-level HALs and has only a small number of configuration options.

Stacks

By default the architectural HAL provides a single block of memory to act as both the startup stack and the interrupt stack. The variant, processor or platform HAL may override this. For example if there are several banks of RAM with different performance characteristics it may be desirable to place the interrupt stack in fast RAM rather than in ordinary RAM.

The assembler startup code sets the stack pointer to the startup stack before switching to C code. This stack used for all HAL initialization, running any C++ static constructors defined either by eCos or by the application, and the `cyg_start` entry point. In configurations containing the eCos kernel `cyg_start` will enable interrupts, activate the scheduler and threads will then run on their own stacks. In non-kernel single-threaded applications the whole system continues to run on the startup stack.

When an interrupt occurs the default behaviour is to switch to a separate interrupt stack. This behaviour is controlled by the common HAL configuration option `CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK`. It reduces the stack requirements of all threads in the system, at the cost of some extra instructions during interrupt handling. In kernel configurations the startup stack is no longer used once the scheduler starts running so its memory can be reused for the interrupt stack. To handle the possibility of nested interrupts the interrupt handling code will detect if it is already on the interrupt stack, so in non-kernel configurations it is also safe to use the same area of memory for both startup and interrupt stacks. This leads to the following scenarios:

1. If interrupt stacks are enabled via `CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK` and the interrupt stack is not provided by the variant, processor or platform HAL then a single block of memory will be used for both startup and interrupt stacks. The size of this block is determined by the common HAL configuration option `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE`, with a default value `CYGNUM_HAL_DEFAULT_INTERRUPT_STACK_SIZE` provided by the M68K architectural HAL.

2. If the use of an interrupt stack is disabled then the M68K architectural HAL will provide just the startup stack, unless this is done by the variant, processor or platform HAL. The size of the startup stack is controlled by `CYGNUM_HAL_M68K_STARTUP_STACK_SIZE`.

3. Otherwise the interrupt and/or startup stacks are provided by other packages and it is up to those packages to provide configuration options for setting the sizes.

Floating Point Support

There are many variants of the basic M68K architecture. Some of these have hardware floating point support. Originally this came in the form of a separate 68881 coprocessor, but with modern variants it will be part of the main processor chip. If the processor does not have hardware floating point then software emulation will be used instead.

If the processor on the target hardware has a floating point unit then the variant or processor HAL will implement the CDL interface `CYGINT_HAL_M68K_VARIANT_FPU`. This allows the architectural HAL and other packages to do the right thing on different hardware.

Saving and restoring hardware floating point context increases interrupt and dispatch latency, code size, and data size. If the application does not actually use floating point then these overheads are unnecessary, and can be suppressed by disabling the configuration option CYGIMP_HAL_M68K_FPU_SAVE. Some applications do use floating point but only in one thread. In that scenario it is also unnecessary to save the floating point context during interrupts and context switches, so the configuration option can be disabled.

The exact behaviour of the hardware floating point unit is determined by the floating point control register %fpcr. By default this is initialized to 0, giving IEE754 standard behaviour, but another initial value can be specified using the configuration option CYGNUM_HAL_M68K_FPU_CR_DEFAULT. For details of the various bits in this control register see appropriate hardware documentation. eCos assumes that the control register does not change on a per-thread basis and hence the register is not saved or restored during interrupt handling or a context switch.

Warning

At the time of writing eCos has not run on an M68K processor with hardware floating point so the support for this is untested.

Other Options

There are configuration options to change the compiler flags used for building this packages. The M68K architectural HAL package does not define any other configuration options that can be manipulated by the user. It does define a number of interfaces such as CYGINT_HAL_M68K_USE_STANDARD_PLATFORM_STUB_SUPPORT which can be used by lower levels of the M68K HAL hierarchy to enable certain functionality within the architectural package. Usually these are of no interest to application developers.

Name

HAL Port — Implementation Details

Description

This documentation explains how the eCos HAL specification has been mapped onto M68K hardware, and should be read in conjunction with that specification. It also describes how variant, processor and platform HALs can modify the default behaviour.

eCos support for any given target will involve either three or four HAL packages: the architectural HAL, the platform HAL, the variant HAL, and optionally a processor HAL. This package, the architectural HAL, provides code and definitions that are applicable to all M68K processors. The platform HAL provides support for one specific board, for example an M5272C3 evaluation board, or possibly for a number of almost-identical boards. The processor HAL, if present, serves mainly to provide details of on-chip peripherals including the interrupt controller. The variant HAL provides functionality that is common to a group of processors, for example all MCFxxxx processors have very similar UARTs and hence can share HAL diagnostic code. There is no fixed specification of what should go into the variant HAL versus the processor HAL. For simplicity the description below only refers to variant HALs, but the work may actually happen in a processor HAL instead.

As a design goal lower-level HALs can always override functionality that is normally provided higher up. For example the architectural HAL will provide the required eCos `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` macros, but these can be provided lower down instead. Many but not all ColdFire processors have the `ff1` and `bitrev` instructions which allow for a more efficient implementation than the default architectural ones. In some areas such as handling context switching the architectural HAL will usually provide the basic functionality but it may be extended by lower HALs, for example to add support for the multiply-accumulate units present in certain ColdFire processors.

The architectural HAL provides header files `cyg/hal/hal_arch.h`, `cyg/hal/hal_intr.h`, `cyg/hal/hal_cache.h`, `cyg/hal/hal_io.h` and `cyg/hal/arch.inc`. These automatically include an equivalent header file from the variant HAL, for example `cyg/hal/var_arch.h`. The variant HAL header will in turn include processor and platform-specific headers. This means that application developers and other packages can simply include the architectural HAL headers without needing to know about variants or platforms. It also allows the variant and platform HALs to override architectural settings.

The port assumes that eCos and application code always runs in supervisor mode, with full access to all hardware and special registers.

Data Types

For eCos purposes all M68K processors are big-endian and 32-bit, so the default data types in `cyg/infra/cyg_type.h` are used. Some variants have external bus widths less than 32-bit, but this does not affect the architectural HAL.

When porting to another variant it is possible to override some or all of the type definitions. The variant HAL needs to implement the CDL interface `CYGINT_HAL_M68K_VARIANT_TYPES` and provide a header file `cyg/hal/var_basetype.h`.

Startup and Exception Vectors

The conventional bootstrap mechanism involves a table of exception vectors at the base of memory. The first two words of this table give the initial program counter and stack pointer. In a typical embedded system the hardware is arranged such that non-volatile flash memory is found at location 0x0 so it is the start of flash that contains the exception vectors and the boot code. The table of exception vectors is used subsequently for interrupt handling and for hardware exceptions such as attempts to execute an illegal instruction. There are a number of common scenarios:

1. On systems with very limited memory flash may remain mapped at location 0 and the table of exception vectors remains mapped there as well. The M68K architecture defines the table to have 256 entries and hence it occupies 1K of memory, but in reality many of the entries are unused so part of the table may get used for code instead. Since the whole exception vector table is in read-only memory parts of the eCos interrupt and exception handling mechanisms have to be statically initialized and macros like `HAL_VSR_SET` are not available.

2. As a minor variation of the previous case, flash remains at location 0 but the table of exception vectors gets remapped elsewhere in the address space, usually RAM. This allows `HAL_VSR_SET` to operate normally but at the cost of increased memory usage. The exception vector table in flash only contains two entries, for the initial program counter and stack pointer. The exception vector table in RAM typically gets initialized at run-time.

3. On systems with more memory it is conventional to rearrange the address map during bootstrap. The flash gets relocated, typically to near the end of the address space, and RAM gets placed at location 0 instead. The exception vector table stays at location 0 but is now in RAM and gets initialized at run-time. The bootstrap exception vector table in flash again only needs two entries. A variation places the RAM elsewhere in the address space and moves the exception vector table there, leaving location 0 unused. This provides some protection against null pointer accesses in errant code.

   As a further complication, larger systems typically support different startup types. The application can be linked against a ROM startup configuration and placed directly in flash, as before. Alternatively there may be a ROM monitor such as RedBoot in the flash, taking care of initial bootstrap. The user's application is linked against a RAM startup configuration, loaded into RAM via the ROM monitor, and debugged using functionality provided by the ROM monitor. Yet another possibility involves a RAM startup application but it gets loaded and run via a hardware debug technology such as BDM, and the ROM monitor is either missing or not used.

The exact hardware details, the various startup types, the steps needed for low-level hardware initialization, and so on are not known to the architectural HAL. Hence although the architectural HAL does provide the basic framework for startup, much of the work is done via macros provided by lower-level HAL packages and those macros are likely to depend on various configuration options. Rather than try to enumerate all the various combinations here it is better to look at the actual code in `vectors.S` and in appropriate variant, processor or platform HALs. `vectors.S` is responsible for any low-level initialization that needs to happen. This includes setting up a standard C environment with the stack pointer set to the startup stack in working RAM, making sure all statically initialized global variables have the correct values, and that all uninitialized global variables are zeroed. Once the C environment has been set up the code jumps to `hal_m68k_c_startup` in file `hal_m68k.c` which completes the initialization and jumps to the application entry point.

Interrupt Handling

The M68K architecture reserves a 1K area of memory for 256 exception vectors. These are used for internal and external interrupts, exceptions, software traps, and special operations such as reset handling. Some of the vectors have well-defined uses. However when it comes to interrupt handling the details will depend on the processor variant and on the platform, and the appropriate package documentation should be consulted for full details. Most platforms will not use the full set of 256 vectors, instead re-using some of this memory for other purposes.

By default the exception vectors are located at location 0, but some variants allow the vectors to be located elsewhere. This is managed by an M68K-specific macro `CYG_HAL_VSR_TABLE`. The default value is 0, but a variant HAL can provide an alternative value.

The standard eCos macros `HAL_VSR_GET` and `HAL_VSR_SET` just manipulate one of the 256 entries in the table of exception vectors. Hence it is usually possible to replace the default handlers for exceptions and traps in addition to interrupt handlers. `hal_intr.h` provides `#define`'s for the more common exception vectors, and additional ones can be provided by the platform or variant. It is the responsibility of the platform or variant HAL to initialize the table, and to provide the `HAL_VSR_SET_TO_ECOS_HANDLER` macro since that requires knowledge of the default table entries.

It should be noted that in some configurations the table of exception vectors may reside in read-only memory so entries cannot be changed. If so then the `HAL_VSR_SET` and `HAL_VSR_SET_TO_ECOS_HANDLER` macros will not be defined. Portable code may need to consider this possibility and test for the existence of these macros before using them.

The architectural HAL provides an entry point `hal_m68k_interrupt_vsr` in the file `hal_arch.S`. When an interrupt occurs the original 68000 pushed the program counter and the status register on to the stack, and then called the VSR via the exception table. On newer variants some additional information is pushed, including details of the interrupt source. `hal_m68k_interrupt_vsr` assumes the latter and can be used directly as the VSR on these newer variants. On older variants a small trampoline is needed which pushes the additional information and then jumps to the generic VSR. Interpreting the additional information is handled via an assembler macro hal_context_extract_isr_vector_shl2 which should be defined by the variant, matching the behaviour of the hardware or the trampoline.

At the architecture level there is no fixed mapping between VSR and ISR vectors. Instead that is left to the variant or platform HAL. The architectural HAL does provide default implementations of HAL_INTERRUPT_ATTACH, HAL_INTERRUPT_DETACH and HAL_INTERRUPT_IN_USE since these just involve updating a static table.

By default the interrupt state control macros HAL_DISABLE_INTERRUPTS, HAL_RESTORE_INTERRUPTS, HAL_ENABLE_INTERRUPTS and HAL_QUERY_INTERRUPTS are implemented by the architectural HAL, and simply involve updating the status register. Disabling interrupts involves setting the three IPL bits to 0x07. Enabling interrupts involves setting those bits to a smaller value, CYGNUM_HAL_INTERRUPT_DEFAULT_IPL_LEVEL, which defaults to 0.

HAL_DISABLE_INTERRUPTS has no effect on non-maskable interrupts. This causes a problem because parts of the system assume that all normal interrupt sources are affected by this macro. If the target hardware can raise non-maskable interrupts then it is the responsibility of application code to install a suitable VSR and handle non-maskable interrupts entirely within the application, bypassing the usual eCos ISR and DSR mechanisms.

The architectural HAL does not provide any support for the interrupt controller management macros like HAL_INTERRUPT_MASK. These can only be implemented on a per-variant, per-processor or per-platform basis.

Exception Handling

Synchronous exception handling is done in much the same way as interrupt handling. The architectural HAL provides a generic entry point hal_m68k_exception_vsr. On some variants this can be used directly as the exception VSR, on others it will be called via a small trampoline.

The details of exception handling vary widely from one variant to the next. Some variants push a great deal of additional information on to the stack for certain exceptions, but not all. The pushed program counter may correspond to the specific instruction that caused the exception, or the next instruction, or there may be only a loose correlation because of buffered writes. The architectural HAL makes no attempt to cope with all these differences, although some variants may provide more advanced support. Otherwise if an exception needs to be handled in a very specific way then it is up to the application to install a suitable VSR and handle the exception directly.

Stacks and Stack Sizes

cyg/hal/hal_arch.h defines values for minimal and recommended thread stack sizes, CYGNUM_HAL_STACK_SIZE_MINIMUM and CYGNUM_HAL_STACK_SIZE_TYPICAL. These values are specific to the current configuration, and are affected mainly by options related to interrupt handling.

By default eCos uses a separate interrupt stack, although this can be disabled through the configuration option CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK. When an interrupt or exception occurs eCos will save the context on the current stack and then switch to the interrupt stack before calling the appropriate ISR interrupt handler. This means that thread stacks can be significantly smaller because there is no need to worry about interrupt handling overheads, just the thread context. However switching the stack does require some extra work and hence increases the interrupt latency. Disabling the interrupt stack removes this processing overhead but requires larger stack sizes. It depends on the application whether or not this is a sensible trade off.

By default eCos does not allow nested interrupts, but this can be controlled via the configuration option CYGSEM_HAL_COMMON_INTERRUPTS_ALLOW_NESTING. Supporting nested interrupts requires larger thread stacks, especially if the separate interrupt stack is also disabled.

Although the M68K has enough registers for typical operation, the calling conventions are memory-oriented. In particular all arguments are pushed on the stack rather than held in registers, and the return address is also pushed rather than ending up in a link register. To allow for this the recommended minimum stack sizes are a little bit larger than for some other architectures. Variant HALs cannot directly affect these stack sizes. However the sizes do depend in part on the size of a thread context, so if for example the processor supports hardware floating point and support for that is enabled then the stack sizes will increase.

Usually the M68K architectural HAL will provide a single block of memory which acts as both the startup and interrupt stack, and there are configuration options to control the size of this block. Alternatively a variant, processor or platform HAL may define either or both of `_HAL_M68K_STARTUP_STACK_` and `_HAL_M68K_INTERRUPT_STACK_BASE_` if for some reason the stacks should not be placed in ordinary RAM.

Thread Contexts and Setjmp/Longjmp

A typical thread context consists of the following:

1. The integer context. This consists of the data registers `%d0` to `%d7` and the address registers `%a0` to `%a6`, The stack pointer register `%a7` does not have to be saved explicitly since it is implicit in the pointer to the saved context.

   The caller-save registers are `%d0`, `%d1`, `%a0`, `%a1`, `%a7` and the status register. The remaining registers are callee-save. Function arguments are always passed on the stack. The result is held in `%d0`.

2. Floating point context, consisting of eight 64-bit floating point registers `%fp0` to `%fp7` and two support registers `%fpsr` and `%fpiar`. Support for this is only relevant if the processor variant has a hardware floating point unit, and even then saving floating point context is optional and can be disabled using a configuration option `CYGIMP_HAL_M68K_FPU_SAVE`. The control register `%fpcr` is not saved as part of the context. It is assumed that a single `%fpcr` value, usually `0`, will be used throughout the application.

   The architectural HAL provides support for the hardware floating point unit. The variant or processor HAL should implement the CDL interface `CYGINT_HAL_M68K_VARIANT_FPU` if this hardware unit is actually present.

3. Some M68K variants have additional hardware units, for example the multiply-accumulate units in certain ColdFire processors. The architectural HAL allows the context to be extended through various macros such as `HAL_CONTEXT_OTHER`.

4. The status register `%sr` and the program counter. These are special because when an interrupt occurs the hardware automatically pushes these onto the stack, but exactly what gets pushed depends on the variant.

`setjmp` and `longjmp` only deal with the integer and fpu contexts. It is assumed that any special hardware units will only be used by application code, not by the compiler. Hence it is the responsibility of application code to define and implement appropriate setjmp semantics for these units. The variant HAL package can override the default implementations if necessary.

When porting to a new M68K variant, if this has a hardware floating point unit then the variant HAL should implement the CDL interface `CYGINT_HAL_M68K_VARIANT_FPU`, thus enabling support provided by the architectural HAL. If the variant has additional hardware units involving state that should be preserved during a context switch or when an interrupt occurs, the variant HAL should define a number of macros. The header file `cyg/hal/var_arch.h` should define `HAL_CONTEXT_OTHER`, `HAL_CONTEXT_OTHER_SIZE`, and `HAL_CONTEXT_OTHER_INIT`, either directly or via `cyg/hal/proc_arch.h`. The assembler header file `cyg/hal/var.inc` should define a number of macros such as `hal_context_other_save_caller`. For details of these macros see the architectural `hal_arch.S` file.

Variants also need to define exactly how the status register and program counter are saved onto the stack when an interrupt or exception occurs. This is handled through C macros `HAL_CONTEXT_PCSR_SIZE`, `HAL_CONTEXT_PCSR_RTE_ADJUST`, and `HAL_CONTEXT_PCSR_INIT`, and a number of assembler macros such as `hal_context_pcsr_save_sr`. Again the architectural files `cyg/hal/hal_arch.h` and `hal_arch.S` provide more details of these.

Bit Indexing

For performance reasons the `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` macros are implemented using assembler functions. A variant HAL can override the default definitions if, for example, the variant has special instructions to perform these operations.

Idle Thread Processing

The default `HAL_IDLE_THREAD_ACTION` implementation is a no-op. A variant HAL may override this, for example to put the processor into sleep mode. Alternative implementations should consider exactly how this macro gets used in eCos kernel code.

Clock Support

The architectural HAL cannot provide the required clock support because it does not know what timer hardware may be available on the target hardware. Instead this is left to either the variant or platform HAL, depending on whether the processor has a suitable on-chip timer or whether an off-chip timer has to be used.

HAL I/O

The M68K architecture does not have a separate I/O bus. Instead all hardware is assumed to be memory-mapped. Further it is assumed that all peripherals on the memory bus are wired appropriately for a big-endian processor and that there is no need for any byte swapping. Hence the various HAL macros for performing I/O simply involve pointers to volatile memory.

The variant, processor and platform equivalents of the `cyg/hal/hal_io.h` header will typically also provide details of some or all of the peripherals, for example register offsets and the meaning of various bits in those registers.

Cache Handling

If the processor has a cache then the variant HAL should implement the CDL interface `CYGINT_HAL_M68K_VARIANT_CACHE`. This causes the architectural header `cyg/hal/hal_cache.h` to pick up appropriate definitions from `cyg/hal/var_cache.h`. The architectural header will provide null defaults for anything not defined by the variant.

Linker Scripts

The architectural HAL will generate the linker script for eCos applications. This involves the architectural file `m68k.ld` and a `.ldi` memory layout file provided lower down, typically by the platform HAL. It is the LDI file which specifies the types and amount of memory available and which places code and data in appropriate places, but most of the hard work is done via macros provided by the architectural `m68k.ld` file.

Diagnostic Support

The architectural HAL does not implement diagnostic support. Instead this is left to the variant or platform HAL, depending on whether suitable peripherals are available on-chip or off-chip.

SMP Support

The M68K port does not have SMP support.

Debug Support

The M68K architectural HAL package provides basic support only for gdb stubs. There is no support for more advanced debug features like hardware watchpoints.

The generic gdb support in the common HAL requires a platform header `<cyg/hal/plf_stub.h`. In practice there is rarely any need for the contents of this file to change between platforms so the architectural HAL can provide a suitable default. It will do so if the CDL interface `CYGINT_HAL_M68K_USE_STANDARD_PLATFORM_STUB_SUPPORT` is implemented.

HAL_DELAY_US Macro

The architectural HAL provides a default implementation of the standard `HAL_DELAY_US` macro using a simply busy loop. To use this support a lower-level HAL should define `_HAL_M68K_DELAY_US_LOOPS_`, typically a small number of about 20 but it will need to be calibrated during the porting process. If the processor has a cache then the lower-level HAL may also define `_HAL_M68K_DELAY_US_LOOPS_UNCACHED_` for the case when a delay loop is triggered while the cache is disabled.

Profiling Support

The M68K architectural HAL implements the `mcount` function, allowing profiling tools like gprof to determine the application's call graph. It does not implement the profiling timer. Instead that functionality needs to be provided by the variant or platform HAL. The implementation of `mcount` requires a dedicated frame pointer register so code should be compiled without the `-fomit-frame-pointer` flag.

Other Functionality

The M68K architectural HAL only implements the functionality provided by the eCos HAL specification and does not export any extra functionality.

Chapter 318. Freescale MCFxxxx Variant Support

Name

CYGPKG_HAL_M68K_MCFxxxx — eCos Support for Freescale MCFxxxx Processors

Description

The Freescale ColdFire family is a range of processors including the MCF5208 and the MCF5282. From a programmer's perspective these processors all share basically the same processor core, albeit with minor differences in the instruction set. They differ in areas like performance, on-chip peripherals and caches. Even when it comes to peripherals there is a lot of commonality. For example many but not all Coldfire processors use the same basic interrupt controller(s) as the MCF5282. Similarly the on-chip UARTs tend to use the same basic design although there are variations in the number of UARTs, the fifo sizes, and in certain details.

The MCFxxxx variant HAL package CYGPKG_HAL_M68K_MCFxxxx provides support for various features that are common to many but not all Coldfire processors. This includes HAL diagnostics via an on-chip UART and interrupt controller management for those processors which have MCF5282-compatible controllers. The variant HAL complements the M68K architectural HAL package. An eCos configuration should also include a processor-specific HAL package such as CYGPKG_HAL_M68K_MCF5272 to support the chip-specific peripherals and cache details, and a platform HAL package such as CYGPKG_HAL_M68K_M5272C3 to support board-level details like external memory chips. The processor or platform HAL can override the functionality provided by the variant HAL.

Configuration

The MCFxxxx variant HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

On most ColdFire platforms the variant HAL will provide the HAL diagnostics support via one of the UARTs. Some platforms may provide their own HAL diagnostics facility, for example output via an LCD. The variant HAL diagnostics support is active if the processor or platform implements the CYGINT_HAL_M68K_MCFxxxx_DIAGNOSTICS_USE_DEFAULT interface. It is also active only in configurations which do not rely on an underlying rom monitor such as RedBoot: if CYGSEM_HAL_USE_ROM_MONITOR is enabled then the default diagnostics channel will automatically be inherited from RedBoot. The variant HAL then provides a number of configuration options related to diagnostics:

CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT

> This selects the destination for HAL diagnostics. The number of UARTs available depends on the processor, and on any given board some of the UARTs may not be connected. Hence the variant HAL looks for configuration options CYGHWR_HAL_M68K_MCFxxxx_UART0, CYGHWR_HAL_M68K_MCFxxxx_UART1 and CYGHWR_HAL_M68K_MCFxxxx_UART2 to see which on-chip UARTs are actually available on the processor and target hardware, and uses this information to let the user select a UART.
>
> Instead of using a uart the diagnostics support can be set to discard all output. This is useful when other packages or application code makes unconditional use of HAL diagnostics facilities, for example to report error conditions, but the target hardware does not have a spare UART. Alternatively when debugging via a hardware debug solution such as BDM it is possible to direct the diagnostics output to a gdb hwdebug file I/O channel. By default this will also discard diagnostics output. However if the application is running inside a gdb session and the gdb **set hwdebug** command has been used then the diagnostics will be output via gdb.
>
> When a UART is in use as the HAL diagnostics channel, that UART should not be used for any other purpose. In particular application code should avoid using it for I/O via the serial driver.

CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD

> When a UART is selected for HAL diagnostics this option specifies the default baud rate. The most common setting is 38400. That provides a compromise between performance and reliability, especially in electrically noisy environments such as an

industrial environment or a test farm. Some platforms may define CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_DEFAULT_BAUD to handle scenarios where another default baud rate is preferable, typically for compatibility with existing software.

CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_ISRPRI

Usually the HAL diagnostics channel is driven in polled mode but in some scenarios interrupts are required. For example, when debugging an application over a serial line on top of the gdb stubs provided by RedBoot, the user should be able to interrupt the application with a control-C. The application will not be polling the HAL diagnostics UART at this point so instead the eCos interrupt management code interacts with the gdb stubs to do the right thing. This configuration option selects the interrupt priority. It should be noted that on some processors with MCF5282-compatible interrupt controllers all priorities for enabled interrupts should be unique, and it is the responsibility of application developers to ensure this condition is satisfied.

The HAL Port

This section describes how the MCFxxxx variant HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and processor HAL documentation.

HAL I/O

The cyg/hal/var_io.h header provides various definitions for on-chip peripherals, where the current processor has peripherals compatible with the MCF5282's or which are available on several different coldfires. This header is automatically included by the architectural cyg/hal/hal_io.h so other packages and application code will usually only include the latter.

It is up to the processor HAL to specify exactly what var_io.h should export. For example the MCF5213's proc_io.h header contains the following:

```
# define HAL_MCFxxxx_HAS_MCF5282_INTC              1
# define HAL_MCFxxxx_INTC0_BASE                    (HAL_MCF521x_IPSBAR + 0x00000C00)
```

This enables support within the variant HAL for a single MCF5282-compatible interrupt controller, and cases var_io.h to export symbols such as:

```
#ifdef HAL_MCFxxxx_HAS_MCF5282_INTC
// Two 32-bit interrupt mask registers
# define HAL_MCFxxxx_INTCx_IMRH                    0x0008
# define HAL_MCFxxxx_INTCx_IMRL                    0x000C
…
# define HAL_MCFxxxx_INTCx_ICRxx_IL_MASK           (0x07 << 3)
# define HAL_MCFxxxx_INTCx_ICRxx_IL_SHIFT          3
```

Symbols such as HAL_MCFxxxx_INTCx_IMRH can be used to access the relevant hardware registers via HAL_READ_UINT32 and HAL_WRITE_UINT32. Symbols like HAL_MCFxxxx_INTCx_ICRxx_IL_MASK can be used to generate or decode the contents of the hardware registers.

The header file does mostly use a naming convention, but is not guaranteed to be totally consistent. There may also be discrepancies with the documentation because the manuals for the various Coldfire processors are not always consistent about their naming schemes. All I/O definitions provided by the variant HAL will start with HAL_MCFxxxx_, followed by the name of the peripheral. If a peripheral is likely to be a singleton, for example an on-chip flash unit, then the name is unadorned. If there may be several instances of the peripheral then the name will be followed by a lower case x. For example:

```
# define HAL_MCFxxxx_CFM_CR                        0x0000
…
# define HAL_MCFxxxx_UARTx_UMR                     0x00
```

Register names will be relative to some base address such as HAL_MCFxxxx_CFM_BASE or HAL_MCFxxxx_UART0_BASE, so code accessing a register would look like:

```
    HAL_READ_UINT32(HAL_MCFxxxx_CFM_BASE + HAL_MCFxxxx_CFM_PROT, reg);
    …
    HAL_WRITE_UINT8(base + HAL_MCFxxxx_UARTx_UTB, '*');
```

Usually the register names are singletons, but in some cases such as the interrupt controller priority registers there may be multiple instances of the register and the names will be suffixed appropriately. For example HAL_MCFxxxx_INTCx_ICRxx_IL_MASK indicates the field IL within one of the ICR registers within one of the interrupt controllers.

As mentioned earlier the processor HAL's proc_io.h will control which definitions are exported by var_io.h. Sometimes the processor HAL will then go on to undefine or redefine some of the symbols, to reflect incompatibilities between the processor's devices and the equivalent devices on the MCF5282. There may also be additional symbols for the devices, and there will be additional definitions for any processor-specific hardware. In particular GPIO pin handling is handled by the processor HAL, not by the variant HAL. Application developers should examine proc_io.h as well as var_io.h and the processor-specific documentation to see exactly what I/O definitions are provided. When porting to a new Coldfire processor it is best to start with an existing processor HAL and copy code as appropriate. A search for _HAS_ in var_io.h will also be informative.

Thread Contexts and Setjmp/Longjmp

All MCFxxxx processors support interrupts and exceptions in a uniform way. When an interrupt or exception occurs the hardware pushes the current program counter, the status register, and an additional 16-bit word containing information about the interrupt source, for a total of 64 bits. Hence the PCSR part of a thread context consists of two 32-bit integers, and the variant HAL provides appropriate C and assembler macros to examine and manipulate these.

Not all MCFxxxx processors have hardware floating point, so support for this is left to the processor HAL package. Some MCFxxxx processors have additional hardware units such as a multiply-accumulator, but these are not currently supported by eCos.

HAL Diagnostics

The various MCFxxxx processors usually have one or more UARTs based on very similar hardware. The variant HAL package can provide HAL diagnostic support using such a UART. There are some minor differences such as fifo sizes, and the UARTs will be accessed at different memory locations. These differences are handled by a small number of macros provided by the processor and platform HAL.

The MCFxxxx variant HAL only provides HAL diagnostic support via a UART if the processor or platform HAL does not provide an alternative implementation. That copes with situations where the on-chip UARTs are not actually accessible on the target board and an alternative communication channel must be used.

If the variant HAL should implement HAL diagnostics then the processor or platform HAL should implement the CDL interface CYGINT_HAL_M68K_MCFxxxx_DIAGNOSTICS_USE_DEFAULT. It should also define one or more of CYGHWR_HAL_M68K_MCFxxxx_UART0, CYGHWR_HAL_M68K_MCFxxxx_UART1 and CYGHWR_HAL_M68K_MCFxxxx_UART2, and ensure that any multi-purpose GPIO pins are set correctly. The variant HAL will take care of the rest.

Cache Handling

MCFxxxx processors support a number of different caching schemes. Partial support for some of is provided by the variant HAL's cyg/hal/var_cache.h, but it is up to the processor HAL to define which caching scheme should be used, as well as parameters such as the cache size.

Exceptions

All MCFxxxx processors support synchronous exceptions in a uniform way, with the hardware pushing sufficient information on to the stack to identify the nature of the exception. This means that the architectural entry point hal_m68k_exception_vsr can be used as the default VSR for all exceptions, with no need for separate trampoline functions.

The variant HAL does not provide any special support for recovering from exceptions.

Interrupts

All MCFxxxx processors supports interrupts in a uniform way. When an interrupt occurs the hardware pushes sufficient information on to the stack to identify the interrupt. Therefore the architectural entry point `hal_m68k_interrupt_vsr` can be used as the default VSR for all interrupts, with the variant just supplying a small number of macros that allow the generic code to extract details of the interrupt source. There is no need for separate trampoline functions for every interrupt source.

On processors which have MCF5282-compatible interrupt and edge port modules the variant HAL can provide the `HAL_INTERRUPT_MASK`, `HAL_INTERRUPT_UNMASK`, `HAL_INTERRUPT_SET_LEVEL`, `HAL_INTERRUPT_ACKNOWLEDGE` and `HAL_INTERRUPT_CONFIGURE` macros. There is support for processors with a single interrupt controller or with two separate interrupt controllers. Otherwise these macros are left to the processor HAL. The allocation of interrupt vectors to the various on-chip devices is also a characteristic of the processor HAL. `proc_intr.h` should be consulted for appropriate definitions, for example `CYGNUM_HAL_ISR_UART0`.

The mask and umask operations are straightforward: if the interrupt controller has the `SIMR` and `CIMR` registers those will be used; otherwise the `IRM` registers will be updated by a read-modify-write cycle. The acknowledge macro is only relevant for external interrupts coming in via the edge port module and will clear the interrupt by writing to the `EPIER` register. There is no simple way to clear interrupts generated by the on-chip peripherals, so that is the responsibility of the various device drivers or of application code. The configure macro is only relevant for external interrupts and involves manipulating the edge port module.

The `HAL_INTERRUPT_SET_LEVEL` macro is used implicitly by higher level code such as `cyg_interrupt_create`. With MCF5282-compatible interrupt controllers the priority level corresponds to the `ICRxx` register. The exact format depends on the processor. Interrupt priorities corresponding to IPL level 7 are non-maskable. Such interrupts cannot be managed safely by the usual eCos ISR and DSR mechanisms. Instead application code will have to install a custom VSR and manage the entire interrupt.

Some MCF5282-compatible interrupt controllers have a major restriction: all interrupt priorities within each controller must be unique. If two interrupts go off at the same time and have exactly the same priority then the controllers' behaviour is undefined. In a typical application some of the interrupts will be handled by eCos device drivers while others will be handled directly by application code. Since eCos cannot know which interrupts may get used, it cannot allocate unique priorities. Instead this has to be left to the application developer. eCos does provide configuration options such as `CYGNUM_KERNEL_COUNTERS_CLOCK_ISR_PRIORITY` and `CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_ISR_PRIORITY` to provide control over the eCos-managed interrupts, and provides default values for these which are unique.

Caution

Non-unique interrupt priorities can lead to very confusing system behaviour. For example on an MCF5282, if the PIT3 system clock (interrupt 0x3a) and ethernet RX frame (interrupt 0x1b) are accidentally given the same priority and go off at the same time, the interrupt controller may actually issue an interrupt 0x3b, the bitwise or of the two interrupt numbers. That interrupt belongs to the on-chip flash module. There may not be an installed handler for that interrupt at all, and even if there is a handler it will only manipulate the flash hardware and not clear the system clock and ethernet interrupts. Hence the system is likely to go into a spin, continually trying to service the wrong interrupt. To track down such problems during debugging it may prove useful to install a breakpoint on the `hal_arch_default_isr` function.

Clock Support

On processors with an MCF5282-compatible programmable interrupt timer module or PIT, the variant HAL can provide the `HAL_CLOCK_INITIALIZE`, `HAL_CLOCK_RESET`, `HAL_CLOCK_READ` and `HAL_CLOCK_LATENCY` macros. These macros are used by the eCos kernel to implement the system clock and may be used for other purposes in non-kernel configurations. When multiple timers are available it is up to the processor or platform HAL to select which one gets used for the system clock. It is also up to the processor or platform HAL to provide various clock-related configuration options such as `CYGNUM_HAL_RTC_PERIOD`. Those options need to take into account the processor clock speed, which is usually a characteristic of the platform and hence not known to the variant HAL.

When porting to a new Coldfire processor, the processor or platform HAL should define the symbols CYGNUM_HAL_INTERRUPT_RTC, _HAL_MCFxxxx_CLOCK_PIT_BASE_, and _HAL_MCFxxxx_CLOCK_PIT_PRE_. Existing ports can be examined for more details.

Reset

On processors with an MCF5282-compatible reset module or RST, the variant HAL can provide the HAL_PLATFORM_RESET macro. That macro is typically used by the gdb stubs support inside RedBoot to reset the hardware between debug sessions, ensuring that each session runs in as close to pristine hardware as possible. The macro uses the SOFTRST bit of the RCR register.

Bit Indexing

By default the variant HAL will provide versions of HAL_LSBIT_INDEX and HAL_MSBIT_INDEX which are more efficient than the default ones in the architectural HAL. The implementation uses the **ff1.l** and **bitrev.l** instructions. If the Coldfire processor does not support these instructions then the processor HAL should define _HAL_M68K_MCFxxxx_NO_FF1_.

Other Issues

The MCFxxxx variant HAL does not affect the implementation of data types, stack size definitions, idle thread processing, linker scripts, SMP support, system startup, or debug support.

Other Functionality

The MCFxxxx variant HAL only implements functionality defined in the eCos HAL specification and does not export any additional functions.

Chapter 319. Freescale MCF5272 Processor Support

Name

CYGPKG_HAL_M68K_MCF5272 — eCos Support for the Freescale MCF5272 Processor

Description

The MCF5272 is one member of the Freescale MCFxxxx ColdFire range of processors. It comes with a number of on-chip peripherals including 2 UARTs, ethernet, and USB slave. The processor HAL package CYGPKG_HAL_M68K_MCF5272 provides support for features that are specific to the MCF5272. It complements the M68K architectural HAL package CYGPKG_HAL_M68K and the variant HAL package CYGPKG_HAL_M68K_MCFxxxx. An eCos configuration should also include a platform HAL package, for example CYGPKG_HAL_M68K_M5272C3 to support board-level details like the external memory chips.

Configuration

The MCF5272 processor HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The component CYGPKG_HAL_M68K_MCF5272_HARDWARE contains configuration options for the available hardware. This includes all GPIO pin settings, with defaults provided by the platform HAL. In turn the pin settings are used to determine defaults for other hardware settings, for example which of the two on-chip uarts are usable. Users can override these settings if necessary, subject to any constraints imposed by the platform HAL, but care has to be taken that the resulting configuration still matches the actual hardware.

The option CYGIMP_HAL_M68K_MCF5272_IDLE controls what happens in configurations containing the eCos kernel when the idle thread runs, i.e. when there is nothing for the processor to do until the next interrupt comes in. Usually the processor made to sleep, halting the cpu but leaving all peripherals active.

The package contains a single configuration option CYGFUN_HAL_M68K_MCF5272_PROFILE_TIMER. This controls the support for gprof-based profiling. By default it is active and enabled if the configuration contains the gprof profiling package, otherwise inactive. The relevant code uses hardware timer 2, so that timer is no longer available for application code. If the timer is required but a platform HAL provides an alternative implementation of the profiling support then this option can be disabled.

The HAL Port

This section describes how the MCF5272 processor HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

HAL I/O

The header file cyg/hal/proc_io.h specifies which generic MCFxxxx devices are present, and provides details of MCF5272-specific devices. This header file is automatically included by the architectural header cyg/hal/hal_io.h, so typically application code and other packages will just include the latter.

It should be noted that the Freescale documentation is occasionally confusing when it comes to numbering devices. For example the four on-chip timers are numbered TMR0 to TMR3, but in the interrupt controller the corresponding interrupts are numbered TMR1 to TMR4. The eCos port consistently starts numbering at 0, so these interrupts have been renamed TMR0 to TMR3.

Interrupt Handling

The header file cyg/hal/proc_intr.h provides VSR and ISR vector numbers for all interrupt sources. The VSR vector number, for example CYGNUM_HAL_VECTOR_TMR0, should be used for calls like cyg_interrupt_get_vsr. It corresponds directly to the M68K exception number. The ISR vector number, for example CYGNUM_HAL_ISR_TMR0, should be used for calls like `cyg_interrupt_create`. This header file is automatically included by the architectural header `cyg/hal/hal_intr.h`, and other packages and application code will normally just include the latter.

The eCos HAL macros `HAL_INTERRUPT_MASK`, `HAL_INTERRUPT_UNMASK`, `HAL_INTERRUPT_SET_LEVEL`, `HAL_INTERRUPT_ACKNOWLEDGE`, and `HAL_INTERRUPT_CONFIGURE` are implemented by the processor HAL. The mask and unmask operations are straightforward, simply manipulating the on-chip interrupt controller. The acknowledge and configure macros are only relevant for external interrupts: internal interrupts generated by on-chip devices do not need to be acknowledged. The set-level operation, used implicitly by higher level code such as `cyg_interrupt_create`, is mapped on to M68K IPL levels so interrupts can be given a priority between 1 and 7. Priority 7 corresponds to non-maskable interrupts and must be used with care: such interrupts cannot be managed safely by the usual eCos ISR and DSR mechanisms; instead application code will have to install a custom VSR and manage the entire interrupt.

Clock Support

The processor HAL provides support for the eCos system clock. This always uses hardware timer 3, which should not be used directly by application code. If gprof-based profiling is in use then that will use hardware timer 2. Timers 0 and 1 are never used by eCos so application code is free to manipulate these as required.

Some of the configuration options related to the system clock, for example `CYGNUM_HAL_RTC_PERIOD`, are actually contained in the platform HAL rather than the processor HAL. These options need to take into account the processor clock speed, a characteristic of the platform rather than the processor.

Cache Handling

The MCF5272 has a small instruction cache of 1024 bytes. This is fully supported by the processor HAL. There is no data cache.

Idle Thread Support

The configuration option `CYGIMP_HAL_M68K_MCF5272_IDLE` controls what happens when the kernel idle thread runs. The default behaviour is to put the processor to sleep until the next interrupt.

Profiling Support

The MCF5272 processor HAL provides a profiling timer for use with the gprof profiling package. This uses hardware timer 2, so application code should not manipulate this timer if profiling is enabled. The M68K architectural HAL implements the `mcount` function so profiling is fully supported on all MCF5272-based platforms.

Other Issues

The MCF5272 processor HAL does not affect the implementation of data types, stack size definitions, linker scripts, SMP support, system startup, or debug support. The architectural HAL's bit index instructions are used rather than the MCFxxxx variant HAL's versions since the MCF5272 does not implement the ff1 and bitrev instructions.

Other Functionality

The MCF5272 processor HAL only implements functionality defined in the eCos HAL specification and does not export any additional functions.

Chapter 320. Freescale M5272C3 Board Support

Name

eCos Support for the Freescale M5272C3 Board — Overview

Description

The Freescale M5272C3 board has an MCF5272 ColdFire processor, 4MB of external SDRAM, 2MB of external flash memory, and connectors plus required support chips for all the on-chip peripherals. By default the board comes with its own dBUG ROM monitor, located in the bottom half of the flash.

For typical eCos development a RedBoot image is programmed into the top half of the flash memory, and the board is made to boot this image rather than the existing dBUG monitor. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

In a typical setup the bottom half of the flash memory is reserved for the dBUG ROM monitor and is not accessible to eCos. That leaves four flash blocks of 256K each. Of these one is used for the RedBoot image and another is used for managing the flash and holding RedBoot fconfig values. The remaining two blocks at 0xFFF40000 and 0xFFF80000 can be used by application code.

By default eCos will only support the four megabytes of external SDRAM present on the initial versions of the board, accessible at location 0x00000000. Later versions come with 16MB. If all 16MB of memory are required then the ACR0 register needs to be changed. The default value is controlled by the configuration option `CYGNUM_HAL_M68K_M5272C3_ACR0`, but this option is only used during ROM startup so in a typical setup it would be necessary to rebuild and update RedBoot. Alternatively the register can be updated by application code, preferably using a high priority static constructor to ensure that the extra memory is visible before any code tries to use that memory. It will also be necessary to change the memory layout so that the linker knows about the additional memory.

By default the 4K of internal SRAM is mapped to location 0x20000000 using the RAMBAR register. This is not used by eCos or by RedBoot so can be used by application code. The M68K architectural HAL has an `iram1.c` testcase to illustrate the linker script support for this. The internal 16K of ROM is left disabled by default because its contents are of no use to most applications. The on-chip peripherals are mapped at 0x10000000 via the MBAR register.

There is a serial driver `CYGPKG_DEVS_SERIAL_MCFxxxx` which supports both on-chip UARTs. One of the UARTs, usually uart0, can be used by RedBoot for communication with the host. If this UART is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the M5272C3 target.

There is an ethernet driver `CYGPKG_DEVS_ETH_MCFxxxx` for the on-chip ethernet device. This driver is also loaded automatically when configuring for the M5272C3 target. The M5272C3 board does not have a unique MAC address, so a suitable address has to be programmed into flash via RedBoot's **fconfig** command.

eCos manages the on-chip interrupt controller. Timer 3 is used to implement the eCos system clock, but timers 0, 1 and 2 are unused and left for the application. The GPIO pins are manipulated only as needed to get the UARTs and ethernet working. eCos will reset the remaining on-chip peripherals (DMA, USB, PLCI, QSPI and PWM) during system startup or soft reset but will not otherwise manipulate them.

Tools

The M5272C3 port is intended to work with GNU tools configured for an m68k-elf target. The original port was done using m68k-elf-gcc version 3.2.1, m68k-elf-gdb version 5.3, and binutils version 2.13.1.

By default eCos is built using the compiler flag `-fomit-frame-pointer`. Omitting the frame pointer eliminates some work on every function call and makes another register available, so the code should be smaller and faster. However without a frame pointer m68k-elf-gdb is not always able to identify stack frames, so it may be unable to provide accurate backtrace information. Removing this compiler flag from the configuration option `CYGBLD_GLOBAL_CFLAGS` avoids such debug problems.

Name

Setup — Preparing the M5272C3 board for eCos Development

Overview

In a typical development environment the M5272C3 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run on the board via the debugger m68k-elf-gdb. Preparing the board therefore involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from the board's flash	`redboot_ROM.ecm`	`redboot_rom.bin`
dBUG	Used for initial setup	`redboot_DBUG.ecm`	`redboot_dbug.srec`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot_ram.bin`
ROMFFE	RedBoot running from the board's flash at 0xFFE00000	`redboot_ROMFFE.ecm`	`redboot_romffe.bin`

For serial communications all versions run with 8 bits, no parity, and 1 stop bit. The dBUG version runs at 19200 baud. The ROM and RAM versions run at 38400 baud. These baud rates can be changed via the configuration option `CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD` and rebuilding RedBoot. By default RedBoot will use the board's terminal port, corresponding to uart0, but this can also be changed via the configuration option `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`. On an M5272C3 platform RedBoot also supports ethernet communication and flash management.

Initial Installation

This process assumes that the board still has its original dBUG ROM monitor and does not require any special debug hardware. It leaves the existing ROM monitor in place, allowing the setup process to be repeated just in case that should ever prove necessary.

Programming the RedBoot rom monitor into flash memory requires an application that can manage flash blocks. RedBoot itself has this capability. Rather than have a separate application that is used only for flash management during the initial installation, a special RAM-resident version of RedBoot is loaded into memory and run. This version can then be used to load the normal flash-resident version of RedBoot and program it into the flash.

The first step is to connect an RS232 cable between the M5272C3 terminal port and the host PC. A suitable cable is supplied with the board. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 19200 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Make sure that the jumper next to the flash chip is set for bootstrap from the bottom of flash, location 0xFFE00000. The details of this jumper depend on the revision of the board, so the supplied board documentation should be consulted for more details. Apply power to the board and you should see a `dBUG>` prompt.

Once dBUG is up and running the RAM-resident version of RedBoot can be downloaded:

```
dBUG> dl
Escape to local host and send S-records now...
```

The required S-records file is `redboot_dbug.srec`, which is normally supplied with the eCos release in the `loaders` directory. If it needs to be rebuilt then instructions for this are supplied below. The file should be sent to the target as raw text using the terminal emulator:

```
S-record download successful!
dBUG>
```

It is now possible to run the RAM-resident version of RedBoot:

```
dBUG> go 0x20000
+FLASH configuration checksum error or invalid key
Ethernet eth0: MAC address 00:00:00:00:00:03
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [DBUG]
Non-certified release, version v2_0_1 - built 09:55:34, Jun 24 2003

Platform: M5272C3 (Freescale MCF5272)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x00400000, 0x0003f478-0x003bd000 available
FLASH: 0xffe00000 - 0x00000000, 8 blocks of 0x00040000 bytes each.
RedBoot>
```

At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. To perform this initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0xfff40000-0xfffc0000: ..
... Erase from 0x00000000-0x00000000:
... Erase from 0xfffc0000-0xffffffff: .
... Program from 0x003bf000-0x003ff000 at 0xfffc0000: .
RedBoot>
```

The flash chip on the M5272C3 board is slow at erasing flash blocks so this operation can take some time. At the end the block of flash at location 0xFFFC0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
DNS server IP address:
GDB connection port: 9000
Force console for special debug messages: false
Network hardware address [MAC]: 0x00:0x00:0x00:0x00:0x00:0x03
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0xfffc0000-0xffffffff: .
... Program from 0x003bf000-0x003ff000 at 0xfffc0000: .
RedBoot>
```

For most of these configuration variables the default value is correct. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server. The other exception is the network hardware address, also known as MAC address. All boards should be given a unique MAC address, not the one in the above example. If there are two boards on the same network trying to use the same MAC address then the resulting behaviour is undefined.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The file `redboot_rom.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
Raw file loaded 0x0003f800-0x000545a3, assumed entry at 0x0003f800
xyzModem - CRC mode, 2(SOH)/84(STX)/0(CAN) packets, 5 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0xfff00000-0xfff40000: .
... Program from 0x0003f800-0x0007f800 at 0xfff00000: .
... Erase from 0xfffc0000-0xffffffff: .
... Program from 0x003bf000-0x003ff000 at 0xfffc0000: .
RedBoot>
```

The flash-resident version of RedBoot has now programmed at location 0xFFF00000, and the flash info block at 0xFFFC0000 has been updated. The initial setup is now complete. Power off the board and set the flash jumper to boot from location 0xFFF00000 instead of 0xFFE00000. Also set the terminal emulator to run at 38400 baud (the usual baud rate for RedBoot), and power up the board again.

```
+Ethernet eth0: MAC address 00:00:00:00:00:03
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version v2_0_1 - built 09:57:50, Jun 24 2003

Platform: M5272C3 (Freescale MCF5272)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x00400000, 0x0000b400-0x003bd000 available
FLASH: 0xffe00000 - 0x00000000, 8 blocks of 0x00040000 bytes each.
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from m68k-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done simply by repeating the above process, using dBUG to load the dBUG version of RedBoot `redboot_dbug.srec`. Alternatively the existing RedBoot install can be used to load a RAM-resident version, `redboot_ram.bin`.

The ROMFFE version of RedBoot can be installed at location 0xFFE00000, replacing dBUG. This may be useful if the system needs more flash blocks than are available with the usual ROM RedBoot. Installing this RedBoot image will typically involve a BDM-based utility.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the dBUG version of RedBoot are:

```
$ mkdir redboot_dbug
$ cd redboot_dbug
$ ecosconfig new m5272c3 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/m68k/mcf52xx/mcf5272/m5272c3/v2_0_1/misc/redboot_DBUG.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot_dbug.srec`.

Rebuilding the RAM and ROM versions involves basically the same process. The RAM version uses the file `redboot_RAM.ecm` and generates a file `redboot_ram.bin`. The ROM version uses the file `redboot_ROM.ecm` and generates a file `redboot_rom.bin`.

BDM

An alternative to debugging an application on top of Redboot is to use a BDM hardware debug solution. On the eCos side this requires building the configuration for RAM startup and with CYGSEM_HAL_USE_ROM_MONITOR disabled. Note that a RAM build of RedBoot automatically has the latter configuration option disabled, so it is possible to run a RAM RedBoot via BDM and bypass the dBUG stages of the installation process.

On the host-side the details depend on exactly which BDM solution is in use. The recommended BDM debug solution is the Ronetix PEEDI. Other solutions such as the P&E USBMultilink device have proved unreliable, so if a PEEDI is not available then it is recommended that application developers should debug their applications on top of RedBoot's gdb stubs.

The PEEDI requires a configuration file peedi.cfg which can be found in the platform HAL's misc directory. The configuration file will initialize the hardware in the same way as standard eCos applications, so applications can be loaded into RAM and run as normal. The configuration file will need minor edits, for example to specify the correct license keys. For full details see the Ronetix documentation. Once the PEEDI is correctly set up m68k-elf-gdb can then connect to it in the usual way:

```
$ m68k-elf-gdb install/tests/kernel/current/tests/tm_basic
GNU gdb 6.4.50.20060226-cvs (eCosCentric)
Copyright (C) 2006 Free Software Foundation, Inc.
GDB is free software, covered by the GNU General Public License, and you are
welcome to change it and/or distribute copies of it under certain conditions.
Type "show copying" to see the conditions.

Transfer rate: 260172 bits/sec, 3217 bytes/write.
(gdb) break cyg_test_exit
Breakpoint 1 at 0x40016172: file /home/bartv/ecos/ecospro-common/infra/current/src/tcdiag.cxx, line 310.
void cyg_test_exit(void);
(gdb) continue
Continuing.

Breakpoint 1, cyg_test_exit () at /home/bartv/ecos/ecospro-common/infra/current/src/tcdiag.cxx:310
310         if (code_checksum != cyg_crc16(_stext, _etext - _stext)) {
(gdb) quit
The program is running.  Exit anyway? (y or n) y
$
```

Unlike the PEEDI, some BDM solutions will not automatically initialize the hardware. Instead this can be achieved using a set of example gdb macros which can be found in the bdm.gdb file in the platform HAL's misc subdirectory. The macros need to be called either through a configuration file or directly to initialize the hardware prior to downloading the eCos application.

Name

Configuration — Platform-specific Configuration Options

Overview

The M5272C3 platform HAL package is loaded automatically when eCos is configured for an M5272C3 target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The M5272C3 platform HAL package supports four separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0xFFF00000 and boots from that location. m68k-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFFF00000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROMFFE
: This is a variant of the ROM startup type which can be used if the application will be programmed into flash at location 0xFFE00000, overwriting the board's dBUG ROM monitor.

DBUG
: This is a variant of the RAM startup which allows applications to be loaded via the board's dBUG ROM monitor rather than via RedBoot. It exists mainly to support the dBUG version of RedBoot which is needed during hardware setup. Once the application has started it will take over all the hardware, and it will not depend on any services provided by dBUG. This startup type does not provide gdb debug facilities.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then one of the serial ports will be claimed for HAL diagnostics. By default eCos will use the terminal port, corresponding to uart0. The auxiliary port, uart1, can be selected instead via the configuration option `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`. The baud rate for the selected port is controlled by `CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD`.

Flash Driver

The platform HAL package contains flash driver support. By default this is inactive, and it can be made active by loading the generic flash package `CYGPKG_IO_FLASH`.

Special Registers

The MCF5272 processor has a number of special registers controlling the cache, on-chip RAM and ROM, and so on. The platform HAL provides a number of configuration options for setting these, for example `CYGNUM_HAL_M68K_M5272C3_RAMBAR` controls the initial value of the RAMBAR register. These options are only used during a ROM or ROMFFE startup. For a RAM startup it will be RedBoot that initializes these registers, so if the default values are not appropriate for the target application then it will be necessary to rebuild RedBoot with new settings for these options. Alternatively it should be possible to reprogram some or all of the registers early on during startup, for example by using a high-priority static constructor.

One of the special registers, MBAR, cannot be controlled via a configuration option. Changing the value of this register could have drastic effects on the system, for example moving the on-chip peripherals to a different location in memory, and it would be very easy to end up with inconsistencies between RedBoot and the eCos application. Instead the on-chip peripherals are always mapped to location 0x10000000.

System Clock

By default the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_PERIOD`, the number of microseconds between clock ticks. Other clock-related settings are recalculated automatically if the period is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are three flags specific to this port:

`-mcpu=5272`
: The m68k-elf-gcc compiler supports many variants of the M68K architecture, from the original 68000 onwards. For an MCF5272 processor `-mcpu=5272` should be used.

`-malign-int`
: This option forces m68k-elf-gcc to align integer and floating point data to a 32-bit boundary rather than a 16-bit boundary. It should improve performance. However the resulting code is incompatible with most published application binary interface specifications for M68K processors, so it is possible that this option causes problems with existing third-party object code.

`-fomit-frame-pointer`
: Traditionally the `%A6` register was used as a dedicated frame pointer, and the compiler was expected to generate link and unlink instructions on procedure entry and exit. These days the compiler is perfectly capable of generating working code without a frame pointer, so omitting the frame pointer often saves some work during procedure entry and exit and makes another register available for optimization. However without a frame pointer register the m68k-elf-gdb debugger is not always able to interpret a thread stack, so it cannot reliably give a backtrace. Removing `-fomit-frame-pointer` from the default flags will make debugging easier, but the generated code may be worse.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the M5272C3 hardware, and shold be read in conjunction with that specification. The M5272C3 platform HAL package complements the M68K architectural HAL, the MCFxxxx variant HAL, and the MCF5272 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services: the UARTs and the ethernet device will not be reinitialized because they may be in use by RedBoot for communication with the host.

For a ROM or ROMFFE startup the HAL will perform additional initialization, setting up the external DRAM and programming the various internal registers. The values used for most of these registers are configurable. Full details can be found in the exported headers `cyg/hal/plf.inc` and `cyg/hal/proc.inc`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

external SDRAM

This is mapped to location 0x00000000. The first 384 bytes are used for hardware exception vectors. The next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM and ROMFFE startup all remaining SDRAM is available. For RAM and DBUG startup available SDRAM starts at location 0x00020000, with the bottom 128K reserved for use by either the RedBoot or dBUG ROM monitors.

on-chip peripherals

These are accessible at location 0x10000000 onwards, as per the defined symbol `HAL_MCFxxxx_MBAR`. This address cannot easily be changed during development because both the ROM monitor and the application must use the same address. The `%mbar` system register is initialized appropriately during a ROM or ROMFFE startup.

on-chip SRAM

The 4K of internal SRAM are normally mapped at location 0x20000000. The `%rambar` register is initialized during a ROM startup using the value of the configuration option `CYGNUM_HAL_M68K_M5272C3_RAMBAR`. Neither eCos nor RedBoot use the internal SRAM so all of it is available to application code.

on-chip ROM

Usually this is left disabled since its contents are of no interest to most applications. If it is enabled then it is usually mapped at location 0x21000000. The `%rombar` register is initialized during a ROM startup using the value of the configuration option `CYGNUM_HAL_M68K_M5272C3_ROMBAR`.

off-chip Flash

This is located at the top of memory, location 0xFFE00000 onwards. For ROM and RAM startups it is assumed that a jumper is used to disable the bottom half of the flash, so location 0xFFE00000 is actually a mirror of 0xFFF00000. For ROMFFE and DBUG startups all of the flash is visible. By default the flash block at location 0xFFF00000 is used to hold RedBoot or another ROM startup application, and the block at location 0xFFFC00000 is used to hold flash management data and the RedBoot **fconfig** variables. The blocks at 0xFFF400000 and 0xFFF80000 can be used by application code.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer 3, which should not be used directly by application code. The gprof-based profiling code uses timer 2, so that is only available when not profiling. Timers 0 and 1 are never used by eCos so application code is free to manipulate these as required. The actual HAL macros for managing the clock are provided by the MCF5272 processor HAL. The specific numbers used are a characteristic of the platform because they depend on the processor speed.

Other Issues

The M5272C3 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MCF5272 processor HAL, the MCFxxxx variant HAL, and the M68K architectural HAL documentation should be consulted for further details.

Other Functionality

The platform HAL package also provides a flash driver for the off-chip AMD AM29PL160C flash chip. This driver is inactive by default, and only becomes active if the configuration includes the generic flash support `CYGPKG_IO_FLASH`.

When building RedBoot with the Robust Boot Loader package `CYGPKG_RBL`, the platform HAL provides a macro for the **rbl condboot** command. If the INT6 button is pressed when **rbl condboot** executes then the boot will be aborted, otherwise it will proceed normally.

Chapter 321. Freescale MCF5275 Processor Support

Name

CYGPKG_HAL_M68K_MCF5275 — eCos Support for Freescale MCF5275 Processors

Description

The Freescale MCF5275 microcontroller family covers the MCF5274, MCF5274L, MCF5275 and MCF5275L ColdFire processors. These differ slightly in the set of peripherals available. The L parts are limited to a single ethernet controller and 2 UARTs, with the non-L parts having two ethernet controllers and 3 UARTs. The MCF5275L and MCF5275 parts have a hardware cryptography accelerator, which is not currently used by eCos.

Note

The eCos MCF52xx ethernet driver currently only supports a single ethernet device (FEC0), so the second ethernet available on the MCF5274 and MCF5275 parts is not currently used by eCos.

The processor HAL package CYGPKG_HAL_M68K_MCF5275 provides support for all MCF5275 processors, although at the time of writing it has only been tested on an MCF5274. It complements the M68K architectural HAL package CYGPKG_HAL_M68K and the variant HAL package CYGPKG_HAL_M68K_MCFxxxx. An eCos configuration should also include a platform HAL package to support board-level details. e.g. how the on-chip peripherals are connected to the outside world.

Configuration

The MCF5275 processor HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The package's CDL script provides default interrupt priorities for some of the mcf5275's on-chip devices. This makes it easier for the various device driver packages to install unique interrupt priorities, as required by the hardware.

Most of the package's configuration options relate to hardware. The settings are generally determined by the platform HAL and there is little need for application developers to change them. The first hardware option is CYGHWR_HAL_M68K_MCF5275_CPU, identifying the specific MCF5275 processor being used. Legal values are MCF5274L, MCF5275L, MCF5274 and MCF5275. Typically the platform HAL will set this option via a CDL constraint.

Component CYGHWR_HAL_M68K_MCF5275_GPIO contains various options related to pin-connectivity. This gives full control over the PAR pin assignment registers, and for those pins configured as GPIO it is also possible to control the pin direction and data settings. These options are used to initialize the processor's GPIO module early on during system initialization, but applications may change settings later on as necessary. The platform HAL can define CYGHWR_HAL_M68K_MCF5275_BOARD_PINS to specify the default I/O pin mapping to be used.

The GPIO settings are used to determine default settings for on-chip peripherals, including the three UARTs, the I²C bus and the QSPI bus. For example if none of the relevant GPIO pins are assigned to UART2 then component CYGHWR_HAL_M68K_MCFxxxx_UART2 will be disabled by default, and that UART cannot be used for HAL diagnostics nor accessed via the serial device driver. It is possible to override these settings if desired, for example if a UART is connected but will be manipulated directly by application code instead of via a device driver.

1. For each of the three on-chip UARTs there will be a component, e.g. CYGHWR_HAL_M68K_MCFxxxx_UART0, determining whether or not the UART is usable on the target hardware. There are additional options CYGHWR_HAL_M68K_MCFxxxx_UART0_RTS and CYGHWR_HAL_M68K_MCFxxxx_UART0_CTS indicating whether or not the hardware handshake lines are connected, and CYGHWR_HAL_M68K_MCFxxxx_UART0_RS485_RTS to indicate that the RTS line controls an RS485 transceiver.
2. Component CYGHWR_HAL_M68K_MCF5275_I2C determines whether or not the processor HAL will instantiate an I²C bus device hal_mcfxxxx_i2c_bus. There are also options to control the interrupt priority and to set the FDR register which

controls the bus speed. The default bus speed will be the standard I²C bus speed of 100KHz, or as close as can be achieved given hardware limitations.

3. Component CYGHWR_HAL_M68K_MCF5275_SPI determines whether or not the processor HAL will instantiate an SPI bus device hal_mcfxxxx_qspi_bus. It contains an additional configuration option for the interrupt priority.

For configurations which include the eCos kernel, CYGIMP_HAL_M68K_MCF5275_IDLE determines what happens when the idle thread runs.

The option CYGPKG_HAL_M68K_MCF5275_ISR_PRIORITIES provides support for configuring the interrupt priorities as detailed in the interrupt priorities section.

The HAL Port

This section describes how the MCF5275 processor HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

HAL I/O

The header file cyg/hal/proc_io.h provides definitions of MCF5275-specific on-chip peripherals. Many of the on-chip peripherals are compatible with those on the MCF5282 or other ColdFire processors, and for those peripherals it is the var_io.h header provided by the MCFxxxx variant HAL which provides the appropriate definitions. Both headers are automatically included by the architectural header cyg/hal/hal_io.h, so typically application code and other packages will just include the latter.

The MCF5275 reserves a 1GB area of memory for the internal peripheral space. Usually this is mapped between 0x40000000 and 0x7FFFFFFF. Most of this space is not used, but accessing it can cause problems including apparently locking up the processor such that either a hard reset or a watchdog timeout is needed. The target-side gdb stubs code can trap most accesses initiated by host-side gdb, but cannot protect against errant accesses by application code.

Interrupt Handling

The header file cyg/hal/proc_intr.h provides VSR and ISR vector numbers for all interrupt sources. The VSR vector number, for example CYGNUM_HAL_VECTOR_TMR0, should be used for calls like cyg_interrupt_get_vsr. It corresponds directly to the M68K exception number. The ISR vector number, for example CYGNUM_HAL_ISR_TMR0, should be used for calls like cyg_interrupt_create. This header file is automatically included by the architectural header cyg/hal/hal_intr.h, and other packages and application code will normally just include the latter.

The eCos HAL macros HAL_INTERRUPT_MASK, HAL_INTERRUPT_UNMASK, HAL_INTERRUPT_ACKNOWLEDGE, and HAL_INTERRUPT_CONFIGURE are implemented by the processor HAL. The mask and unmask operations are straightforward, simply manipulating the IMR registers in the on-chip interrupt controllers. The acknowledge macro is only relevant for external interrupts coming in via the edge port module and will clear the interrupt by writing to the EPIER register. There is no simple way to clear interrupts generated by other sources. Instead each such interrupt has to be cleared in a device-specific way, and that is the responsibility of the appropriate device driver. The configure macro is only relevant for external interrupts and involves manipulating the edge port module.

The HAL_INTERRUPT_SET_LEVEL macro, used implicitly by higher level code such as cyg_interrupt_create, is also implemented by the processor HAL. In the MCF5275 processor interrupt priorities have to be managed very carefully. Interrupts are managed via two interrupt controllers, INTC0 and INTC1. Each controller contains ICRxx control registers for each interrupt to manage that interrupt's priority. The HAL_INTERRUPT_SET_LEVEL macro simply fills in the ICRxx register.

An ICRxx value is a six-bit number. The top three bits correspond to the standard M68K IPL interrupt level. The bottom three bits give a finer-grained priority within that IPL level. For example, if the priority argument to cyg_interrupt_create is 42 then that corresponds to an IPL level of 5 and a finer-grained priority of 2. If the system has been configured to support nested interrupts and a level 42 interrupt goes off, the processor's IPL level will be set to 5 so all interrupts with priorities < 48 will remain blocked. The finer-grained priority controls what happens when two interrupts with the same IPL level go off at the same time.

Interrupt priorities between 0 and 7 would correspond to an IPL level of 0. The interrupt controller can only raise an interrupt if the IPL level is at least 1, so the smallest valid interrupt priority is 8. Interrupt priorities between 56 and 63 correspond to IPL level 7, and such interrupts are non-maskable and must be used with care. These interrupts cannot be managed safely by the usual eCos ISR and DSR mechanisms, instead application code will have to install a custom VSR and manage the entire interrupt. This means that interrupt priorities should normally be in the range 8 to 55.

As a special case, external interrupts coming in via the edge port module have hard-wired priorities which do not clash with the programmable ones. For these the priority argument to `HAL_INTERRUPT_SET_LEVEL` and higher-level code is ignored.

The MCF5275 interrupt controllers have a major restriction: all interrupt priorities within each controller must be unique. If two interrupts go off at the same time and have exactly the same priority then the controllers' behaviour is undefined. In a typical application some of the interrupts will be handled by eCos device drivers while others will be handled directly by application code. Since eCos cannot know which interrupts may get used, it cannot allocate unique priorities. Instead this has to be left to the application developer. eCos does provide configuration options such as `CYGNUM_KERNEL_COUNTERS_CLOCK_ISR_PRIORITY` and `CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_ISR_PRIORITY` to provide control over the eCos-managed interrupts, and provides default values for these which are unique.

To ensure that the configured interrupt priorities are unique the processor HAL comes with a test case `intrpri`. The source code for this can be found in the package's `tests` subdirectory. The test examines the ICRxx registers in both interrupt controllers. It will report all priorities that are in use, and report a failure if a non-unique priority is detected. This code may prove useful for application developers trying to allocate interrupt priorities.

Caution

Non-unique interrupt priorities can lead to very confusing system behaviour. For example if the PIT3 system clock (interrupt 0x27) and UART2 (interrupt 0x0F) are accidentally given the same priority and go off at the same time, the interrupt controller may actually issue an interrupt 0x2F, the bitwise-or of the two interrupt numbers. That interrupt belongs to the on-chip USB module. There may not be an installed handler for that interrupt at all, and even if there is a handler it will only manipulate the USB hardware and not clear the system clock and UART interrupts. Hence the system is likely to go into a spin, continually trying to service the wrong interrupt. To track down such problems during debugging it may prove useful to install a breakpoint on the `hal_arch_default_isr` function.

Clock Support

The processor HAL provides support for the eCos system clock. This always uses hardware timer PIT3, which should not be manipulated directly by application code. If gprof-based profiling is enabled then that will use hardware timer PIT2. PIT timers 0 and 1 are never used by eCos so application code is free to manipulate these as required.

Some of the configuration options related to the system clock, for example `CYGNUM_HAL_RTC_PERIOD`, are actually contained in the platform HAL rather than the processor HAL. These options need to take into account the processor clock speed, a characteristic of the platform rather than the processor.

Cache Handling

The MCF5275 has 16K of cache. Usually this will be set up as a split cache, 8K for instructions and 8K for data, which should give the best performance for typical applications. The standard HAL cache macros are supported.

On some platforms it may be better to organize the cache differently. For example if the platform involves running code only out of internal SRAM which may access external data, it may be possible to improve performance by using a 16K data cache instead of a split cache. This is controlled by `CYGIMP_HAL_M68K_MCF5275_CACHE_MODE`, which may be either a fixed `#define` or a configuration option depending on the platform. For more details see the header file `proc_cache.h`.

The HAL also defines a macro `HAL_MEMORY_BARRIER()` which acts to synchronize the pipeline, delaying execution until all previous operations including all pending writes are complete. This will usually be necessary when interacting with devices that access memory directly.

Other Issues

The MCF5275 processor HAL does not affect the implementation of data types, stack size definitions, SMP support, system startup, or debug support. The MCFxxxx variant HAL versions of `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` are used since the processor supports the `ff1.l` and `bitrev.l` instructions. `HAL_DELAY_US` is implemented as a simple counting loop. `HAL_IDLE_THREAD_ACTION` may be defined depending on configuration option `CYGIMP_HAL_M68K_MCF5275_IDLE`.

Other Functionality

The processor HAL will instantiate a cyg_i2c_bus structure `hal_mcfxxxx_i2c_bus` when the configuration option `CYGHWR_HAL_M68K_MCFxxxx_I2C` is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the `CYGPKG_DEVS_I2C_MCFxxxx` device driver. The processor HAL does not know what I²C devices may be attached to the bus so that is left to the platform HAL.

The processor HAL will instantiate a cyg_spi_bus structure `hal_mcfxxxx_qspi_bus` when the configuration option `CYGHWR_HAL_M68K_MCFxxxx_SPI` is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the `CYGPKG_DEVS_SPI_MCFxxxx_QSPI` device driver. The processor HAL does not know what SPI devices may be attached to the bus so that is left to the platform HAL. All SPI device structures should be placed in the table `mcfxxxx_qspi`.

Chapter 322. Freescale MCF5282 Processor Support

Name

CYGPKG_HAL_M68K_MCF5282 — eCos Support for the Freescale MCF5282 Processor

Description

The MCF5282 is one member of the Freescale MCFxxxx ColdFire range of processors. It comes with a number of on-chip peripherals including 3 UARTs and ethernet. The processor HAL package CYGPKG_HAL_M68K_MCF5282 provides support for features that are specific to the MCF5282. It complements the M68K architectural HAL package CYGPKG_HAL_M68K and the variant HAL package CYGPKG_HAL_M68K_MCFxxxx. An eCos configuration should also include a platform HAL package, for example CYGPKG_HAL_M68K_M5282EVB to support board-level details like the external memory chips.

The MCF5282 processor HAL supports the MCF5280. The only difference between these two processors is the presence of on-chip flash. The platform HAL and the ecos.db **target** entry will handle this difference.

Configuration

The MCF5282 processor HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The package's CDL script provides default interrupt priorities for some of the mcf5282's on-chip devices. This makes it easier for the various device driver packages to install unique interrupt priorities, as required by the hardware.

The HAL Port

This section describes how the MCF5282 processor HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

HAL I/O

The header file cyg/hal/proc_io.h provides definitions of all on-chip peripherals, except for some UART definitions which are provided by the variant HAL instead. This header file is automatically included by the architectural header cyg/hal/hal_io.h, so typically application code and other packages will just include the latter. There are default INIT macros for the various on-chip devices which can be used by platform initialization code, although on any given platform some of the devices may need special attention.

The MCF5282 reserves a 1-gbyte area of memory for the internal peripheral space. Usually this is mapped between 0x40000000 and 0x7fffffff. Most of this space is not used, but accessing it can cause problems including apparently locking up the processor such that either a hard reset or a watchdog timeout is needed. The target-side gdb stubs code can trap most accesses initiated by host-side gdb, but cannot protect against errant accesses by application code.

It should be noted that the Freescale documentation is occasionally confusing when it comes to numbering devices. For example the four on-chip programmable timers are numbered PIT1 to PIT4, but in the interrupt controller the corresponding interrupts are numbered PIT0 to PIT3. The eCos port consistently starts numbering at 0, so the timers have been renamed PIT0 to PIT3.

Interrupt Handling

The header file cyg/hal/proc_intr.h provides VSR and ISR vector numbers for all interrupt sources. The VSR vector number, for example CYGNUM_HAL_VECTOR_TMR0, should be used for calls like cyg_interrupt_get_vsr. It corresponds directly to the M68K exception number. The ISR vector number, for example CYGNUM_HAL_ISR_TMR0, should be used for calls like cyg_interrupt_create. This header file is automatically included by the architectural header cyg/hal/hal_intr.h, and other packages and application code will normally just include the latter.

The eCos HAL macros HAL_INTERRUPT_MASK, HAL_INTERRUPT_UNMASK, HAL_INTERRUPT_ACKNOWLEDGE, and HAL_INTERRUPT_CONFIGURE are implemented by the processor HAL. The mask and unmask operations are straightforward, simply manipulating the IMR registers in the on-chip interrupt controllers. The acknowledge macro is only relevant for external interrupts coming in via the edge port module and will clear the interrupt by writing to the EPIER register. There is no simple way to clear interrupts generated by other sources. Instead each such interrupt has to be cleared in a device-specific way, and that is the responsibility of the appropriate device driver. The configure macro is only relevant for external interrupts and involves manipulating the edge port module.

The HAL_INTERRUPT_SET_LEVEL macro, used implicitly by higher level code such as cyg_interrupt_create, is also implemented by the processor HAL. In the MCF5282 processor interrupt priorities have to be managed very carefully. Interrupts are managed via two interrupt controllers, INTC0 and INTC1. Each controller contains ICRxx control registers for each interrupt to manage that interrupt's priority. The HAL_INTERRUPT_SET_LEVEL macro simply fills in the ICRxx register.

An ICRxx value is a six-bit number. The top three bits correspond to the standard M68K IPL interrupt level. The bottom three bits give a finer-grained priority within that IPL level. For example, if the priority argument to cyg_interrupt_create is 42 then that corresponds to an IPL level of 5 and a finer-grained priority of 2. If the system has been configured to support nested interrupts and a level 42 interrupt goes off, the processor's IPL level will be set to 5 so all interrupts with priorities < 48 will remain blocked. The finer-grained priority controls what happens when two interrupts with the same IPL level go off at the same time.

Interrupt priorities between 0 and 7 would correspond to an IPL level of 0. The interrupt controller can only raise an interrupt if the IPL level is at least 1, so the smallest valid interrupt priority is 8. Interrupt priorities between 56 and 63 correspond to IPL level 7, and such interrupts are non-maskable and must be used with care. These interrupts cannot be managed safely by the usual eCos ISR and DSR mechanisms, instead application code will have to install a custom VSR and manage the entire interrupt. This means that interrupt priorities should normally be in the range 8 to 55.

As a special case, external interrupts coming in via the edge port module have hard-wired priorities which do not clash with the programmable ones. For these the priority argument to HAL_INTERRUPT_SET_LEVEL and higher-level code is ignored.

The MCF5282 interrupt controllers have a major restriction: all interrupt priorities within each controller must be unique. If two interrupts go off at the same time and have exactly the same priority then the controllers' behaviour is undefined. In a typical application some of the interrupts will be handled by eCos device drivers while others will be handled directly by application code. Since eCos cannot know which interrupts may get used, it cannot allocate unique priorities. Instead this has to be left to the application developer. eCos does provide configuration options such as CYGNUM_KERNEL_COUNTERS_CLOCK_ISR_PRIORITY and CYGNUM_DEVS_SERIAL_MCFxxxx_SERIAL0_ISR_PRIORITY to provide control over the eCos-managed interrupts, and provides default values for these which are unique.

To ensure that the configured interrupt priorities are unique the processor HAL comes with a test case intrpri. The source code for this can be found in the package's tests subdirectory. The test examines the ICRxx registers in both interrupt controllers. It will report all priorities that are in use, and report a failure if a non-unique priority is detected. This code may prove useful for application developers trying to allocate interrupt priorities.

Caution

Non-unique interrupt priorities can lead to very confusing system behaviour. For example if the PIT3 system clock (interrupt 0x3a) and ethernet RX frame (interrupt 0x1b) are accidentally given the same priority and go off at the same time, the interrupt controller may actually issue an interrupt 0x3b, the bitwise or of the two interrupt numbers. That interrupt belongs to the on-chip flash module. There may not be an installed handler for that interrupt at all, and even if there is a handler it will only manipulate the flash hardware and not clear the system clock and ethernet interrupts. Hence the system is likely to go into a spin, continually trying to service the wrong interrupt. To track down such problems during debugging it may prove useful to install a breakpoint on the hal_arch_default_isr function.

Clock Support

The processor HAL provides support for the eCos system clock. This always uses hardware timer PIT3, which should not be manipulated directly by application code. If gprof-based profiling is enabled then that will use hardware timer PIT2. PIT timers 0 and 1 are never used by eCos so application code is free to manipulate these as required.

Some of the configuration options related to the system clock, for example `CYGNUM_HAL_RTC_PERIOD`, are actually contained in the platform HAL rather than the processor HAL. These options need to take into account the processor clock speed, a characteristic of the platform rather than the processor.

Cache Handling

The MCF5282 has 2K of cache. Usually this will be set up as a split cache, 1K for instructions and 1K for data, which should give the best performance for typical applications. The standard HAL cache macros are supported.

On some platforms it may be better to organize the cache differently. For example if the platform involves running code only out of internal flash but may access external data, it may be possible to improve performance by using a 2K data cache instead of a split cache. This is controlled by `CYGIMP_HAL_M68K_MCF5282_CACHE_MODE`, which may be either a fixed `#define` or a configuration option depending on the platform. For more details see the header file `proc_cache.h`.

Other Issues

The MCF5282 processor HAL does not affect the implementation of data types, stack size definitions, bit indexing, idle thread processing, linker scripts, SMP support, system startup, or debug support.

Other Functionality

The MCF5282 processor HAL only implements functionality defined in the eCos HAL specification and does not export any additional functions.

Chapter 323. Freescale M5282EVB Board Support

Name

eCos Support for the Freescale M5282EVB Board — Overview

Description

The Freescale M5282EVB board has an MCF5282 ColdFire processor, 16MB of external SDRAM, 2MB of external flash memory, plus required support chips for the on-chip peripherals. By default the board comes with its own dBUG ROM monitor, located in the bottom half of the flash.

For typical eCos development a RedBoot image is programmed into the top half of the flash memory, and the board is made to boot this image rather than the existing dBUG monitor. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The memory map used by both eCos and RedBoot is as follows:

Memory	Base	Length
External SDRAM	0x00000000	0x01000000
Internal RAM	0x20000000	0x00010000
On-chip Peripherals	0x40000000	0x40000000
On-chip Flash	0xF0000000	0x00080000
External Flash	0xFFE00000	0x00200000

eCos can be configured for one of four startup types:

RAM
: This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. m68k-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

  With a minor change to the eCos configuration this startup type can also be used to debug applications via BDM.

DBUG
: This is a variant of the RAM startup which allows applications to be loaded via the board's dBUG ROM monitor rather than via RedBoot. Once the application has started it will take over all the hardware, and it will not depend on any services provided by dBUG. This startup type does not provide gdb debug facilities. It is used primarily for building a special version of RedBoot, used during hardware setup.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFFF00000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

ROMFFE
: This is a variant of the ROM startup type which can be used if the application will be programmed into flash at location 0xFFE00000, overwriting the board's dBUG ROM monitor.

For all startup types the external SDRAM is used to hold all data. For RAM and dBUG startup the code also resides in external SDRAM, with the first 64K reserved for use by the ROM monitor. The 64K of internal RAM is not used, either by RedBoot or by eCos, so all of it is available to the application. The 512K of internal flash is not currently used.

In a typical setup the bottom half of the external flash is reserved for the dBUG ROM monitor and is not accessible to eCos. That leaves 16 flash blocks of 64K each. Of these the first two are used for the RedBoot image and another is used for managing the flash and holding RedBoot fconfig values. The remaining 13 blocks from 0xFFF20000 to 0xFFFF0000 can be used by application code.

Alternatively it is possible to build an application for ROM startup and program it into flash at 0xFFF00000, replacing RedBoot. For a larger application ROMFFE startup can be used instead, making all of external flash available to application code.

RedBoot can communicate with the host using either ethernet or one of the UARTs - usually uart0 corresponding to the terminal port on the m5282evb board.

All configurations for the M5282EVB target include an ethernet driver package `CYGPKG_DEVS_ETH_MCFxxxx`. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package `CYGPKG_IO_ETH_DRIVERS`. Typically the choice of eCos template causes the right thing to happen. For example the default template does not include any TCP/IP stack so `CYGPKG_IO_ETH_DRIVERS` is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver. The ethernet device can be shared by RedBoot and the application, so it is possible to debug a networked application over ethernet.

The M5282EVB board does not have a serial EPROM or similar hardware providing a unique network MAC address. Instead a suitable address has to be programmed into flash via RedBoot's **fconfig** command.

All configurations for the M5282EVB target include a serial device driver package `CYGPKG_DEVS_SERIAL_MCFxxxx`. The driver as a whole is inactive unless the generic serial support, `CYGPKG_IO_SERIAL_DEVICES` is enabled. Exactly which of the on-chip UARTs are supported is controlled by configuration options within the platform HAL. By default both uart0 and uart1 are supported, corresponding to the terminal and auxiliary ports. If the UART is needed by the application then it cannot also be used by RedBoot for gdb traffic, so another communication channel such as ethernet should be used instead.

All configurations for the M5282EVB target also include a watchdog device driver `CYGPKG_DEVS_WATCHDOG_MCF5282`. This driver is inactive unless the generic watchdog support `CYGPKG_IO_WATCHDOG` is loaded.

The on-chip interrupt controllers and the edge port module are managed by eCos using macros provided by the MCF5282 processor HAL. PIT timer 3 is normally used to implement the eCos system clock. If gprof-based profiling is enabled then that will use PIT timer 2. PIT timers 0 and 1 are unused and can be manipulated by the application. The GPIO pins are manipulated only as needed to get the UART(s) and ethernet working. eCos will reset the remaining on-chip peripherals (DMA, GPT, DMA timers, QSPI, I²C, FlexCAN, and QADC) during system startup or soft reset, but will not otherwise manipulate them.

Tools

The M5282EVB port is intended to work with GNU tools configured for an m68k-elf target. The original port was done using m68k-elf-gcc version 3.2.1, m68k-elf-gdb version 5.3, and binutils version 2.13.1.

By default eCos is built using the compiler flag `-fomit-frame-pointer`. Omitting the frame pointer eliminates some work on every function call and makes another register available, so the code should be smaller and faster. However without a frame pointer m68k-elf-gdb is not always able to identify stack frames, so it may be unable to provide accurate backtrace information. Removing this compiler flag from the configuration option `CYGBLD_GLOBAL_CFLAGS` avoids such debug problems.

A typical setup involves m68k-elf-gdb interacting with RedBoot using either serial or ethernet. Alternatively it is possible to debug via the BDM port. The package's `misc` subdirectory contains a script `bdm.gdb` that contains macros for the low-level hardware initialization normally performed by the ROM startup code. The application should be linked with an eCos configuration using RAM startup, and with the options `CYGSEM_HAL_ROM_MONITOR` and `CYGSEM_HAL_USE_ROM_MONITOR` disabled to stop eCos accessing any services provided by RedBoot. Diagnostic output will be sent out of uart0.

Name

Setup — Preparing the M5282EVB board for eCos Development

Overview

In a typical development environment the M5282EVB board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run on the board via the debugger m68k-elf-gdb. Preparing the board therefore involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from the board's flash	`redboot_ROM.ecm`	`redboot_rom.bin`
dBUG	Used for initial setup	`redboot_DBUG.ecm`	`redboot_dbug.srec`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot_ram.bin`
ROMFFE	RedBoot running from the board's flash at 0xFFE00000	`redboot_ROMFFE.ecm`	`redboot_romffe.bin`

For serial communications all versions run with 8 bits, no parity, and 1 stop bit. The dBUG version runs at 19200 baud. The ROM and RAM versions run at 38400 baud. These baud rates can be changed via the configuration option `CYGNUM_HAL_M68K_M5282EVB_DIAG_BAUD`. By default RedBoot will use the board's terminal port, corresponding to uart0, but this can also be changed via the configuration option `CYGHWR_HAL_M68K_M5282EVB_DIAGNOSTICS_PORT`. On an M5282EVB platform RedBoot also supports ethernet communication and flash management.

Initial Installation

This process assumes that the board still has its original dBUG ROM monitor and does not require any special debug hardware. It leaves the existing ROM monitor in place, allowing the setup process to be repeated just in case that should ever prove necessary.

Programming the RedBoot rom monitor into flash memory requires an application that can manage flash blocks. RedBoot itself has this capability. Rather than have a separate application that is used only for flash management during the initial installation, a special RAM-resident version of RedBoot is loaded into memory and run. This version can then be used to load the normal flash-resident version of RedBoot and program it into the flash.

The first step is to connect an RS232 cable between the M5282EVB terminal port and the host PC. A suitable cable is supplied with the board. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 19200 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Make sure that jumper jp16 is set for bootstrap from the bottom of flash, location 0xFFE00000. Apply power to the board and you should see a `dBUG>` prompt.

Once dBUG is up and running the RAM-resident version of RedBoot can be downloaded:

```
dBUG> dl
Escape to local host and send S-records now...
```

The required S-records file is `redboot_dbug.srec`, which is normally supplied with the eCos release in the `loaders` directory. If it needs to be rebuilt then instructions for this are supplied below. The file should be sent to the target as raw text using the terminal emulator:

```
S-record download successful!
dBUG>
```

It is now possible to run the RAM-resident version of RedBoot:

```
dBUG> go 0x10000
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
... waiting for BOOTP information
Ethernet eth0: MAC address 00:00:00:00:00:03
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [DBUG]
Non-certified release, version UNKNOWN - built 23:36:11, Mar 31 2004

Platform: M5282EVB (Motorola MCF5282)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x01000000, 0x0002f274-0x00fed000 available
FLASH: 0xffe00000 - 0x00000000, 32 blocks of 0x00010000 bytes each.
RedBoot>
```

At this stage, RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. There will also be a delay while RedBoot tries to contact a local BOOTP server. To perform the flash initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0xfff20000-0xffff0000: ..
... Erase from 0x00000000-0x00000000:
... Erase from 0xffff0000-0xffffffff: .
`... Program from 0x00ff0000-0x01000000 at 0xffff0000: .
RedBoot>
```

At this stage the block of flash at location 0xFFFF0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
DNS server IP address:
GDB connection port: 9000
Force console for special debug messages: false
Network hardware address [MAC]: 0x00:0x00:0x00:0x00:0x00:0x03
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0xffff0000-0xffffffff: .
... Program from 0x00ff0000-0x01000000 at 0xffff0000: .
RedBoot>
```

For most of these configuration variables the default value is correct. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server. The other exception is the network hardware address, also known as the MAC address. All boards should be given a unique MAC address, not the one in the above example. If there are two boards on the same network trying to use the same MAC address then the resulting behaviour is undefined.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The file `redboot_rom.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
Raw file loaded 0x0002f400-0x00045af7, assumed entry at 0x0002f400
```

```
xyzModem - CRC mode, 772(SOH)/0(STX)/0(CAN) packets, 5 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0xfff00000-0xfff20000: .
... Program from 0x0002f400-0x0004f400 at 0xfff00000: .
... Erase from 0xffff0000-0xffffffff: .
... Program from 0x00ff0000-0x01000000 at 0xffff0000: .
RedBoot>
```

The flash-resident version of RedBoot has now been programmed at location 0xFFF00000, and the flash info block at 0xFFFF0000 has been updated. The initial setup is now complete. Power off the board and set the flash jumper to boot from location 0xFFF00000 instead of 0xFFE00000. Also set the terminal emulator to run at 38400 baud (the usual baud rate for RedBoot), and power up the board again.

```
+Ethernet eth0: MAC address 00:00:00:00:00:03
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 23:44:10, Mar 31 2004

Platform: M5282EVB (Motorola MCF5282)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x01000000, 0x0000d390-0x00fed000 available
FLASH: 0xffe00000 - 0x00000000, 32 blocks of 0x00010000 bytes each.
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from m68k-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done simply by repeating the above process, using dBUG to load the dBUG version of RedBoot `redboot_dbug.srec`. Alternatively the existing RedBoot install can be used to load a RAM-resident version, `redboot_ram.bin`.

The ROMFFE version of RedBoot can be installed at location 0xFFE00000, replacing dBUG. This may be useful if the system needs more flash blocks than are available with the usual ROM RedBoot. Installing this RedBoot image will typically involve a BDM-based utility.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the dBUG version of RedBoot are:

```
$ mkdir redboot_dbug
$ cd redboot_dbug
$ ecosconfig new m5282evb redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/m68k/mcf52xx/mcf5282/m5282evb/current/misc/redboot_DBUG.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot_dbug.srec`.

Rebuilding the RAM and ROM versions involves basically the same process. The RAM version uses the file `redboot_RAM.ecm` and generates a file `redboot_ram.bin`. The ROM version uses the file `redboot_ROM.ecm` and generates a file `redboot_rom.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The M5282EVB platform HAL package is loaded automatically when eCos is configured for an M5282EVB target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The M5282EVB platform HAL package supports four separate startup types, controlled by the configuration option CYG_HAL_STARTUP:

RAM This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0xFFF00000 and boots from that location. m68k-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output, but that can be disabled via CYGSEM_HAL_USE_ROM_MONITOR.

ROM This startup type can be used for finished applications which boot directly from flash at location 0xFFF00000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. The flash-resident version of RedBoot uses this startup type.

ROMFFE This is a variant of the ROM startup type which can be used if the application will be programmed into flash at location 0xFFE00000, overwriting the board's dBUG ROM monitor.

DBUG This is a variant of the RAM startup which allows applications to be loaded via the board's dBUG ROM monitor rather than via RedBoot. It exists mainly to support the dBUG version of RedBoot which is needed during hardware setup. Once the application has started it will take over all the hardware, and it will not depend on any services provided by dBUG. This startup type does not provide gdb debug facilities.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option CYGSEM_HAL_ROM_MONITOR should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option CYGSEM_HAL_USE_ROM_MONITOR should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via BDM.

If the application does not rely on a ROM monitor for diagnostic services then one of the serial ports will be claimed for HAL diagnostics. By default eCos will use the terminal port, corresponding to uart0. The auxiliary port, uart1, can be selected instead via the configuration option CYGHWR_HAL_M68K_M5282EVB_DIAGNOSTICS_PORT. The baud rate for the selected port is controlled by CYGNUM_HAL_M68K_M5282EVB_DIAG_BAUD.

Flash Driver

The platform HAL package contains flash driver support for the external flash. By default this is inactive, and it can be made active by loading the generic flash package CYGPKG_IO_FLASH.

Special Registers

The MCF5282 processor has a number of special registers controlling the cache, on-chip RAM and flash, and so on. The platform HAL provides a number of configuration options for setting these, for example `CYGNUM_HAL_M68K_M5282EVB_RAMBAR` controls the initial value of the RAMBAR register.

System Clock

By default the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_PERIOD`, the number of microseconds between clock ticks. Other clock-related settings are recalculated automatically if the period is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are three flags specific to this port:

`-m5200`
The m68k-elf-gcc compiler supports many variants of the M68K architecture, from the original 68000 onwards. A `-m` option should be used to select the specific variant in use, and with current tools `-m5200` is the closest match for an MCF5282 processor.

`-malign-int`
This option forces m68k-elf-gcc to align integer and floating point data to a 32-bit boundary rather than a 16-bit boundary. It should improve performance. However the resulting code is incompatible with most published application binary interface specifications for M68K processors, so it is possible that this option causes problems with existing third-party object code.

`-fomit-frame-pointer`
Traditionally the `%A6` register was used as a dedicated frame pointer, and the compiler was expected to generate link and unlink instructions on procedure entry and exit. These days the compiler is perfectly capable of generating working code without a frame pointer, so omitting the frame pointer often saves some work during procedure entry and exit and makes another register available for optimization. However, without a frame pointer register, the m68k-elf-gdb debugger is not always able to interpret a thread stack, so it cannot reliably give a backtrace. Removing `-fomit-frame-pointer` from the default flags will make debugging easier, but the generated code may be worse.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the M5282EVB hardware, and should be read in conjunction with that specification. The M5282EVB platform HAL package complements the M68K architectural HAL, the MCFxxxx variant HAL, and the MCF5282 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services: the UARTs and the ethernet device will not be reinitialized because they may be in use by RedBoot for communication with the host. Full details of this initialization can be found in the function `hal_m68k_m5282evb_init` in `platform.c`.

For a ROM or ROMFFE startup the HAL will perform additional initialization, setting up the external DRAM and programming the various internal registers. The values used for some of these registers are configurable. Full details can be found in the exported header `cyg/hal/plf.inc`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External SDRAM

This is mapped to location 0x00000000. Most of the first kilobyte is used for hardware exception vectors. The eCos virtual vectors are also placed here, allowing RAM-based applications to use services provided by the ROM monitor. For ROM and ROMFFE startup all remaining SDRAM is available. For RAM and DBUG startup available SDRAM starts at location 0x00010000, with the bottom 64K reserved for use by either the RedBoot or dBUG ROM monitors.

Internal RAM

The 64K of internal RAM are normally mapped at location 0x20000000. Neither eCos nor RedBoot use the internal RAM so all of it is available to application code.

On-chip Peripherals

These are accessible at location 0x40000000 onwards, as per the defined symbol `HAL_MCF5282_ISPBAR`.

Note

On some other coldfire processors the equivalent register is known as `%mbar`. The symbol `HAL_MCFxxxx_MBAR` is an alias for `HAL_MCF5282_ISPBAR`, making it easier to share device drivers.

On-chip Flash

The 512K of internal flash are normally mapped at location 0xF0000000. Currently this is not used by eCos or RedBoot.

External Flash

This is located at the top of memory, location 0xFFE00000 onwards. For ROM startup it is assumed that a jumper is used to disable the bottom half of the flash, so location 0xFFE00000 is actually a mirror of 0xFFF00000. For ROMFFE and DBUG startups all of the flash is visible. RAM startup will work irrespective of the jumper setting.

In a typical setup the first two 64K flash blocks at location 0xFFF00000 are used to hold RedBoot, and the block at location 0xFFFF0000 is used to hold flash management data and the RedBoot **fconfig** variables. The remaining blocks can be used by application code.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer PIT3, which should not be used directly by application code. The actual HAL macros for managing the clock are provided by the MCF5282 processor HAL. The specific numbers used are a characteristic of the platform because they depend on the processor speed. The gprof-based profiling code uses PIT2. Timers PIT0 and PIT1 are not used by eCos so application code is free to manipulate these as required.

Other Issues

The M5282EVB platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MCF5282 processor HAL, the MCFxxxx variant HAL, and the M68K architectural HAL documentation should be consulted for further details.

Other Functionality

The platform HAL package also provides a flash driver for the off-chip AMD AM29LV160 flash chip. This driver is inactive by default, and only becomes active if the configuration includes the generic flash support `CYGPKG_IO_FLASH`.

The platform HAL provides one additional function to manipulate the on-board LEDs: `void hal_m5282evb_led_set(which, what)`. The `which` argument specifies the LED and should be either 0 or 1. The `what` argument should be non-zero to switch the LED on, zero to switch it off. Note that only two of the four user LEDs can be manipulated in this way: the other two are normally connected to signals needed by one of the uarts.

Chapter 324. Freescale M5282LITE Board Support

Name

eCos Support for the Freescale M5282LITE Board — Overview

Description

The Freescale M5282LITE board has an MCF5282 ColdFire processor, 16MB of external SDRAM, 2MB of external flash memory, and connectors plus required support chips for the on-chip peripherals. By default the board comes with its own dBUG ROM monitor located in the external flash.

For typical eCos development a RedBoot image is programmed into the external flash replacing the existing dBUG monitor. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The memory map used by both eCos and RedBoot is as follows:

Memory	**Base**	**Length**
External SDRAM	0x00000000	0x01000000
Internal RAM	0x20000000	0x00010000
On-chip Peripherals	0x40000000	0x40000000
On-chip Flash	0xF0000000	0x00080000
External Flash	0xFFE00000	0x00200000

eCos can be configured for one of three startup types:

RAM
: This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. m68k-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

With a minor change to the eCos configuration this startup type can also be used to debug applications via BDM.

DBUG
: This is a variant of the RAM startup which allows applications to be loaded via the board's dBUG ROM monitor rather than via RedBoot. Once the application has started it will take over all the hardware, and it will not depend on any services provided by dBUG. This startup type does not provide gdb debug facilities. It is used primarily for building a special version of RedBoot, used during hardware setup.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFFE00000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

For all startup types the external SDRAM is used to hold all data. For RAM and dBUG startup the code also resides in external SDRAM, with the first 64K reserved for use by the ROM monitor. The 64K of internal RAM is not used, either by RedBoot or by eCos, so all of it is available to the application. The 512K of internal flash is not currently used.

In a typical setup the first two 64K flash blocks are used for holding the RedBoot image, and the last block is used for managing the flash and holding the RedBoot fconfig values. The remaining 29 blocks from 0xFFE20000 to 0xFFFEFFFF can be used by application code.

RedBoot can communicate with the host using either ethernet or one of the UARTs - usually uart0 corresponding to the existing serial connector on the M5282LITE board.

All configurations for the M5282LITE target include an ethernet driver package CYGPKG_DEVS_ETH_MCFxxxx. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package CYGPKG_IO_ETH_DRIVERS. Typically the choice of eCos template causes the right thing to happen. For example the default template does not include any TCP/IP stack so CYGPKG_IO_ETH_DRIVERS is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver. The ethernet device can be shared by RedBoot and the application, so it is possible to debug a networked application over ethernet.

The M5282LITE board does not have a serial EPROM or similar hardware providing a unique network MAC address. Instead a suitable address has to be programmed into flash via RedBoot's **fconfig** command.

All configurations for the M5282LITE target include a serial device driver package CYGPKG_DEVS_SERIAL_MCFxxxx. The driver as a whole is inactive unless the generic serial support, CYGPKG_IO_SERIAL_DEVICES is enabled. Exactly which of the on-chip UARTs are supported is controlled by configuration options within the platform HAL. By default only uart0 is supported since on the standard board that is the only one with a connector. If the UART is needed by the application then it cannot also be used by RedBoot for gdb traffic, so another communication channel such as ethernet should be used instead.

All configurations for the M5282LITE target also include a watchdog device driver CYGPKG_DEVS_WATCHDOG_MCF5282. This driver is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded.

The on-chip interrupt controllers and the edge port module are managed by eCos using macros provided by the MCF5282 processor HAL. PIT timer 3 is normally used to implement the eCos system clock. If gprof-based profiling is enabled then that will use PIT timer 2. PIT timers 0 and 1 are unused and can be manipulated by the application. The GPIO pins are manipulated only as needed to get the UART(s) and ethernet working. eCos will reset the remaining on-chip peripherals (DMA, GPT, DMA timers, QSPI, I²C, FlexCAN, and QADC) during system startup or soft reset, but will not otherwise manipulate them.

Tools

The M5282LITE port is intended to work with GNU tools configured for an m68k-elf target. The original port was done using m68k-elf-gcc version 3.2.1, m68k-elf-gdb version 5.3, and binutils version 2.13.1.

By default eCos is built using the compiler flag -fomit-frame-pointer. Omitting the frame pointer eliminates some work on every function call and makes another register available, so the code should be smaller and faster. However without a frame pointer m68k-elf-gdb is not always able to identify stack frames, so it may be unable to provide accurate backtrace information. Removing this compiler flag from the configuration option CYGBLD_GLOBAL_CFLAGS avoids such debug problems.

A typical setup involves m68k-elf-gdb interacting with RedBoot using either serial or ethernet. Alternatively it is possible to debug via the BDM port. The package's misc subdirectory contains a script bdm.gdb that contains macros for the low-level hardware initialization normally performed by the ROM startup code. The application should be linked with an eCos configuration using RAM startup, and with the options CYGSEM_HAL_ROM_MONITOR and CYGSEM_HAL_USE_ROM_MONITOR disabled to stop eCos accessing any services provided by RedBoot. Diagnostic output will be sent out of uart0.

Name

Setup — Preparing the M5282LITE board for eCos Development

Overview

In a typical development environment the M5282LITE board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run on the board via the debugger m68k-elf-gdb. Preparing the board therefore involves programming a suitable RedBoot image into flash memory, replacing the existing dBUG monitor.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from the board's flash	`redboot_ROM.ecm`	`redboot_rom.bin`
dBUG	Used for initial setup	`redboot_DBUG.ecm`	`redboot_dbug.srec`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot_ram.bin`

For serial communications all versions run with 8 bits, no parity, and 1 stop bit. The dBUG version runs at 19200 baud. The ROM and RAM versions run at 38400 baud. These baud rates can be changed via the configuration option `CYGNUM_HAL_M68K_M5282LITE_DIAG_BAUD` and rebuilding RedBoot. On the standard board only UART0 has a serial connector so by default RedBoot will use that. If the board has been extended to provide connectors for the other on-chip uarts then the configuration option `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT` can be used to make RedBoot use one of thoe. On an M5282LITE platform RedBoot also supports ethernet communication and flash management.

Initial Installation

This process assumes that the board still has its original dBUG ROM monitor and does not require any special debug hardware. Programming the RedBoot rom monitor into flash memory requires an application that can manage flash blocks. RedBoot itself has this capability. Rather than have a separate application that is used only for flash management during the initial installation, a special RAM-resident version of RedBoot is loaded into memory and run. This version can then be used to load the normal flash-resident version of RedBoot and program it into the flash.

The first step is to connect an RS232 cable between the M5282LITE serial port and the host PC. A suitable cable is supplied with the board. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 19200 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Apply power to the board and you should see a `dBUG>` prompt.

Once dBUG is up and running the RAM-resident version of RedBoot can be downloaded:

```
dBUG> dl
Escape to local host and send S-records now...
```

The required S-records file is `redboot_dbug.srec`, which is normally supplied with the eCos release in the `loaders` directory. If it needs to be rebuilt then instructions for this are supplied below. The file should be sent to the target as raw text using the terminal emulator:

```
S-record download successful!
dBUG>
```

It is now possible to run the RAM-resident version of RedBoot:

```
dBUG> go 0x10000
FLASH configuration checksum error or invalid key
```

```
... waiting for BOOTP information
Ethernet eth0: MAC address 00:00:00:00:00:03
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [DBUG]
Non-certified release, version UNKNOWN - built 11:26:11, Jul 24 2004

Platform: M5282LITE (Motorola MCF5282)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x01000000, 0x0002d0f0-0x00fed000 available
FLASH: 0xffe00000 - 0x00000000, 32 blocks of 0x00010000 bytes each.
RedBoot>
```

At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. There will also be a delay while RedBoot tries to contact a local BOOTP server. To perform the flash initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0xffff0000-0xffffffff: .
`... Program from 0x00ffef00-0x00fff000 at 0xffff0000: .
RedBoot>
```

At this stage the block of flash at location 0xFFFF0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
DNS server IP address:
GDB connection port: 9000
Force console for special debug messages: false
Network hardware address [MAC]: 0x00:0xff:0x12:0x34:0x01:0x08
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0xffff0000-0xffffffff: .
... Program from 0x00fef000-0x00fff000 at 0xffff0000: .
RedBoot>
```

For most of these configuration variables the default value is correct. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server. The other exception is the network hardware address, also known as MAC address. All boards should be given a unique MAC address, not the one in the above example. If there are two boards on the same network trying to use the same MAC address then the resulting behaviour is undefined.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The file `redboot_rom.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
Raw file loaded 0x0002d400-0x00042c2b, assumed entry at 0x0002d400
xyzModem - CRC mode, 691(SOH)/0(STX)/0(CAN) packets, 5 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
```

```
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0xffe00000-0xffe20000: .
... Program from 0x0002d400-0x0004d400 at 0xffe00000: .
... Erase from 0xffff0000-0xffffffff: .
... Program from 0x00fef000-0x00fff000 at 0xffff0000: .
RedBoot>
```

The flash-resident version of RedBoot has now programmed at location 0xFFE00000, and the flash info block at 0xFFFF0000 has been updated. The initial setup is now complete. Power off the board, set the terminal emulator to run at 38400 baud (the usual baud rate for RedBoot), and power up the board again.

```
+Ethernet eth0: MAC address 00:ff:12:34:01:08
IP: 10.1.1.71/255.255.255.0, Gateway: 10.1.1.241
Default server: 10.1.1.1, DNS server IP: 10.1.1.240

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 15:41:51, Jul 24 2004

Platform: M5282LITE (Motorola MCF5282)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x01000000, 0x0000bef8-0x00fed000 available
FLASH: 0xffe00000 - 0x00000000, 32 blocks of 0x00010000 bytes each.
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from m68k-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done by loading a RAM-resident version of RedBoot, `redboot_ram.bin`, rather than the dBUG version of RedBoot used above. The ROM version can then be loaded into memory using RedBoot's **load** and the flash version version can be updated using **fis create RedBoot**.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the dBUG version of RedBoot are:

```
$ mkdir redboot_dbug
$ cd redboot_dbug
$ ecosconfig new m5282lite redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/m68k/mcf52xx/mcf5282/m5282lite/current/misc/redboot_DBUG.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot_dbug.srec`.

Rebuilding the RAM and ROM versions involves basically the same process. The RAM version uses the file `redboot_RAM.ecm` and generates a file `redboot_ram.bin`. The ROM version uses the file `redboot_ROM.ecm` and generates a file `redboot_rom.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The M5282LITE platform HAL package is loaded automatically when eCos is configured for an M5282LITE target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The M5282LITE platform HAL package supports three separate startup types: RAM, DBUG and ROM. The configuration option `CYG_HAL_STARTUP`: controls which startup type is being used. For typical application development RAM startup should be used, and the application will be run via m68k-elf-gdb interacting with RedBoot using either serial or ethernet. It is assumed that the low-level hardware initialization, including setting up the memory map, has already been performed by RedBoot. By default the application will use certain services provided by RedBoot via the virtual vector mechanism, including diagnostic output, but that can be disabled via `CYGSEM_HAL_USE_ROM_MONITOR`.

ROM startup can be used for applications which boot directly from flash. All the hardware will be initialized, and the application is self-contained. This startup type is used by the flash-resident version of RedBoot, and can also be used for finished applications.

DBUG startup can be used for applications which will be loaded via the DBUG ROM monitor rather than RedBoot. As with RAM startup it is assumed that the memory map has already been set up, but the application will not use any services provided by the ROM monitor.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via BDM.

If the application does not rely on a ROM monitor for diagnostic services then one of the serial ports will be claimed for HAL diagnostics. By default eCos will use UART0 since on the standard board that is the only uart with a suitable connector. If the board has been extended with additional transceiver chips and connectors for UART1 or UART2 then one of those can be selected via the `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`. The baud rate for the selected port is controlled by `CYGNUM_HAL_M68K_M5282LITE_DIAG_BAUD`.

Optional Hardware

The M5282LITE board can be customized in a number of ways, primarily by connecting additional hardware to the MCU port. There are a number of configuration options which allow the platform HAL to adapt to minor changes to the hardware:

`CYGHWR_HAL_M68K_M5282LITE_UART0_RTS`

> On the default hardware UART0 RTS and CTS are not connected. If the uart will only be used for interacting with RedBoot and debugging, that should be fine. If the uart will be used for another purpose, for example PPP, then it will usually be desirable to support RTS/CTS hardware handshaking. The board has an option pad to allow the serial connector's RTS pin to be wired to the processor's DTOUT3 pin. Alternatively any of the DTIN3, DTOUT1 or DTIN1 signals on the MCU port could be wired instead. This configuration option can be used to specify how the board has been wired. Note that CTS would have to be wired as well as RTS.

CYGHWR_HAL_M68K_M5282LITE_UART0_CTS

As with RTS, CTS is not wired on the default board. Although there is an option pad this is not usable: the option pad would wire the serial connector's CTS pin to the processor's DTIN3 pin, but DTIN3 cannot be configured to carry the uart CTS signal. Instead one of the DTOUT2, DTIN2, DTOUT0, or DTIN0 signals on the MCU port should be used.

CYGHWR_HAL_M68K_M5282LITE_UART1_CONNECTED
CYGHWR_HAL_M68K_M5282LITE_UART1_RTS
CYGHWR_HAL_M68K_M5282LITE_UART1_RTS_RS485
CYGHWR_HAL_M68K_M5282LITE_UART1_CTS

The default board has no connector for the on-chip UART1. However all the signals are accessible on the MCU port so it is possible to wire up a suitable transceiver chip and connector. Enabling CYGHWR_HAL_M68K_M5282LITE_UART1_CONNECTED specifies that the RX and TX signals are connected. RTS is optional and can come from any of DTOUT3, DTIN3, DTOUT1 or DTIN1, although obviously the same signal cannot be used for both UART0 and UART1. RTS may be used either to tristate an RS485 transceiver in which case CTS should be left disconnected, or it can be used for RS232 hardware handshaking in which case CTS must also be connected. The CTS signal can come from any of DTOUT2, DTIN2, DTOUT0 or DTIN0.

CYGHWR_HAL_M68K_M5282LITE_UART2_CONNECTED

The on-chip UART2 is not connected on the standard board. However if this uart is needed then it can be accessed via the MCU port, using either the A1A0 SCL/SDA signals normally used for I²C, or the A3A2 CANTX/CANRX signals normally used for CAN communication. This UART does not support RTS or CTS.

Flash Driver

The platform HAL package contains flash driver support for the external flash device. By default this is inactive, and it can be made active by loading the generic flash package CYGPKG_IO_FLASH.

Special Registers

The MCF5282 processor has a number of special registers controlling the cache, on-chip RAM and flash, and so on. The platform HAL provides a number of configuration options for setting these, for example CYGNUM_HAL_M68K_M5282LITE_RAMBAR controls the initial value of the RAMBAR register.

System Clock

By default the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option CYGNUM_HAL_RTC_PERIOD, the number of microseconds between clock ticks. Other clock-related settings are recalculated automatically if the period is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are three flags specific to this port:

-m5200

The m68k-elf-gcc compiler supports many variants of the M68K architecture, from the original 68000 onwards. A -m option should be used to select the specific variant in use, and with current tools -m5200 is the closest match for an MCF5282 processor.

-malign-int

This option forces m68k-elf-gcc to align integer and floating point data to a 32-bit boundary rather than a 16-bit boundary. It should improve performance. However the resulting code is incompatible with most published application binary interface specifications for M68K processors, so it is possible that this option causes problems with existing third-party object code.

`-fomit-frame-pointer`
: Traditionally the `%A6` register was used as a dedicated frame pointer, and the compiler was expected to generate link and unlink instructions on procedure entry and exit. These days the compiler is perfectly capable of generating working code without a frame pointer, so omitting the frame pointer often saves some work during procedure entry and exit and makes another register available for optimization. However without a frame pointer register the m68k-elf-gdb debugger is not always able to interpret a thread stack, so it cannot reliably give a backtrace. Removing `-fomit-frame-pointer` from the default flags will make debugging easier, but the generated code may be worse.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the M5282LITE hardware, and should be read in conjunction with that specification. The M5282LITE platform HAL package complements the M68K architectural HAL, the MCFxxxx variant HAL, and the MCF5282 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services: the UARTs and the ethernet device will not be reinitialized because they may be in use by RedBoot for communication with the host. Full details of this initialization can be found in the function `hal_m68k_m5282lite_init` in `platform.c`.

For a ROM startup the HAL will perform additional initialization, setting up the external DRAM and chip selects. Full details can be found in the exported header `cyg/hal/plf.inc`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External SDRAM

This is mapped to location 0x00000000. Most of the first kilobyte is used for hardware exception vectors. The eCos virtual vectors are also placed here, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup all remaining SDRAM is available. For RAM and DBUG startup available SDRAM starts at location 0x00010000, with the bottom 64K reserved for use by either the RedBoot or dBUG ROM monitors.

Internal RAM

The 64K of internal RAM are normally mapped at location 0x20000000. Neither eCos nor RedBoot use the internal RAM so all of it is available to application code.

On-chip Peripherals

These are accessible at location 0x40000000 onwards, as per the defined symbol `HAL_MCF5282_ISPBAR`.

Note

On some other coldfire processors the equivalent register is known as `%mbar`. The symbol `HAL_MCFxxxx_MBAR` is an alias for `HAL_MCF5282_ISPBAR`, making it easier to share device drivers.

On-chip Flash

The 512K of internal flash are normally mapped at location 0xF0000000. Currently this is not used by eCos or RedBoot.

External Flash

This is located at the top of memory, location 0xFFE00000 onwards. In a typical setup the first two 64K flash blocks at location 0xFFE00000 are used to hold RedBoot, and the last flash block at location 0xFFFF0000 is used to hold flash management data and the RedBoot **fconfig** variables. The remaining blocks can be used by application code.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer PIT3, which should not be used directly by application code. The actual HAL macros for managing the clock are provided by the MCF5282 processor HAL. The specific numbers used are a characteristic of the platform because they depend on the processor speed. The gprof-based profiling code uses PIT2. Timers PIT0 and PIT1 are not used by eCos so application code is free to manipulate these as required.

Other Issues

The M5282LITE platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MCF5282 processor HAL, the MCFxxxx variant HAL, and the M68K architectural HAL documentation should be consulted for further details.

Other Functionality

The platform HAL package also provides a flash driver for the off-chip ST M29W160EB flash chip or compatible. This driver is inactive by default, and only becomes active if the configuration includes the generic flash support `CYGPKG_IO_FLASH`.

Chapter 325. SSV DNP/5280 Board Support

Name

eCos Support for the SSV DNP/5280 and DNP/5282 Modules — Overview

Description

The SSV DNP/5280 module has an MCF5280 ColdFire processor, 16MB of external SDRAM, 8MB of external flash memory, an ethernet phy chip, and in later revisions a DS1306 real-time clock. The module needs to be plugged into a suitable carrier board, typically an SSV DNP/EVA2_SV6 or a DNP/EVA6, but custom boards may be used. The carrier board provides power as well as connectors for the ethernet and some of the on-chip devices. The DNP/5282 module is similar but has a smaller footprint. The modules are supplied with some firmware already programmed into the external flash. This firmware can be either RedBoot, a ROM monitor based on eCos, or dBUG.

This package `CYGPKG_HAL_M68K_DNP5280` provides a port to both modules. Specifically it supports the following targets:

`dnp5280`
: A DNP/5280 module plugged into an EVA2_SV6 carrier board.

`dnp5280_v12`
: A V1.2 DNP/5280 plugged into an EVA2_SV6 carrier board. This adds support for the DS1306 clock device on this revision of the module.

`dnp5282`
: A DNP/5282 plugged into an EVA6 carrier board.

eCos configuration options can be used to change the settings. `CYGHWR_HAL_M68K_MCF528x_HARDWARE_DNP528x_BOARD` determines the carrier board. This in turn affects the default GPIO pin settings and hence which of the on-chip peripherals are accessible. These pin settings are also controlled by configuration options. Hence custom carrier boards can be supported by creating an initial configuration for one of the standard targets and then changing the pin settings to reflect the I/O capabilities of the actual carrier board.

Typical eCos development involves using RedBoot as the board's firmware, replacing dBUG if necessary. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

The eCos port can be configured for one of three startup types:

RAM
: This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. m68k-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output. The RAM startup type can also be used for finished applications: RedBoot can be made to load and run such applications automatically following bootstrap.

  With a minor change to the eCos configuration this startup type can also be used to debug applications via BDM. eCos will no longer assume the presence of RedBoot and hence will not make any virtual vector calls to obtain RedBoot services.

DBUG
: This is another variant of RAM startup, used only when initializing a board. It can be used to run a special RAM-resident version of RedBoot on top of the dBUG ROM monitor, allowing a ROM startup version of RedBoot to be programmed into flash.

ROM
: This should be used for applications which will boot directly from flash at location 0xFF800000, replacing any ROM monitor. The application will be self-contained. eCos startup code will perform all necessary hardware initialization. ROM startup is used for building the flash-resident version of RedBoot, but can also be used for finished applications.

Supported Hardware

The memory map used by both eCos and RedBoot is as follows:

Memory	Base	Length
External SDRAM	0x00000000	0x01000000
Internal RAM	0x20000000	0x00010000
On-chip Peripherals	0x40000000	0x40000000
External Flash	0xFF800000	0x00800000

DNP/5282 modules also have on-chip flash at 0xF0000000. For all startup types the external SDRAM is used to hold all data. For RAM and DBUG startup the code also resides in external SDRAM, with the first 64K reserved for use by the ROM monitor. In a typical setup RedBoot will occupy the first two external flash blocks, and it will also use the last flash block for storing **fconfig** run-time configuration settings and the **fis** directory.

Code and data can be placed in the internal RAM using the linker script section ".iram_text" for code, and ".iram_data" and ".iram_bss" for initialized and unitialized data respectively. The M68K architectural HAL contains a testcase `iram1.c` which demonstrates how to use these linker sections.

RedBoot can communicate with the host using either ethernet or one of the UARTs - usually uart0 because the DNP/EVA2_SV6 carrier board only provides a connector for that board.

All configurations for the DNP/5280 and DNP/5282 targets include an ethernet driver package `CYGPKG_DEVS_ETH_MCFxxxx`. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package `CYGPKG_IO_ETH_DRIVERS`. Typically the choice of eCos template causes the right thing to happen. For example the default template does not include any TCP/IP stack so `CYGPKG_IO_ETH_DRIVERS` is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver. The ethernet device can be shared by RedBoot and the application, so it is possible to debug a networked application over ethernet.

The DNP/5280 board does not have a serial EPROM or similar hardware providing a unique network MAC address. Instead a suitable address has to be programmed into flash via RedBoot's **fconfig** command.

The on-chip uarts are supported via the serial device driver package `CYGPKG_DEVS_SERIAL_MCFxxxx`. The driver as a whole is inactive unless the generic serial support, `CYGPKG_IO_SERIAL_DEVICES` is enabled. Only those uarts for which GPIO pins are configured appropriately are available. By default this is only uart0 when using an EVA2_SV6 carrier board, and both uart0 and uart1 when using an EVA6 carrier board. One of the uarts, typically uart0, may also be used for HAL diagnostics. If so it should not be accessed via the serial driver.

All configurations for the DNP/5280 target also include a watchdog device driver `CYGPKG_DEVS_WATCHDOG_MCF5282`. This driver is inactive unless the generic watchdog support `CYGPKG_IO_WATCHDOG` is loaded.

An I²C bus device driver is also included, but will not be built by default. If the DNP/5280 is plugged into a DNP/EVA2-SV6 carrier board the relevant pins are already in use, connected to the dip switch. Even if a different carrier board is being used the same pins may still be needed for GPIO or for uart2. If the I²C bus can be safely enabled on the target hardware then GPIO pin configuration options should be adjusted to connect the SCL and SDA signals. The MCF5282 processor HAL will then instantiate a cyg_i2c_bus structure `hal_mcfxxxx_i2c_bus`, allowing appropriate `CYG_I2C_DEVICE` structures to be defined.

Similarly an SPI bus device driver is included but will not be built by default. If the GPIO pins are adjusted to connect the QSPI DOUT, DIN and CLK signals then the MCF5282 processor HAL will instantiate an SPI bus device `hal_mcfxxxx_qspi_bus`, allowing appropriate `CYG_MCFxxxx_QSPI_DEVICE` structures to be defined.

Some releases may come with a driver `CYGPKG_DEVS_CAN_FLEXCAN` for the on-chip CAN device. This will be inactive unless the generic CAN support `CYGPKG_IO_CAN` is added to the configuration. In addition it will be necessary to adjust the GPIO pins to connect the CANTX and CANRX signals.

When configured for a `dnp5280_v12` target the configuration will include a wallclock driver `CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1306`. This will be used automatically by the C library's time-related functions, for example `time` and `asctime`, and can be changed by an eCos-specific function `cyg_libc_time_settime`.

All configurations will include a flash device driver `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2` for the external flash. In addition when configured for a `dnp5282` target the configuration will include a flash driver `CYGPKG_DEVS_FLASH_M68K_MCFxxxx_CFM`. Both drivers will be inactive unless the generic flash support `CYGPKG_IO_FLASH` is added to the configuration.

On an EVA2_SV6 carrier board the platform HAL provides utility routines for accessing the LEDs and dip switch. The on-chip interrupt controllers and the edge port module are managed by eCos using macros provided by the MCF5282 processor HAL. PIT timer 3 is normally used to implement the eCos system clock. If gprof-based profiling is enabled then that will use PIT timer 2. PIT timers 0 and 1 are unused and can be manipulated by the application. The remaining on-chip peripherals are not used by eCos.

Tools

The DNP/5280 port is intended to work with GNU tools configured for an m68k-elf target. The original port was done using m68k-elf-gcc version 3.2.1, m68k-elf-gdb version 5.3, and binutils version 2.13.1.

By default eCos is built using the compiler flag `-fomit-frame-pointer`. Omitting the frame pointer eliminates some work on every function call and makes another register available, so the code should be smaller and faster. However without a frame pointer m68k-elf-gdb is not always able to identify stack frames, so it may be unable to provide accurate backtrace information. Removing this compiler flag from the configuration option `CYGBLD_GLOBAL_CFLAGS` avoids such debug problems.

A typical setup involves m68k-elf-gdb interacting with RedBoot using either serial or ethernet. Alternatively it is possible to debug via the BDM port. The package's `misc` subdirectory contains a script `bdm.gdb` that contains macros for the low-level hardware initialization normally performed by the ROM startup code. The application should be linked with an eCos configuration using RAM startup, and with the options `CYGSEM_HAL_ROM_MONITOR` and `CYGSEM_HAL_USE_ROM_MONITOR` disabled to stop eCos accessing any services provided by RedBoot. Diagnostic output will be sent out of uart0.

Name

Setup — Preparing the DNP/5280 board for eCos Development

Overview

In a typical development environment the DNP/5280 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run on the board via the debugger m68k-elf-gdb. Boards may be shipped with one of two ROM monitors in the flash, either RedBoot or dBUG. If the latter, dBUG must be replaced so preparing the board involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from the board's flash	`redboot_ROM.ecm`	`redboot_rom.bin`
dBUG	Used for initial setup	`redboot_DBUG.ecm`	`redboot_dbug.srec`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot_ram.bin`

For serial communications all versions run with 8 bits, no parity, and 1 stop bit. The dBUG version runs at 115200 baud. The ROM and RAM versions usually run at 38400 baud, but this can be changed via a RedBoot **fconfig** option or by manipulating the configuration option `CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD` and then rebuilding RedBoot. By default RedBoot will use the board's terminal port, corresponding to uart0, but this can also be changed via the configuration option `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`. On the DNP/5280 and DNP/5282 platforms RedBoot also supports ethernet communication and flash management.

Initial Installation

This process assumes that the board currently has the dBUG ROM monitor in flash and does not require any special debug hardware. Programming the RedBoot rom monitor into flash memory requires an application that can manage flash blocks. RedBoot itself has this capability. Rather than have a separate application that is used only for flash management during the initial installation, a special RAM-resident version of RedBoot is loaded into memory and run. This version can then be used to load the normal flash-resident version of RedBoot and program it into the flash.

The first step is to connect an RS232 cable between the DNP/5280 terminal port and the host PC. A suitable cable is supplied with the board. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 115200 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Make sure that the RCM jumper is set to boot into dBUG rather than directly into uCLinux. Apply power to the board and you should see a `dBUG>` prompt.

Once dBUG is up and running the RAM-resident version of RedBoot can be downloaded:

```
dBUG> dl
Escape to local host and send S-records now...
```

The required S-records file is `redboot_dbug.srec`, which is normally supplied with the eCos release in the `loaders` directory. If it needs to be rebuilt then instructions for this are supplied below. The file should be sent to the target as raw text using the terminal emulator:

```
S-record download successful!
dBUG>
```

It is now possible to run the RAM-resident version of RedBoot:

```
dBUG> go 0x10000
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
... waiting for BOOTP information
Ethernet eth0: MAC address 00:00:00:00:00:03
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [DBUG]
Non-certified release, version UNKNOWN - built 21:15:10, Mar 16 2004

Platform: DNP/5280 (Freescale MCF5280)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x01000000, 0x0002f4c8-0x00fed000 available
FLASH: 0xff800000 - 0x00000000, 128 blocks of 0x00010000 bytes each.
RedBoot>
```

At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. There will also be a delay while RedBoot tries to contact a local BOOTP server. To perform the flash initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0xffff0000-0xffffffff: .
... Program from 0x00ff0000-0x00100000 at 0xffff0000: .
RedBoot>
```

At this stage the block of flash at location 0xFFFF0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Console baud rate: 115200
DNS server IP address:
GDB connection port: 9000
Force console for special debug messages: false
Network hardware address [MAC]: 0x00:0x00:0x00:0x00:0x00:0x03
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0xffff0000-0xffffffff: .
... Program from 0x00ff0000-0x01000000 at 0xffff0000: .
RedBoot>
```

For most of these configuration variables the default value is correct. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server. The other exception is the network hardware address, also known as MAC address. All boards should be given a unique MAC address, not the one in the above example. If there are two boards on the same network trying to use the same MAC address then the resulting behaviour is undefined.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The file `redboot_rom.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
Raw file loaded 0x0002f800-0x0004613f, assumed entry at 0x0002f800
xyzModem - CRC mode, 726(SOH)/1(STX)/0(CAN) packets, 6 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0xff800000-0xff820000: .
... Program from 0x0002f800-0x0004f800 at 0xff800000: .
... Erase from 0xffff0000-0xffffffff: .
... Program from 0x00ff0000-0x01000000 at 0xffff0000: .
RedBoot>
```

The flash-resident version of RedBoot has now programmed at location 0xFF800000, and the flash info block at 0xFFFF0000 has been updated. The initial setup is now complete. Reset the board:

```
+Ethernet eth0: MAC address 00:00:00:00:00:03
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 20:52:02, Mar 16 2004

Platform: DNP/5280 (Freescale MCF5280)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x01000000, [0x0000d3c8-0x00fed000 available
FLASH: 0xff800000 - 0x00000000, 128 blocks of 0x00010000 bytes each.
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from m68k-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done by loading a RAM-resident version of RedBoot, `redboot_ram.bin`, rather than the DBUG version of RedBoot used above. The ROM version can then be loaded into memory using RedBoot's **load** command, and the flash version can be updated using **fis create RedBoot**.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the dBUG version of RedBoot are:

```
$ mkdir redboot_dbug
$ cd redboot_dbug
$ ecosconfig new dnp5280 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/m68k/mcf52xx/mcf5282/dnp5280/current/misc/redboot_DBUG.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot_dbug.srec`.

Rebuilding the RAM and ROM versions involves basically the same process. The RAM version uses the file `redboot_RAM.ecm` and generates a file `redboot_ram.bin`. The ROM version uses the file `redboot_ROM.ecm` and generates a file `redboot_rom.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The DNP/5280 platform HAL package is loaded automatically when eCos is configured for a dnp5280, dnp5280_v12 or dnp5282 target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The DNP/5280 platform HAL package supports three separate startup types: RAM, DBUG, and ROM. The configuration option `CYG_HAL_STARTUP` controls which startup type is being used. For typical application development RAM startup should be used, and the application will be run via m68k-elf-gdb interacting with RedBoot using either serial or ethernet. It is assumed that the low-level hardware initialization, including setting up the memory map, has already been performed by RedBoot. By default the application will use certain services provided by RedBoot via the virtual vector mechanism, including diagnostic output, but that can be disabled via `CYGSEM_HAL_USE_ROM_MONITOR`.

ROM startup can be used for applications which boot directly from flash. All the hardware will be initialized, and the application is self-contained. This startup type is used by the flash-resident version of RedBoot, and can also be used for finished applications.

DBUG startup can be used for applications which will be loaded via the DBUG ROM monitor rather than RedBoot. As with RAM startup it is assumed that the memory map has already been set up, but the application will not use any services provided by the ROM monitor.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via BDM.

If the application does not rely on a ROM monitor for diagnostic services then one of the serial ports will be claimed for HAL diagnostics. By default eCos will use uart0. If the actual hardware has connectors for uart1 or uart2, one of these can be selected instead via the configuration option `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`. The baud rate for the selected port is controlled by `CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD`.

Optional Hardware

The platform HAL assumes that a DNP/5280 module is plugged into a standard DNP/EVA2_SV6 carrier board, and that a DNP/5282 module is plugged into a DNP/EVA6. This can be changed via the configuration option `CYGHWR_HAL_M68K_MCF528x_HARDWARE_DNP528x_BOARD`. The choice of carrier board determines the default settings of the various GPIO pins, in other words which pins are connected to on-chip peripherals. For example an EVA2_SV6 board only has a single uart transceiver and connector so only uart0's signals are connected to the appropriate pins. An EVA6 has two transceivers and connectors so both uart0 and uart1 are connected. When using a non-standard carrier board it is possible to define the pin connectivity via configuration options in the CDL component `CYGHWR_HAL_M68K_MCF528x_GPIO`. The configuration should adjust accordingly, enabling or disabling devices as appropriate. Mostly this happens in the MCF5282 processor HAL and the MCFxxxx variant HAL.

Special Registers

The MCF5282 processor has a number of special registers controlling the cache, on-chip RAM, and so on. The platform HAL provides a number of configuration options for setting these, for example `CYGNUM_HAL_M68K_DNP5280_RAMBAR` controls the initial value of the RAMBAR register.

System Clock

By default the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_PERIOD`, the number of microseconds between clock ticks. Other clock-related settings are recalculated automatically if the period is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are three flags specific to this port:

`-m5200`

The m68k-elf-gcc compiler supports many variants of the M68K architecture, from the original 68000 onwards. A `-m` option should be used to select the specific variant in use, and with current tools `-m5200` is the closest match for an MCF5282 processor.

`-malign-int`

This option forces m68k-elf-gcc to align integer and floating point data to a 32-bit boundary rather than a 16-bit boundary. It should improve performance. However the resulting code is incompatible with most published application binary interface specifications for M68K processors, so it is possible that this option causes problems with existing third-party object code.

`-fomit-frame-pointer`

Traditionally the `%A6` register was used as a dedicated frame pointer, and the compiler was expected to generate link and unlink instructions on procedure entry and exit. These days the compiler is perfectly capable of generating working code without a frame pointer, so omitting the frame pointer often saves some work during procedure entry and exit and makes another register available for optimization. However without a frame pointer register the m68k-elf-gdb debugger is not always able to interpret a thread stack, so it cannot reliably give a backtrace. Removing `-fomit-frame-pointer` from the default flags will make debugging easier, but the generated code may be worse.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the DNP/5280 hardware, and should be read in conjunction with that specification. The DNP/5280 platform HAL package complements the M68K architectural HAL, the MCFxxxx variant HAL, and the MCF5282 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize those devices for which there are active device drivers. There is an exception for RAM startup applications which depend on a ROM monitor for certain services: the UARTs and the ethernet device will not be reinitialized because they may be in use by RedBoot for communication with the host. Full details of this initialization can be found in the function `hal_m68k_dnp5280_init` in `platform.c`.

For a ROM startup the HAL will perform additional initialization, setting up the external DRAM and chip selects. Full details can be found in the exported header `cyg/hal/plf.inc`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External SDRAM

This is mapped to location 0x00000000. Most of the first kilobyte is used for hardware exception vectors. The eCos virtual vectors are also placed here, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup all remaining SDRAM is available. For RAM and DBUG startup available SDRAM starts at location 0x00010000, with the bottom 64K reserved for use by either the RedBoot or dBUG ROM monitors.

Internal RAM

The 64K of internal RAM are normally mapped at location 0x20000000. Neither eCos nor RedBoot use the internal RAM so all of it is available to application code.

On-chip Peripherals

These are accessible at location 0x40000000 onwards, as per the defined symbol `HAL_MCF5282_ISPBAR`.

Note

On some other ColdFire processors the equivalent register is known as `%mbar`. The symbol `HAL_MCFxxxx_MBAR` is an alias for `HAL_MCF5282_ISPBAR`, making it easier to share device drivers.

On-chip Flash

When configured for a DNP/5282 the on-chip flash will be located at 0xF0000000. This flash is not used by either eCos or RedBoot so it is all available for use by application code.

External Flash

This is located at the top of memory, location 0xFF800000 onwards. In a typical setup the first two 64K flash blocks at location 0xFF800000 are used to hold RedBoot, and the block at location 0xFFFF0000 is used to hold flash management data and the RedBoot **fconfig** variables. The remaining blocks can be used by application code.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer PIT3, which should not be used directly by application code. The actual HAL macros for managing the clock are provided by the MCF5282 processor HAL. The specific numbers used are a characteristic of the platform because they depend on the processor speed. The gprof-based profiling code uses PIT2. Timers PIT0 and PIT1 are not used by eCos so application code is free to manipulate these as required.

Other Issues

The DNP/5280 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MCF5282 processor HAL, the MCFxxxx variant HAL, and the M68K architectural HAL documentation should be consulted for further details.

Other Functionality

The platform HAL package provides a flash driver for the off-chip AMD AM29LV640 flash chip. This driver is inactive by default, and only becomes active if the configuration includes the generic flash support `CYGPKG_IO_FLASH`.

The platform HAL provides some additional functions for manipulating the LEDs and dipswitch on the DNP/EVA2_SV6 carrier board:

`void hal_dnp5280_led_set(which, what)`

> This can be used to switch one of the LEDs on or off. The `which` argument specifies the LED and should be a number between 0 and 7. The `what` argument should be non-zero to switch the LED on, zero to switch it off. This function must not be called if the processor's QA and QB pins are not actually connected to the LEDs.

`int hal_dnp5280_dipswitch_read(which)`

> This allows application code to query the state of one of the dip switches. The `which` argument should be a number between 1 and 8.

`int hal_dnp5280_dipswitch_read_all(void)`

> This allows application code to query the state of all the dip switches in one go. The result is an 8-bit number with bit 0 corresponding to dipswitch 1.

Chapter 326. Motorola MCF521x Processor Support

Name

CYGPKG_HAL_M68K_MCF521x — eCos Support for Freescale MCF521x Processors

Description

The Freescale MCF521x group of processors is part of the larger family of Coldfire processors. The MCF521x group has several members including the MCF5211, MCF5212 and MCF5213. They differ from other Coldfire processors in that there is no external memory bus, instead all memory is on-chip. For example the MCF5213 has 256KB on-chip flash and 32K of on-chip SRAM. All MCF521x processors have basically the same set of peripherals (CAN is not available on the MCF5211 or MCF5212) but differ in the amount of on-chip memory.

The processor HAL package CYGPKG_HAL_M68K_MCF521x provides support for all MCF521x processors, although at the time of writing it has only been tested on an MCF5213. It complements the M68K architectural HAL package CYGPKG_HAL_M68K and the variant HAL package CYGPKG_HAL_M68K_MCFxxxx. An eCos configuration should also include a platform HAL package, for example CYGPKG_HAL_M68K_M5213EVB to support board-level details like how the on-chip peripherals are connected to the outside world. It should be noted that compared with other eCos Coldfire ports rather more work is done by the MCF521x processor HAL and rather less by the platform HAL. This is possible because of the lack of an external memory bus.

Configuration

The MCF521x processor HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The configuration option CYGHWR_HAL_M68K_MCF521x_PROCESSOR defines the exact processor type, for example MCF5213. Usually it will be set by the platform HAL and should not be manipulated by the user.

The option CYG_HAL_STARTUP determines whether the application will reside in RAM or in ROM (flash). With just 32K of RAM on the MCF5213 only fairly simple applications will fit into RAM so the default is ROM startup. This can make debugging significantly more difficult because it requires the use of hardware breakpoints, and the processor only supports a small number of these. Debugging RAM startup applications can be rather easier because the debugger can insert breakpoints by modifying the code. Hence it may sometimes be convenient to debug a cut-down version of an application linked against a RAM startup eCos configuration. Alternatively with ROM startup individual functions can be placed in a “.2ram” section which means they will be copied from flash to RAM during initialization and execute from RAM. Again this may make debugging rather easier, assuming sufficient RAM is available.

For ROM startup the table of M68K exception vectors can reside either in ROM or in RAM. This table occupies 512 bytes (a full M68K exception vector table is 1K but on an MCF521x running eCos only half of this is needed). Keeping it in ROM saves a significant portion of the scarce RAM, but means that some eCos functionality (such as the HAL_VSR_SET macros) is not available. Few applications require that functionality so by default the vectors are kept in ROM.

The processor HAL gives application developers full control over how the GPIO pins should be initialized, using configuration options such as CYGHWR_HAL_M68K_MCF521x_GPIO_PORTQS_QS0. That pin is normally used for QSPI but can also be used for CAN, UART0, or as a general-purpose input or output. For a GPIO output it is also possible to specify whether the pins should be initialized high or low. The default settings for each pin are determined by the platform HAL. However there may be various jumpers or an expansion connector on the board, in which case the platform HAL may not know exactly how the various pins should be set up. Hence the processor HAL allows application developers to override the default settings for every pin. There are also configuration options for controlling the pin slew rates and drive strengths.

The GPIO pin settings are used to determine default values for a variety of other hardware-related configuration options. For example CYGHWR_HAL_M68K_MCFxxxx_UART0 will be enabled if either the TX or RX lines are connected, and that option is used elsewhere in the system when deciding which UARTs are potentially usable for HAL diagnostics or should have serial device driver support. The user may be able to override some of these settings, to handle scenarios where a pin should come up as a GPIO output but may later get switched to e.g. a UART tx line. The platform HAL may impose some restrictions.

If the SPI bus should be enabled then there is a configuration option `CYGNUM_HAL_M68K_MCF521x_QSPI_ISRPRI` to control the interrupt priority of the QSPI bus device. MCF521x processors use the same interrupt controller as the MCF5282, and this has a limitation that all interrupt priorities should be unique. The processor HAL provides non-conflicting defaults for the various on-chip devices but when changing interrupt priorities it is the application developer's responsibility to maintain unique priorities.

If the I^{2}C bus should be enabled then again there is a configuration option `CYGNUM_HAL_M68K_MCF521x_I2C_ISRPRI` to control the interrupt priority of the I^{2}C device. There is also a configuration option `CYGNUM_HAL_M68K_MCF521x_I2C_FDR` to set the `FDR` register which controls the I^{2}C bus speed. The default speed is the I^{2}C standard 100KHz, or as close to that as the hardware allows, but if all attached I^{2}C devices can operate at a faster speed then this option may be adjusted accordingly.

The processor HAL provides a configuration option `CYGNUM_HAL_RTC_PERIOD` to control the system clock speed. The default setting is 10 milliseconds between clock interrupts or as close to that as the hardware allows, giving a 100Hz system clock.

In kernel configurations the behaviour of the idle thread can be controlled using `CYGIMP_HAL_M68K_MCF521x_IDLE`. The default behaviour is `wait` where the cpu, flash and SRAM enter a low power mode but all peripherals continue operating normally. Any interrupt will bring the processor out of low power mode.

The processor HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are three flags specific to the MCF521x port:

`-m528x`
: The m68k-elf-gcc compiler supports many variants of the M68K architecture, from the original 68000 onwards. A `-m` option should be used to select the specific variant in use, and as far as the compiler is concerned the MCF521x has the same cpu core as the MCF5282.

`-malign-int`
: This option forces m68k-elf-gcc to align integer and floating point data to a 32-bit boundary rather than a 16-bit boundary. It should improve performance. However the resulting code is incompatible with most published application binary interface specifications for M68K processors, so it is possible that this option causes problems with existing third-party object code.

`-fomit-frame-pointer`
: Traditionally the `%A6` register was used as a dedicated frame pointer, and the compiler was expected to generate link and unlink instructions on procedure entry and exit. These days the compiler is perfectly capable of generating working code without a frame pointer, so omitting the frame pointer often saves some work during procedure entry and exit and makes another register available for optimization. However without a frame pointer register the m68k-elf-gdb debugger is not always able to interpret a thread stack, so it cannot reliably give a backtrace. Removing `-fomit-frame-pointer` from the default flags will make debugging easier, but the generated code may be worse.

The HAL Port

This section describes how the MCF521x processor HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

Memory Map and Linker Script

On most platforms the memory map is determined by the platform HAL. However, on an MCF521x processor, all memory is on-chip and the memory map can be determined by the processor HAL, so less work has to be done to port to different MCF521x platforms. For ROM startup, the memory map is as follows:

0x00000000
: The base of on-chip flash, and the table of exception vectors. Usually the first 512 bytes are used for exception vectors, but if `CYGIMP_HAL_STARTUP_VECTORS_IN_RAM` is enabled then only 8 bytes of flash are needed and the exception vectors are relocated to RAM at 0x20000000.

The M68K architecture reserves 1K for the table of exception vectors but on an MCF521x only half of this is needed. Memory between the end of the flash exception vectors and 0x00000400 is used for certain eCos functions such as startup and the interrupt VSR.

0x00000400

The MCF521x on-chip flash requires a 24-byte hal_mcfxxxx_cfm_security_settings data structure at this location. This structure controls the initial locked status of flash blocks and related security settings. eCos provides default settings which leave everything disabled, but the relevant structure `hal_68k_mcf5213_security_settings` is declared weak so applications can override this if desired.

0x00000418 onwards

Code and constant data are placed in on-chip flash immediately after the CFM security settings. If the application does not fill the whole of flash then any remaining flash blocks may be used for storing persistent data using the standard eCos flash API functions such as `cyg_flash_program`.

0x20000000-0x200001FF

This is the base address for the on-chip SRAM. If the run-time exception vectors are placed in RAM via the configuration option `CYGIMP_HAL_STARTUP_VECTORS_IN_RAM` then the first 512 bytes are used for the table of exception vectors. Otherwise this SRAM is available for application data.

0x20000000 onwards or
0x20000200 onwards

On-chip SRAM is used for holding application data, both initialized data held in the `.data` region and uninitialized data in the `.bss` region. Any SRAM left over at the end can be used for a standard C heap accessed via `malloc` and `free`.

The on-chip SRAM can also be used to hold code placed in `.2ram` section. This mechanism is used by the CFM flash driver for certain low-level functions which cannot normally execute from flash. It can also be used for application functions. For code held in flash the debugger must use hardware breakpoints and the processor supports only a limited number of these. For code held in RAM the debugger can use software breakpoints, modifying the instructions at run-time, so there is no limit on the number of breakpoints. Hence placing certain functions in `.2ram` sections and hence in RAM may facilitate debugging. Obviously on-chip RAM is a scarce resource so this technique will not always be applicable.

0x40000000 onwards

The on-chip peripherals are mapped into memory starting at this addres.

For RAM startup the on-chip flash is ignored (although the CFM security settings will still affect the flash device driver). Instead all code and data gets placed into RAM and must somehow fit into the limited amount of available on-chip RAM. This can be useful for specialized applications and for debugging certain problems.

Since all MCF521x memory is on-chip the processor does not have a cache and the default empty cache macros provided by the architectural HAL will be used.

The processor HAL provides the `.ldi` file which, in conjunction with the architectural `m68k.ld` file, is used to generate the linker script.

HAL I/O

The header file `cyg/hal/proc_io.h` provides definitions of MCF521x-specific on-chip peripherals. Many of the on-chip peripherals are compatible with those on the MCF5282, and for those peripherals it is the `var_io.h` header provided by the MCFxxxx variant HAL which provides the appropriate definitions. Both headers are automatically included by the architectural header `cyg/hal/hal_io.h`, so typically application code and other packages will just include the latter.

Interrupt Handling

MCF521x processors implement standard Coldfire interrupt and exception handling, and comes with a single MCF5282-compatible interrupt controller and edge port module. Therefore all interrupt and exception handling is left to the architectural and MCFxxxx variant HAL. The processor's cyg/hal/proc_intr.h serves mainly to define symbols such as CYGNUM_HAL_ISR_UART0, mapping the MCF521x on-chip interrupt sources to the interrupt vectors.

In the default configuration, an MCF521x boots from flash and the exception vectors are held in flash. Hence the HAL_VSR_SET macro and associated functionality are not available. This behaviour can be changed via the configuration option CYGIMP_HAL_STARTUP_VECTORS_IN_RAM.

Clock Support

MCF521x processors come with two MCF5282-compatible programmable interrupt timers. PIT1 is used for the system clock using functionality provided by the variant HAL. PIT0 is available for use by the application. Timer-based profiling is not available since there is not enough RAM available for the arrays needed to hold profiling information.

The MCF521x processor HAL depends on the platform HAL to provide a configuration option CYGHWR_HAL_SYSTEM_CLOCK_HZ, corresponding to the default processor clock speed. The input clock can be provided in various ways and it is only the platform HAL which knows how the clock has been implemented on a given board.

Other Issues

The MCF521x processor HAL does not affect the implementation of data types, stack size definitions, SMP support, system startup, or debug support. The MCFxxxx variant HAL versions of HAL_LSBIT_INDEX and HAL_MSBIT_INDEX are used since the processor supports the ff1.l and bitrev.l instructions.

Other Functionality

The MCF521x processor HAL can instantiate a single flash device structure using the functionality provided by the CYGPKG_DEVS_FLASH_M68K_MCFxxxx_CFM device driver. This will only happen if the generic flash support CYGPKG_IO_FLASH is part of the configuration. Not all applications require flash driver support so to avoid unnecessary code and data overheads the generic flash support is not included in the standard eCos templates. Instead it will have to be added explicitly to the configuration.

The processor HAL will instantiate a cyg_i2c_bus structure hal_mcf521x_i2c_bus when the configuration option CYGHWR_HAL_M68K_MCF521x_I2C is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the CYGPKG_DEVS_I2C_MCFxxxx device driver. The processor HAL does not know what I²C devices may be attached to the bus so that is left to the platform HAL.

The processor HAL will instantiate a cyg_spi_bus structure hal_mcf521x_qspi_bus when the configuration option CYGHWR_HAL_M68K_MCF521x_SPI is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the CYGPKG_DEVS_SPI_MCFxxxx_QSPI device driver. The processor HAL does not know what SPI devices may be attached to the bus so that is left to the platform HAL. All SPI device structures should be placed in the table mcf521x_qspi.

Chapter 327. Motorola M5213EVB Board Support

Name

CYGPKG_HAL_M68K_M5213EVB — eCos Platform HAL

Description

The Motorola M5212EVB board has an MCF5213 ColdFire processor, support chips for the on-chip peripherals such as the UARTs and CAN bus, power and clock circuitry, a Zigbee chip attached to the MCF5213's SPI serial bus, some LEDs and switches, and an expansion connector for application-specific devices. The MCF5213 does not have an external memory bus, instead applications have to fit into the 256KB of on-chip flash and 32KB of on-chip SRAM.

The platform HAL package CYGPKG_HAL_M68K_M5213EVB provides the platform-specific support needed to configure and build eCos. It complements the M68K architectural HAL, the MCFxxxx variant HAL, and the MCF521x processor HAL. On the M5213EVB the role of the platform HAL is small compared with many other eCos platforms. The absence of an external memory bus means that the differences between one MCF5213 platform and the next will be comparatively small, and much of the work that would normally be done by the platform HAL can instead be done by the processor HAL. The main responsibilities of the platform HAL are to control the hardware clock and to define the default GPIO pin settings.

For typical application development eCos will be configured for a ROM startup. An application linked against eCos will be programmed into the base of flash, location 0x0, using a BDM debug solution. The application will run as soon as the board is reset, or it can be debugged over a BDM device such as the Ronetix PEEDI using the **m68k-elf-gdb** debugger. Alternatively it is possible to configure eCos for a RAM startup, load the application into RAM via m68k-elf-gdb and BDM, and execute it from RAM. However with only 32KB of RAM to work with this will only be possible for comparatively simple applications. Even for ROM startup application complexity will be limited by the 32KB of SRAM for data and the 256KB of flash for code.

All configurations for the M5213EVB include serial, watchdog, flash, I²C and SPI device drivers. However these are not always active:

1. The serial device CYGPKG_DEVS_SERIAL_MCFxxxx is inactive unless the generic serial support CYGPKG_IO_SERIAL is loaded and the configuration option CYGPKG_IO_SERIAL_DEVICES is enabled. Exactly which of the on-chip UARTs are supported depends on options in the processor HAL such as CYGHWR_HAL_M68K_MCFxxxx_UART0, which in turn depend on the GPIO pin settings. With the default settings all three UARTs can be accessed via the serial device driver, using standard I/O facilities and names such as /dev/ser0. However by default UART0 will also be used as the HAL diagnostics channel and if so it should not be accessed via the serial driver. The MCFxxxx variant HAL and the serial device driver provide relevant configuration options.

2. The watchdog device driver CYGPKG_DEVS_WATCHDOG_MCFxxxx is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG is loaded into the configuration. The latter provides functions such as watchdog_reset for manipulating the watchdog.

3. The flash device driver CYGPKG_DEVS_FLASH_M68K_MCFxxxx_CFM is inactive unless the generic flash support CYGPKG_IO_FLASH is loaded into the configuration. The latter provides functions such as cyg_flash_program for manipulating the on-chip flash.

4. The I²C bus driver CYGPKG_DEVS_I2C_MCFxxxx is automatically available to the application and can be accessed through functions such as cyg_i2c_tx provided by the generic I²C package CYGPKG_IO_I2C. The M5213EVB board does not have any I²C devices on board but the I²C SDA and SCL signals can be accessed via the expansion connector so devices can be attached that way. It would then be up to the application to instantiate appropriate cyg_i2c_device structures. If the application does not use any I²C functionality then it will all be eliminated at link-time and the application will not suffer any unnecessary overheads. The I²C and FlexCAN support are mutually exclusive.

5. The SPI bus driver CYGPKG_DEVS_SPI_MCFxxxx_QSPI is automatically available to the application and can be accessed through functions such as cyg_spi_transfer provided by the generic SPI package CYGPKG_IO_SPI. The M5213EVB has a single on-board SPI device, the Zigbee chip, and the platform HAL provides a cyg_spi_device structure cyg_spi_zigbee_mc13191. The SPI signals are available on the expansion connector so additional devices can be attached that way. It

would then be up to the application to instantiate appropriate cyg_spi_device structures. If the application does not use any SPI functionality then it will all be eliminated at link-time and the application will not suffer any unnecessary overheads

6. The FlexCAN device driver `CYGPKG_DEVS_CAN_FLEXCAN` is inactive unless the generic CAN support `CYGPKG_IO_CAN` is loaded into the configuration. It is also necessary to set the appropriate jumpers, specifically the CAN_EN jumpers must be closed and the COM_SEL jumpers must be set to CAN. The corresponding configuration option `CYGHWR_HAL_M68K_M5213EVB_CAN_EN` should then enabled. The driver provides a single channel, by default “can0”. The FlexCAN and I^{2}C support are mutually exclusive.

The on-chip interrupt controller and the edge port module are managed by eCos using macros provided by the MCFxxxx variant HAL. PIT timer 1 is normally used to implement the eCos system clock. PIT timer 0 is unused and can be manipulated by the application. The remaining peripherals (DMA, GPT, DTIM, ADC, PWM, FLEXCAN) are not used by eCos.

Some standard eCos functionality is not available on the M5213EVB board. On most platforms in a development environment the RedBoot ROM monitor is programmed into flash, allowing applications to be loaded into RAM and debugged over a serial line or ethernet. This is not possible on an M5213EVB. Even if RedBoot's data requirements could be squeezed into the 32KB of available SRAM there would not be enough left for applications. Instead on an M5213EVB debugging involves a hardware debug solution such as BDM and the application is programmed directly into flash. Other eCos functionality such as the Robust Boot Loader (RBL) package or the common HAL's virtual vector mechanism are only relevant in systems containing RedBoot, so will not work on an M5213EVB. The 32KB RAM limitation also means that some of the more advanced eCos functionality such as TCP/IP networking, the JFFS2 flash file system, and gprof-based profiling, will not fit into an M5213EVB.

Setup and eCos Configuration

Both eCos and applications should be built using the GNU tools m68k-elf-gcc, m68k-elf-g++, and so on. The original port of eCos to the M5213EVB was done using m68k-elf-gcc version 3.4.4 (eCosCentric). The recommended BDM debug solution is the Ronetix PEEDI. This requires a configuration file peedi.cfg which can be found in the platform HAL's misc directory. The configuration file will initialize the hardware in the same way as the ROM startup code. It will need minor edits, for example to specify the correct license keys and to select the CORE_FLASH for the M5213EVB. For full details see the Ronetix documentation.

Note

Application development using eCosPro releases prior to version 3.1 operated via the processor's BDM port, the on-chip debug module and a proprietary stub program **m68k-elf-cfpe-stub**. This is no longer supported.

Once the PEEDI is set up applications can be linked against an eCos configuration built with either RAM or ROM startup mode. Applications can then be debugged via **m68k-elf-gdb** either used directly at the command line or via an integrated development environment such as Eclipse.

The M5213EVB board comes with a large number of jumpers. This means that the platform HAL does not automatically know which on-chip peripherals should be connected to the appropriate pins and which pins should be left for general purpose I/O. For example usually processor pin 7 will be used for the UART0 RX line but by removing a jumper it can be disconnected from the RS232 transceiver. Instead some other device can be hooked up to this pin via the expansion connector and the pin should be set up as a GPIO output to drive that device. Jumpers also control which input clock should be used, and that affects how eCos should initialize the clock hardware.

The default eCos configuration will assume the default jumper settings as follows:

CLKSEL 1 and 2 in, 3 to 6 out

Use the external 8MHz reference crystal oscillator Y1 in PLL mode. This will be multiplied internally to give an 80MHz system clock.

UART0_EN all in
UART1_EN all in
UART2_EN all in

All on-chip UARTs have all of TX, RX, RTS and CTS connected to the RS232 transceivers.

COM_SEL all set tot UART

The DB9 socket for UART2_CAN carries the UART2 signals.

LED_EN in	The processor can drive the LEDs.
BDM_EN in	The debug port is used for BDM and not JTAG.

The platform HAL does not concern itself with other jumpers such as those controlling the I^{2}C pull-ups, although obviously these will have to be set appropriately if the corresponding on-chip peripherals are to function correctly.

If any of these jumper settings are changed then configuration options within the platform HAL will need to be changed accordingly. If some other clock input is enabled or if the system clock should run at some speed other than 80MHz then `CYGHWR_HAL_M68K_M5213EVB_SYNCR` and `CYGHWR_HAL_SYSTEM_CLOCK_HZ` should be edited. The first of these determines what gets programmed into the SYNCR register and the processor reference manual should be consulted for more information. The second informs eCos what the actual system clock speed will be. This depends on the hardware as well as the SYNCR setting so cannot be calculated.

If the LED_EN jumper is disconnected then the configuration option `CYGHWR_HAL_M68K_M5213EVB_LED_EN` should be disabled. Similary if any of the jumper blocks UART0_EN, UART1_EN or UART2_EN are disconnected then the corresponding configuration options `CYGHWR_HAL_M68K_M5213EVB_UART0_EN` etc. should be disabled. This assumes all of the jumpers in a jumper block are either in or out. If instead say UART1 still has its TX line connected but not RX, RTS or CTS then the processor HAL provides finer-grained configuration options such as `CYGHWR_HAL_M68K_MCF521x_GPIO_PORTUB_UB1` which allow the application developer to specify exactly which pins should be used for what purpose.

The coarse-grained platform HAL options such as `CYGHWR_HAL_M68K_M5213EVB_LED_EN` are used to determine the default values of various processor HAL options such as `CYGHWR_HAL_M68K_MCF521x_GPIO_PORTTC`. Application developers can always edit the latter options rather than the platform HAL ones to gain full control over each pin. The processor HAL will initialize all the pins as per its GPIO options, and the information is also used by the configuration system to determine whether, for example, the serial device driver should allow access to UART2.

Assuming default jumper settings there is no need to change any of the configuration options. eCos can be built and applications linked as normal. Because only very simple applications will fit into the 32KB of on-chip SRAM the default startup mode is ROM, requiring that the application be programmed into flash at location 0. Any suitable flash programming utility can be used for this as well as the Ronetix PEEDI. Assumed that all the GNU tools are already installed, the examples below assume that a PEEDI JTAG/BDM debugger is attached to the M5213EVB and listening for connections on TCP/IP port 9000.

Programming ROM images with a Ronetix PEEDI

This section describes how to program ROM images using a Ronetix PEEDI debugger.

The PEEDI must be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. It must then be used to download and program the ROM image into the internal flash. The following steps give a typical outline for doing this. Consult the PEEDI documentation for alternative approaches, such as using FTP or HTTP instead of TFTP.

Preparing the Ronetix PEEDI JTAG/BDM debugger

1. Prepare a PC to act as a host and start a TFTP server on it.
2. Connect the PEEDI JTAG/BDM debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the PEEDI (straight through, not null modem).
3. Verify the PEEDI is using up-to-date firmware, of version 11.10.1 or later. If the firmware is not recent enough, follow the PEEDI User Manual's instructions which describe how to update the PEEDI firmware.
4. Locate the PEEDI configuration file `peedi.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/m68k/mcf52xx/mcf521x/m5213evb/`*`VERSION`*`/misc` relative to the root of your eCos installation.
5. Place the PEEDI configuration file in a location on the PC accessible to the TFTP server. Later you will configure the PEEDI to load this file via TFTP as its configuration file.

6. Open `peedi.cfg` in an editor such as emacs or notepad and insert your own license information in the `[LICENSE]` section.

7. Install and configure the PEEDI in line with the PEEDI Quick Start Guide or User's Manual, especially configuring PEEDI's RedBoot with the network information. Configure it to use the `peedi.cfg` target configuration file on the TFTP server at the appropriate point of the **config** process, for example with a path such as: `tftp://192.168.7.9/peedi.cfg`

8. Reset the PEEDI.

9. Connect to the PEEDI's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see output similar to the following:

```
$ telnet peedi-0
Trying 172.16.19.140...
Connected to peedi-0.
Escape character is '^]'.

PEEDI - Powerful Embedded Ethernet Debug Interface

m5213evb>
```

Preparing the M5213EVB for programming with PEEDI

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the BDM device.

If programming a GDB stub ROM or an application which uses serial output, you should first:

1. Connect an adaptor from the serial pins on the board to an RS232 DB9 serial connector or cable, then connect from there to a serial port on the host computer with a null modem DB9 RS232 serial cable.

2. Start a suitable terminal emulator on the host computer such as **minicom** on Linux or PuTTY on Windows. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

For all applications, you must:

1. Connect the board to the PEEDI using an appropriate cable from the BDM interface connector to the Target port on the PEEDI.

2. Power up the M5213EVB.

3. Connect to the PEEDI's telnet CLI on port 23 as before.

4. Confirm correct connection with the PEEDI with the **reset reset** command as follows:

```
m5213evb> reset reset
++ info: RESET and BKPT asserted
++ info: RESET released
++ info: BKPT released
++ info: core 0: initialized

m5213evb>
```

Installation into Flash using the Ronetix PEEDI

The following describes the procedure for installing a ROM application into on-chip Flash using the Ronetix PEEDI, using the tm_basic test as an example of such an application.

1. Use **m68k-elf-objcopy** to convert the linked application, in ELF format, into binary format. For example:

```
$ m68k-elf-objcopy -O binary programname programname.bin
```

2. Copy the binary file (.bin file) into a location on the host computer accessible to its TFTP server.

3. Connect to the PEEDI's telnet interface, and program the image into Flash with the following command, replacing *`TFTP_SERVER`* with the address of the TFTP server and *`/BINPATH`* with the location of the .bin file relative to the TFTP server root directory. For example for the tm_basic test:

   ```
   m5213evb> flash program tftp://TFTP_SERVER/BINPATH/tm_basic.bin bin 0x0 erase
   ++ info: Programming image file: tftp://TFTP_SERVER/BINPATH/tm_basic.bin
   ++ info: Programming directly

   programming at 0x0000A000
   erasing     at 0x0000B000 (page #22)
   erasing     at 0x0000B800 (page #23)
   programming at 0x0000B000

   ++ info: successfully programmed 48.00 KB in 1.45 sec

   m5213evb>
   ```

Once programmed into flash the application can be run simply by resetting the board. This may be acheived through the PEEDI telnet session by running the command **reset reset** and issuing the **go** command. For example:

```
m5213evb> reset reset
++ info: user reset
m5213evb>
++ info: RESET and BKPT asserted
++ info: RESET released
++ info: BKPT released
++ info: core 0: initialized

m5213evb> go
```

UART0 will be used for the HAL diagnostics channel so any output generated by the application will appear there. The default communication parameters are 8 bits, no parity, 1 stop bit, and 38400 baud. HAL diagnostics are managed by the MCFxxxx variant HAL and there are two main configuration options: `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT` can be used to change the UART used or to cause diagnostics to be discarded completely; `CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD` can be used to change the baud rate. In the case of the tm_basic image, output similar to the following should be visible:

Example 327.1. m5213evb Real-time characterization

```
INFO:<code from 0x00000000 -> 0x0000a900, CRC e654>
            Startup, main stack : stack used   356 size  2152
             Startup : Idlethread stack used    76 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   14.28 microseconds (14 raw clock ticks)

Testing parameters:
   Clock samples:            32

Programming the application with ecoflash

eCos comes with its own utility **ecoflash** that is an expect script. Your host must therefore also have expect installed in order to run **ecoflash**. The expect program is not distributed along with eCosPro but is available for most Linux distributions and from ActiveState for Windows. Assuming both **ecoflash** and expect have been correctly installed, to program an executable `tm_basic` into flash would involve a command such as:

```
$ ecoflash -b m5213evb -t 'remote peedi-0:9000' program tm_basic
Erasing 0x00000000 - 0x0000b6c7
Writing 0x00000000 - 0x00003fff (16384 bytes) from file "/tmp/tm_basic.1358785576", offset 0
Writing 0x00004000 - 0x00007fff (16384 bytes) from file "/tmp/tm_basic.1358785576", offset 16384
Writing 0x00008000 - 0x0000b6c7 (14024 bytes) from file "/tmp/tm_basic.1358785576", offset 32768
```

The `-b` argument identifies the target hardware and the `-t` option informs **ecoflash** how to access the board in the current development environment. Here it is told to interact with a Ronetix JTAG/BDM PEEDI with the hostname `peedi-0` listening on TCP/IP port 9000. For repeated use **ecoflash** supports various environment variables:

```
$ export ECOFLASH_BOARD=m5213evb
$ export ECOFLASH_TARGET='remote peedi-0:9000'
$ ecoflash program tm_basic
Erasing 0x00000000 - 0x0000b6c7
Writing 0x00000000 - 0x00003fff (16384 bytes) from file "/tmp/tm_basic.1358785576", offset 0
Writing 0x00004000 - 0x00007fff (16384 bytes) from file "/tmp/tm_basic.1358785576", offset 16384
Writing 0x00008000 - 0x0000b6c7 (14024 bytes) from file "/tmp/tm_basic.1358785576", offset 32768
```

For the Windows **CMD** environment replace **export** with **SET** above. The separate **ecoflash** documentation in the section ecoflash Flash Programming Utility should be consulted for further details.

Debugging the application with gdb

More commonly some debugging will be necessary and **m68k-elf-gdb** can be used for this. It can be invoked directly for command line use, or it may be used indirectly as the backend for an integrated development environment such as Eclipse. Typical command-line usage for a ROM startup application would involve:

```
$ m68k-elf-gdb --quiet hello
(gdb) shell ecoflash -b m5213evb -t 'remote peedi-0:9000' program hello
Erasing 0x00000000 - 0x00004ad7
Writing 0x00000000 - 0x00003fff (16384 bytes) from file "/tmp/hello.1358786211", offset 0
Writing 0x00004000 - 0x00004ad7 (2776 bytes) from file "/tmp/hello.1358786211", offset 16384
(gdb) set remote memory-write-packet-size 128
(gdb) set remote memory-read-packet-size 128
(gdb) target remote peedi-0:9000
Remote debugging using peedi-0:9000
0x0000045c in main (argc=9146, argv=0x0) at hello.c:53
(gdb) set $pc=hal_m68k_exception_reset
Current language:  auto; currently asm
(gdb) hbreak main
Hardware assisted breakpoint 1 at 0x420: file hello.c, line 48.
(gdb) c
Continuing.

Breakpoint 1, main (argc=9146, argv=0x0) at hello.c:48
48          CYG_TEST_INIT();
Current language:  auto; currently c
```

In typical usage most of these commands will be automated via a macro in the user's `.gdbinit` file. The first two commands limit the size of data transfers between gdb and the PEEDI. This may or may not be necessary, but problems in this area have been observed with some versions of the tools. The shell command invokes **ecoflash** to program the `hello` program into flash. The target command connects gdb to a Ronetix PEEDI listening on TCP/IP port 9000. The entry point for an M5213EVB eCos application is `hal_m68k_exception_reset`. Normally the entry point is set automatically by gdb when the application is loaded into memory, but when debugging an application in flash there is no load phase so the program counter has to be set explicitly.

Normally gdb uses software breakpoints which means that it will modify the instructions in RAM to trigger a breakpoint exception. That is not possible for code in flash. Instead hardware breakpoints must be specified via the **hbreak** command instead of the more usual **break** command. The MCF5213 only supports four hardware breakpoints, one of which may be needed by gdb to implement functionality such as single-stepping at the C level, so debugging a flash-based application can prove more difficult than a RAM-based application. It should also be noted that m68k-elf-gdb has no built-in awareness of eCos data structures so there is no support for thread-aware debugging. On other platforms it is the target-side gdb stubs embedded into RedBoot that provide such support.

For very simple applications where both code and data will fit into the 32KB of available SRAM it is possible to set the configuration option `CYG_HAL_STARTUP` to RAM and then build eCos and the application for that startup. Running such an application via command-line gdb involves:

```
% m68k-elf-gdb --quiet hello
(gdb) set remote memory-write-packet-size 128
(gdb) set remote memory-read-packet-size 128
(gdb) target remote peedi-0:9000
Remote debugging using peedi-0:9000
(gdb) load
Loading section .ram_vectors, size 0x200 lma 0x20000000
Loading section .m68k_start, size 0x48 lma 0x20000200
Loading section .text, size 0x46ac lma 0x20000248
Loading section .rodata, size 0x585 lma 0x200048f4
Loading section .data, size 0x17c lma 0x20004e7c
Start address 0x20000200, load size 20469
Transfer rate: 50385 bits/sec, 108 bytes/write.
(gdb) break main
Breakpoint 1 at 0x2000038e: file hello.c:48
(gdb) c
Continuing.

Breakpoint 1, main (argc=9146, argv=0x0) at hello.c:48
48          CYG_TEST_INIT();
(gdb)
```

The same commands are used to connect to the PEEDI and to set the communication parameters, and again a gdb macro would normally be used for this. The application is then loaded into RAM, which automatically sets the program counter. Ordinary software breakpoints can now be used.

HAL Port Implementation Details

The M5213EVB platform HAL has very limited functionality compared with more typical eCos platform HALs. Because there is no external memory bus much of the work normally done by the platform HAL can instead be done higher up in the MCF521x processor HAL, and hence the code can be shared with other MCF521x-based platforms.

The M5213EVB platform HAL does not override the behaviour of any of the higher-level HALs. The M68K architectural HAL handles the bulk of system startup, interrupt and exception handling, thread context management, and the main linker script. The MCFxxxx variant HAL provides the diagnostics support, interrupt controller management, the system clock, reset, microsecond delay, and the LSBIT and MSBIT utility macros. The MCF521x processor HAL defines the memory map and provides processor-specific startup code, idle thread support. It also initializes the GPIO pins, and instantiates flash, SPI and I²C bus devices. The platform HAL mainly provides the default settings for the GPIO pins and the system clock.

When the configuration option `CYGHWR_HAL_M68K_M5213EVB_LED_EN` is enabled, indicating that the four LEDs are connected to the appropriate GPIO pins, the platform HAL package provides a utility function for manipulating the LEDs:

```
#include <cyg/hal/hal_arch.h>

externC void hal_m5213evb_led_set(int, int);
```

The first argument identifies the LED and should be a number between 0 and 3. The second argument should be 1 to switch the LED on, 0 to switch it off.

When SPI support is enabled in the processor HAL via the configuration option `CYGHWR_HAL_M68K_MCF521x_SPI` the platform HAL will instantiate a cyg_spi_device structure `cyg_spi_zigbee_mc13192` for the on-board Zigbee chip. The platform HAL does not attempt to initialize or otherwise interact with this chip.

The platform HAL provides the necessary support for the ecoflash flash programming utility. The `m5213evb.ecf` configuration file and the `m5213evb_flash.elf` target-side executable may have been installed automatically when you installed eCos. If not, the `misc` subdirectory contains the configuration file and a configuration template `ecoflash.ecm` which can be used to rebuild the target-side executable.

Chapter 328. Freescale M5208EVBe Platform HAL

Name

eCos Support for the Freescale M5208EVBe and M5208EVB (Intec Automation) Boards — Overview

Description

This package `CYGPKG_HAL_M68K_M5208EVBE` provides a port to the Freescale M5208EVBe board. The older M5208EVB is also supported via CDL configuration. The port supports RedBoot programmed into the external flash. This can be used for application bootstrap. It also provides gdb stub functionality, allowing developers to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet. Alternatively a BDM hardware debug module can be used.

The eCos port can be configured for one of three startup types:

RAM
: This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. m68k-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output. The RAM startup type can also be used for finished applications: RedBoot can be made to load and run such applications automatically following bootstrap.

RAMBDM
: This is a variant of RAM startup which can be used for debugging using a BDM hardware debug module, if for some reason an application cannot be run on top of RedBoot. The main difference between RAMBDM and RAM startup is that the former does not assume the presence of RedBoot and hence will not make any virtual vector calls to obtain RedBoot services.

ROM
: This startup type can be used for finished applications which will be programmed into external flash at location 0x00000000, and which will execute as soon as the processor starts running. The application will be self-contained with no dependencies on services provided by other software. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

Hardware

The memory map used by both eCos and RedBoot for the M5208EVBe is as follows:

Memory	**Base**	**Length**	**Write-protected**
External Flash	0x00000000	0x00800000	Yes
External SDRAM	0x40000000	0x02000000	No
Internal RAM	0x80000000	0x00004000	No
On-chip Peripherals	0xF0000000	0x10000000	No

For the older M5208EVB platform the eCos and RedBoot memory map is:

Memory	**Base**	**Length**	**Write-protected**
External Flash	0x00000000	0x00200000	Yes
External SDRAM	0x40000000	0x02000000	No
Internal RAM	0x80000000	0x00004000	No
On-chip Peripherals	0xF0000000	0x10000000	No

By default caching is enabled for the external flash and SDRAM. There is no need to cache the internal RAM, and caching the peripherals would break all device drivers. As a debugging aid the flash is set to write-protected, which should catch some null pointer indirections. The flash driver will temporarily set this part of the address space to read-write when modifying the flash.

For all startup types the M68K exception vectors, the eCos virtual vector table, and a small amount of additional data is placed at the base of SDRAM. For ROM startup the application's data starts immediately afterwards. For RAM and RAMBDM startup application code starts at 0x40010000, with just under 64K reserved for use by RedBoot, and data follows after the code.

Typically the first 128K of flash is used for RedBoot, and the last 64K of flash is used for RedBoot's FIS and fconfig data. The remainder of the flash is available for use by the application, and is supported via the V2 AMD flash driver CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2. That driver is inactive unless the generic flash support CYGPKG_IO_FLASH has been included in the configuration. The amount of flash available is the main difference between the newer M5208EVBe board and the older M5208EVB. The default M5208EVBe platform HAL uses CFI to determine the actual flash chips present, with the M5208EVB being restricted to the known/fixed 2MB flash due to hardware mapping of the flash chip. The generic flash support provides an API that ensures an application need not worry about the details of which flash chips are present.

Code and data can be placed in the internal RAM using the linker script section “.iram_text” for code, and “.iram_data” and “.iram_bss” for initialized and unitialized data respectively. The M68K architectural HAL contains a testcase iram1.c which demonstrates how to use these linker sections.

Of the three on-chip UARTs, UART0 and UART1 have on-board RS232 transceivers and UART2 is available via GPIO configuration on the CN1 I/O header. Normally UART0 will be used as the default diagnostics channel for RedBoot and for stand-alone applications, and may also be inherited as the diagnostics/debug channel when debugging a RAM startup application over serial.

The on-chip ethernet device is supported via the device driver CYGPKG_DEVS_ETH_MCFxxxx. This driver will be inactive unless the generic ethernet support CYGPKG_IO_ETH_DRIVERS is included in the configuration. Typically that will happen automatically when the configuration is created using the net template. For RedBoot or applications run on top of RedBoot the ethernet MAC address will typically be supplied by an **fconfig** setting. Otherwise the address will be set by a configuration option in the ethernet driver. Care should be taken that no two boards on the same network segment accidentally use the same MAC address.

The I²C bus is supported by the generic package CYGPKG_IO_I2C and the device driver CYGPKG_DEVS_I2C_MCFxxxx. Both of these will be included automatically in any configuration for the M5208EVBe, but will be eliminated at link-time if the application does not use any I²C functionality. The I²C bus instance is called hal_mcfxxxx_i2c_bus.

The QSPI bus is supported by the generic package CYGPKG_IO_SPI and the device driver CYGPKG_DEVS_SPI_MCFxxxx_QSPI. Both of these will be included automatically in any configuration for the M5208EVBe, but will be eliminated at link-time if the application does not use any SPI functionality. The SPI bus instance is called hal_mcfxxxx_qspi_bus, and the platform HAL also instantiates an SPI device object hal_m5208evbe_m13192.

All eCos configurations for the M5208EVBe also include a watchdog device driver CYGPKG_DEVS_WATCHDOG_MCFxxxx_SCM. That driver is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG has been added to the configuration, and should be accessed via the API provided by that package.

eCos also manages the interrupt controllers, the FlexBus settings, and the SDRAM controller. The Crossbar switch is set to favour I/O rather than the cpu, avoiding problems with DMA underruns. Timer PIT0 is normally used for the eCos system clock, and when using the profiling package CYGPKG_PROFILE_GPROF PIT1 will be used for the profiling timer. The remaining hardware is available for use by the application.

Tools

The M5208EVBe port is intended to work with GNU tools configured for an m68k-elf target. The original port was done using m68k-elf-gcc version 4.4.5c m68k-elf-gdb version 7.2, and binutils version 2.20.1.

By default eCos is built using the compiler flag -fomit-frame-pointer. Omitting the frame pointer eliminates some work on every function call and makes another register available, so the code should be smaller and faster. However without a frame pointer m68k-elf-gdb is not always able to identify stack frames, so it may be unable to provide accurate backtrace information. Removing this compiler flag from the configuration option CYGBLD_GLOBAL_CFLAGS avoids such debug problems.

Name

Setup — Preparing the M5208EVBe board for eCos Development

Overview

In a typical development environment the M5208EVBe board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run via either ethernet or serial using the m68k-elf-gdb debugger. Preparing the board therefore involves programming a suitable RedBoot image into flash memory. Alternatively it is possible to use a BDM hardware debug module to load and run a RAMBDM startup application, with no need to install RedBoot into flash first. Some functionality provided by RedBoot via virtual vectors will not be available in that scenario. In particular the ethernet driver will not be able to access an fconfig setting for the MAC address, and instead it will use a fixed address controlled by a configuration option.

Setting Up BDM

The recommended BDM debug solution is the Ronetix PEEDI. This requires a configuration file `peedi.m5208evbe.cfg` which can be found in the platform HAL's `misc` directory. The configuration file will initialize the hardware in the same way as the ROM startup code. It will need minor edits, for example to specify the correct license keys and to select the CORE_FLASH respectively for the M5208EVBe or M5208EVB. For full details see the Ronetix documentation.

Once the PEEDI is set up applications can be linked against an eCos configuration built with RAMBDM startup mode. That is largely equivalent to RAM startup but disables the use of virtual vectors, so it does not assume that RedBoot is present. Applications can then be run via m68k-elf-gdb:

```
% m68k-elf-gdb install/tests/kernel/current/tests/tm_basic
…
(gdb) target remote peedi:9000
Remote debugging using peedi:9000
0x00015b6c in ?? ()
(gdb) load
Loading section .m68k_start, size 0xa4 lma 0x40010000
Loading section .text, size 0xaadc lma 0x400100a4
Loading section .rodata, size 0xfc1 lma 0x4001ab80
Loading section .data, size 0x14c lma 0x4001bb44
Start address 0x40010000, load size 48269
Transfer rate: 250 KB/sec, 8044 bytes/write.
(gdb) break cyg_test_exit
Breakpoint 1 at 0x40016670: file /work/ecos/ecospro-common/packages/infra/current/src/tcdiag.cxx, line 316.
(gdb) continue
Continuing.

Breakpoint 1, cyg_test_exit () at /work/ecos/ecospro-common/packages/infra/current/src/tcdiag.cxx:316
316   cyg_test_exit(void)
$
```

The application output will go via the configured HAL diagnostics channel, as per `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`. The default settings will send the output via UART0 at 115200 baud, 8 bits, no parity, and 1 stop bit. The baud rates can be changed via the configuration option `CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD`. It is also possible to set the diagnostics port to discard all output or to use the gdb hwdebug fileio channel. The latter requires running an extra gdb command after loading the application:

```
…
(gdb) load
Loading section .m68k_start, size 0xa4 lma 0x40010000
Loading section .text, size 0xaa9c lma 0x400100a4
Loading section .rodata, size 0xfc1 lma 0x4001ab40
Loading section .data, size 0x150 lma 0x4001bb04
Start address 0x40010000, load size 48209
Transfer rate: 250 KB/sec, 8034 bytes/write.
(gdb) set hwdebug
```

```
(gdb) break cyg_test_exit
Breakpoint 1 at 0x40016670: file /work/ecos/ecospro-common/packages/infra/current/src/tcdiag.cxx, line 316.
(gdb) continue
…
```

The application output will now be sent to gdb, which will display it.

Installing RedBoot

The following RedBoot configurations are supported for the M5208EVBe and M5208EVB boards:

Startup	Description	Use	Files
ROM	Runs from the board's flash	`redboot_ROM.ecm`	`redboot.elf`, `redboot.bin`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot.elf`, `redboot.bin`

Note that the RAM and RAMBDM startups are equivalent as far as RedBoot is concerned. The RAM startup version of RedBoot can be run either via BDM or on top of an already installed ROM RedBoot. eCosPro releases come with prebuilt RedBoot images renamed to incorporate the startup type, for example `redboot_ROM.bin`. It is the ROM RedBoot binary that needs to be programmed into flash at location 0x00000000. This may involve a third party flash programming utility. Alternatively it is possible to first run up the RAM startup version via BDM and then use that to program the ROM binary into flash. The eCosPro installation's "loaders/m5208evbe" directory contains the prebuilt RedBoot images for the M5208EVBe target and the "loaders/m5208evb" directory the prebuilt RedBoot images for the M5208EVB. The following example assumes you are using a Ronetix PEEDI BDM debugger to load the appropriate RAM RedBoot prebuilt for your target.

```
% m68k-elf-gdb <path>/redboot.elf
…
(gdb) target remote peedi:9000
Remote debugging using peedi:9000
fis_lookup (name=0x4001bc80 "@\001\ufffd8", num=0x40016a7a) at /work/ecos/ecospro-common/packages/redboot/current/src/
267   {
(gdb) load
Loading section .m68k_start, size 0x98 lma 0x40010000
Loading section .text, size 0x16dd8 lma 0x40010098
Loading section .rodata, size 0x3afc lma 0x40026e70
Loading section .data, size 0xb08 lma 0x4002a96c
Start address 0x40010000, load size 111732
Transfer rate: 274 KB/sec, 12414 bytes/write.
(gdb) continue
```

The RAM RedBoot will now output its banner and prompt via UART0, again at 115200 baud 8 bits no parity 1 stopbit, and will accept commands:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 00:ff:12:34:56:78
IP: 10.1.1.181/255.255.255.0, Gateway: 10.1.1.241
Default server: 0.0.0.0
DNS server IP: 10.1.1.240, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [RAM]
…
Platform: M5208EVBe (Freescale MCF5208)
RAM: 0x40000000-0x41000000 [0x40036424-0x40fed000 available]
FLASH: 0x00000000-0x007fffff, 64 x 0x10000 blocks, 64 x 0x10000 blocks
RedBoot>
```

At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. In this example RedBoot is using a default MAC address and has contacted a local bootp server to get the IP address information. To perform the flash initialization use the **fis init** command.

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
** Initialize FLASH Image System
... Erase from 0x007f0000-0x007fffff: .
... Program from 0x40ff0000-0x41000000 to 0x007f0000: .
RedBoot>
```

Now the block of flash at location 0x007F0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address:
DNS server IP address:
GDB connection port: 9000
Force console for special debug messages: false
Network hardware address [MAC]: 0x00:0xff:0x12:0x34:0x01:0x15
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x007f0000-0x007fffff: .
... Program from 0x40ff0000-0x41000000 to 0x007f0000: .
RedBoot>
```

For most of these configuration variables the default value will be acceptable, at least initially. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server. The other exception is the network hardware address, also known as MAC address. All boards should be given a unique MAC address, not the one in the above example. If there are two boards on the same network trying to use the same MAC address then the resulting behaviour is undefined.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work this involves first loading it into RAM and then programming it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The ROM startup build of `redboot.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
CRaw file loaded 0x40036800-0x40051dfb, assumed entry at 0x40036800
xyzModem - CRC mode, 878(SOH)/0(STX)/0(CAN) packets, 3 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x00000000-0x0001ffff: ..
... Program from 0x40036800-0x40051dfc to 0x00000000: ..
... Erase from 0x007f0000-0x007fffff: .
... Program from 0x40ff0000-0x41000000 to 0x007f0000: .
RedBoot>
```

The flash-resident version of RedBoot has now been programmed at location 0x00000000, and the flash info block at 0x007F0000 has been updated. The initial setup is now complete. The BDM gdb session is no longer required so can be ctrl-C'd and exited. BDM can be disconnected if desired. When the board is powercycled the ROM version of RedBoot should now start up:

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 00:ff:12:34:01:15
IP: 10.1.1.182/255.255.255.0, Gateway: 10.1.1.241
Default server: 0.0.0.0, DNS server IP: 10.1.1.240

RedBoot(tm) bootstrap and debug environment [ROM]
…
```

```
Platform: M5208EVBe (Freescale MCF5208)
RAM: 0x40000000-0x41000000 [0x4000be10-0x40fed000 available]
FLASH: 0x00000000-0x007fffff, 64 x 0x10000 blocks, 64 x 0x10000 blocks
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from m68k-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done via BDM, as above, or by loading a RAM RedBoot binary via the ROM RedBoot's **load -r -m ymodem -b 0x40010000** and started with the **go** command. The ROM version can then be loaded into memory and programmed into flash as before.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot are:

```
$ mkdir redboot_rom
$ cd redboot_rom
$ ecosconfig new m5208evbe redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/m68k/mcf52xx/mcf520x/m5208evbe/<vsn>/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot.bin`, as well as the ELF executable `redboot.elf`. Rebuilding the RAM involves basically the same process but using the file `redboot_RAM.ecm`. For the older M5208EVB board the "ecosconfig new m5208evbe redboot" command in the above example should replaced by "ecosconfig new m5208evb redboot".

Name

Configuration — Platform-specific Configuration Options

Overview

The M5208EVBe platform HAL package is loaded automatically when eCos is configured for a m5208evbe target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The platform HAL is complemented by the M68K architectural HAL `CYGPKG_HAL_M68K`, the MCFxxxx variant HAL `CYGPKG_HAL_M68K_MCFxxxx`, and the MCF520x processor HAL `CYGPKG_HAL_M68K_MCF520x`.

Startup

The M5208EVBe platform HAL package supports three separate startup types: RAM, RAMBDM and ROM. The configuration option `CYG_HAL_STARTUP`: controls which startup type is being used. For typical application development RAM startup should be used, and the application will be run via m68k-elf-gdb interacting with RedBoot using either serial or ethernet. It is assumed that the low-level hardware initialization, including setting up the memory map, has already been performed by RedBoot. By default the application will use certain services provided by RedBoot via the virtual vector mechanism, including diagnostic output, but that can be disabled via `CYGSEM_HAL_USE_ROM_MONITOR`. RAMBDM startup is a variant of RAM startup which has `CYGSEM_HAL_USE_ROM_MONITOR` disabled by default, and is intended for debugging over BDM instead of via RedBoot.

ROM startup can be used for applications which boot directly from flash. All the hardware will be initialized, and the application is self-contained. This startup type is used by the flash-resident version of RedBoot, and can also be used for finished applications.

M5208EVBe or M5208EVB

By default selecting the m5208evbe target will build code for the newer M5208EVBe board, with its CFI compliant flash interface. Normally the M5208EVBe board has 8MB of on-board flash available.

If support is needed for the older M5208EVB board then the CDL configuration option `CYGPKG_HAL_M68K_M5208EVBE_FLASH_2MB` can be enabled in the configuration. This provides support for the non-CFI flash interface needed to access to the 2MB of on-board flash on the M5208EVB.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via BDM.

Diagnostics

Diagnostics support is provided by the MCFxxxx variant HAL. For RAM startup the application will inherit its diagnostics channel from RedBoot: when debugging over ethernet diagnostics will travel over the TCP connection between **m68k-elf-gdb** and RedBoot; if RedBoot is set to discard its diagnostics then application diagnostics will be discarded as well; otherwise diagnostics will be sent via UART0.

For other startup types the default diagnostics channel can be set to either of the UARTs, or eCos can be configured to discard all diagnostics. The relevant configuration option is `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`.

Optional Hardware

The MCF520x processor HAL provides configuration options for the GPIO pin assignment registers, effectively controlling which of the on-chip peripherals are connected to the outside board. These settings are used in term to set the defaults for various devices, for example which UARTs are available and whether or not the hardware handshake lines are connected. The platform HAL provides default setttings for all these registers appropriate for a M5208EVBe board, but application developers can override these settings as required. Alternatively application can manipulate the processor's GPIO unit directly.

Cache and On-Chip RAM

The platform HAL contains configuration options for the values of the RAMBAR, CACR, ACR0 and ACR1 control registers. The first of these determines the location of on-chip RAM and does not usually need to be changed by application developers. The other three registers determine the caching behaviour. The default settings enable caching for the external flash and SDRAM only.

System Clock

The board is set to operate at 166.67/83.33 MHz, corresponding to the cpu and peripheral clocks respectively. However PLL dithering is enabled, slightly reducing the effective clock frequency. Programmable interrupt timer PIT0 is used to implement the eCos system clock. By default this is set to tick approximately once every 10ms, corresponding to a 100Hz clock. The frequency can be changed via the configuration option `CYGNUM_HAL_RTC_PERIOD`, which is used to program the timer's PIT Modulus Register. Other clock-related settings are recalculated automatically if the period is changed.

It should be noted that the effects of clock dithering are not precise, and hence the resulting system clock will not run at exactly 100Hz. A consequence of this is that conversions between seconds/nanoseconds and system clock ticks will not be precise and may suffer from rounding errors. If application code requires very precise timings then it may be necessary to do some experimenting and fine tuning.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are three flags specific to this port:

`-m528x`
: The m68k-elf-gcc compiler supports many variants of the M68K architecture, from the original 68000 onwards. A `-m` option should be used to select the specific variant in use, and with current tools `-m528x` is appropriate for an MCF520x processor.

`-malign-int`
: This option forces m68k-elf-gcc to align integer and floating point data to a 32-bit boundary rather than a 16-bit boundary. It should improve performance. However the resulting code is incompatible with most published application binary interface specifications for M68K processors, so it is possible that this option causes problems with existing third-party object code.

`-fomit-frame-pointer`
: Traditionally the `%A6` register was used as a dedicated frame pointer, and the compiler was expected to generate link and unlink instructions on procedure entry and exit. These days the compiler is perfectly capable of generating working code without a frame pointer, so omitting the frame pointer often saves some work during procedure entry and exit and makes another register available for optimization. However without a frame pointer register the m68k-elf-gdb debugger is not always able to interpret a thread stack, so it cannot reliably give a backtrace. Removing `-fomit-frame-pointer` from the default flags will make debugging easier, but the generated code may be worse.

Name

Test Programs — Details

Test Programs

The M5208EVBe platform HAL contains a simple test program which allows various aspects of the board to be tested.

m5208evbe (SPI and LED) Test

The `m5208evbe` program tests the SPI driver by checking for presence of the on-board M13192 ZigBee transceiver. It currently does no more than verify presence of the device. Also, depending on the setting of the JP16:13 jumpers the device will display some patterns on the on-board LEDs. If the jumpers are not present or the GPIO configuration for the platform does not have the TIMER pins T3:0 configured for GPIO the LED changes will not be seen.

Chapter 329. Motorola MCF532x Processor Support

Name

CYGPKG_HAL_M68K_MCF532x — eCos Support for Freescale MCF532x Processors

Description

The Freescale MCF532x group of processors is part of the larger family of ColdFire processors. The MCF532x group has several members including the MCF5327, MCF5328, MCF53281 and MCF5329. These differ in the set of peripherals available, for example the MCF5327 lacks on-chip ethernet.

The processor HAL package CYGPKG_HAL_M68K_MCF532x provides support for all MCF532x processors, although at the time of writing it has only been tested on an MCF5329. It complements the M68K architectural HAL package CYGPKG_HAL_M68K and the variant HAL package CYGPKG_HAL_M68K_MCFxxxx. An eCos configuration should also include a platform HAL package, for example CYGPKG_HAL_M68K_COBRA5329, to support board-level details like how the on-chip peripherals are connected to the outside world.

The package contains very little code. Instead it consists mainly of definitions, enabling appropriate code in the MCFxxxx variant HAL and in the various device drivers.

Configuration

The MCF532x processor HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Most of the package's configuration options relate to hardware. The settings are generally determined by the platform HAL and there is little need for application developers to change them. The first hardware option is CYGHWR_HAL_MCF532x_PROCESSOR, identifying the specific MCF532x processor being used. Legal values are MCF5327, MCF5328, MCF53281 and MCF5329. Typically the platform HAL will set this option via a CDL constraint.

Component CYGHWR_HAL_M68K_MCF532x_GPIO contains various options related to pin-connectivity. This gives full control over the PAR pin assignment registers, and for those pins configured as GPIO it is also possible to control the pin direction and data settings. These options are used to initialize the processor's GPIO module early on during system initialization, but applications may change settings later on as necessary.

The GPIO settings are used to determine default settings for the three on-chip uarts, the I²C bus and the QSPI bus. For example if none of the relevant GPIO pins are assigned to uart2 then component CYGHWR_HAL_M68K_MCFxxxx_UART2 will be disabled by default, and that uart cannot be used for HAL diagnostics nor accessed via the serial device driver. It is possible to override these settings if desired, for example if a uart is connected but will be manipulated directly by application code instead of via a device driver.

1. For each of the three on-chip uarts there will be a component, e.g. CYGHWR_HAL_M68K_MCFxxxx_UART0, determining whether or not the uart is usable on the target hardware. There are additional options CYGHWR_HAL_M68K_MCFxxxx_UART0_RTS and CYGHWR_HAL_M68K_MCFxxxx_UART0_CTS indicating whether or not the hardware handshake lines are connected, and CYGHWR_HAL_M68K_MCFxxxx_UART0_RS485_RTS to indicate that the RTS line controls an RS485 transceiver.

2. Component CYGHWR_HAL_M68K_MCF532x_I2C determines whether or not the processor HAL will instantiate an I²C bus device hal_mcfxxxx_i2c_bus. There are also options to control the interrupt priority and to set the FDR register which controls the bus speed. The default bus speed will be the standard I²C bus speed of 100KHz, or as close as can be achieved given hardware limitations.

3. Component CYGHWR_HAL_M68K_MCF532x_SPI determines whether or not the processor HAL will instantiate an SPI bus device hal_mcfxxxx_qspi_bus. It contains an additional configuration option for the interrupt priority.

For configurations which include the eCos kernel, CYGIMP_HAL_M68K_MCF532x_IDLE determines what happens when the idle thread runs.

The HAL Port

This section describes how the MCF532x processor HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

HAL I/O

The header file cyg/hal/proc_io.h provides definitions of MCF532x-specific on-chip peripherals. Many of the on-chip peripherals are compatible with those on the MCF5282 or other ColdFire processors, and for those peripherals it is the var_io.h header provided by the MCFxxxx variant HAL which provides the appropriate definitions. Both headers are automatically included by the architectural header cyg/hal/hal_io.h, so typically application code and other packages will just include the latter.

Interrupt Handling

MCF532x processors implement standard ColdFire interrupt and exception handling, and come with two MCF5282-compatible interrupt controllers and an edge port module. Therefore all interrupt and exception handling is left to the architectural and MCFxxxx variant HAL. The interrupt controllers are slightly enhanced relative to the MCF5282, with extra registers to facilitate masking and unmasking interrupts. These enhancements are supported. Unlike the MCF5282 interrupt priorities do not have to be unique, so valid interrupt priorities are in the range 1 to 6 corresponding to M68K IPL levels.

The processor's cyg/hal/proc_intr.h serves mainly to define symbols such as CYGNUM_HAL_ISR_UART0, mapping the MCF532x on-chip interrupt sources to the interrupt vectors.

Clock

Typically hardware timer PIT3 will be used for the eCos system clock, and that timer should not be manipulated directly by application code. If gprof-based profiling is enabled then that will use hardware timer PIT2. PIT timers 0 and 1 are not used by eCos so application code is free to manipulate these as required. Some of the configuration options related to the system clock, for example CYGNUM_HAL_RTC_PERIOD, are actually contained in the platform HAL rather than the processor HAL. These options need to take into account the processor clock speed, a characteristic of the platform rather than the processor.

Caching

The processor HAL provides full support for the 16K of unified cache in copyback mode. If desired the cache can also operate in write-through mode, the cache macros will still function correctly. However for a processor running at typically 240MHz write-through cache mode is likely to slow down execution significantly, especially if other devices such as ethernet or the LCD controller need concurrent access to main memory.

The HAL also defines a macro HAL_MEMORY_BARRIER() which acts to synchronize the pipeline, delaying execution until all previous operations including all pending writes are complete. This will usually be necessary when interacting with devices that access memory directly.

Other Issues

The MCF532x processor HAL does not affect the implementation of data types, stack size definitions, SMP support, system startup, or debug support. The MCFxxxx variant HAL versions of HAL_LSBIT_INDEX and HAL_MSBIT_INDEX are used since the processor supports the ff1.l and bitrev.l instructions. HAL_DELAY_US is implemented as a simple counting loop. HAL_IDLE_THREAD_ACTION may be defined depending on configuration option CYGIMP_HAL_M68K_MCF532x_IDLE.

Other Functionality

The processor HAL will instantiate a cyg_i2c_bus structure hal_mcfxxxx_i2c_bus when the configuration option CYGHWR_HAL_M68K_MCFxxxx_I2C is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the CYGPKG_DEVS_I2C_MCFxxxx device driver. The processor HAL does not know what I^{2}C devices may be attached to the bus so that is left to the platform HAL.

The processor HAL will instantiate a cyg_spi_bus structure hal_mcfxxxx_qspi_bus when the configuration option CYGHWR_HAL_M68K_MCFxxxx_SPI is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the CYGPKG_DEVS_SPI_MCFxxxx_QSPI device driver. The processor HAL does not know what SPI devices may be attached to the bus so that is left to the platform HAL. All SPI device structures should be placed in the table mcfxxxx_qspi.

Chapter 330. senTec Cobra5329 Board Support

Name

eCos Support for the senTec Cobra5329 Board — Overview

Description

The senTec Cobra5329 platform consists of a small module which plugs into a carrier board. The module contains: an MCF5329 ColdFire processor; 16MB of external SDRAM; 16MB of external flash memory; a configuration dip switch; a wallclock device on the I²C bus; a temperature sensor, also on the I²C bus; a multiplexer for the SPI chip select signals; and an ethernet phy. By default the module comes with the dBUG ROM monitor programmed in the external flash. The carrier board adds: power circuitry; transceivers for two RS232 ports; a CAN transceiver; four LEDs; an MMC socket connected to the SPI bus and multiplexed chip select 0; a touch screen controller, also attached to the SPI bus and chip select 1; and connectors for the various peripherals.

This package `CYGPKG_HAL_M68K_COBRA5329` provides a port to the Cobra5329 platform. The port assumes that the cpu module is plugged into a standard carrier board. If instead it is plugged into a custom carrier board with different I/O capabilities then it may still be possible to use the port by adjusting the eCos configuration. However the port has only been tested on a standard board.

For typical eCos development a RedBoot image is programmed into the external flash replacing the existing dBUG monitor. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet. Alternatively a BDM hardware debug module can be used.

The eCos port can be configured for one of four startup types:

RAM
: This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. m68k-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output. The RAM startup type can also be used for finished applications: RedBoot can be made to load and run such applications automatically following bootstrap.

RAMBDM
: This is a variant of RAM startup which can be used for debugging using a BDM hardware debug module, if for some reason an application cannot be run on top of RedBoot. The main difference between RAMBDM and RAM startup is that the former does not assume the presence of RedBoot and hence will not make any virtual vector calls to obtain RedBoot services.

DBUG
: This is another variant of RAM startup, used only when initializing a board. It can be used to run a special RAM-resident version of RedBoot on top of the dBUG ROM monitor, allowing a ROM startup version of RedBoot to be programmed into flash.

ROM
: This startup type can be used for finished applications which will be programmed into external flash at location 0x00000000, and which will execute as soon as the processor starts running. The application will be self-contained with no dependencies on services provided by other software. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

Hardware

The memory map used by both eCos and RedBoot is as follows:

Memory	Base	Length	Cached	Write-protected
External Flash	0x00000000	0x01000000	Write-through	Yes
Flash Shadow	0x01000000	0x3F000000	Write-through	Yes
External SDRAM	0x40000000	0x01000000	Copyback	No

Memory	Base	Length	Cached	Write-protected
Internal RAM	0x80000000	0x00008000	Uncached	No
Dummy	0xC0000000	0x20000000	Uncached	Yes
On-chip Peripherals	0xE0000000	0x20000000	Uncached	No

There is a potential problem with external memory accesses on the MCF5329 (device erratum 6): spurious accesses to unpopulated parts of the address space can hang the processor. To avoid this problem the external flash is replicated throughout the bottom of the address space, and a dummy region is created at address 0xC0000000. As a debugging aid the flash is set to write-protected, which should catch some null pointer indirections. The flash driver will temporarily set this part of the address space to read-write when modifying the flash.

For all startup types the M68K exception vectors, the eCos virtual vector table, and a small amount of additional data is placed at the base of SDRAM. For ROM startup the application's data starts immediately afterwards. For RAM and RAMBDM startup application code starts at 0x40010000, with just under 64K reserved for use by RedBoot, and data follows after the code. For DBUG startup application code starts at 0x40020000, with 128K reserved for use by dBUG.

Typically the first 128K of flash is used for RedBoot, and the last 64K of flash @ 0x00FF0000 is used for RedBoot's FIS and fconfig data. The remainder of the flash is available for use by the application, and is supported via the V2 AMD flash driver `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2`. That driver is inactive unless the generic flash support `CYGPKG_IO_FLASH` has been included in the configuration.

Code and data can be placed in the internal RAM using the linker script section “.iram_text” for code, and “.iram_data” and “.iram_bss” for initialized and unitialized data respectively. The M68K architectural HAL contains a testcase `iram1.c` which demonstrates how to use these linker sections.

Of the three on-chip uarts only uart0 and uart1 have external transceivers and connectors. Uart0 is normally used as the default diagnostics channel for RedBoot and for stand-alone applications, and may also be inherited as the diagnostics/debug channel when debugging a RAM startup application over serial. The default settings are 38400 baud 8n1, except when running on top of dBUG when the baud rate is set to 115200 instead. If uart0 is not used for diagnostics then it can be accessed via the serial driver `CYGPKG_DEVS_SERIAL_MCFxxxx` using the device name “/dev/ser0”. Similarly uart1 can be accessed via the serial device driver using the name “/dev/ser1”. The device driver is inactive unless the generic serial support option `CYGPKG_IO_SERIAL_DEVICES` is enabled.

The on-chip ethernet device is supported via the device driver `CYGPKG_DEVS_ETH_MCFxxxx`. This driver will be inactive unless the generic ethernet support `CYGPKG_IO_ETH_DRIVERS` is included in the configuration. Typically that will happen automatically when the configuration is created using the `net` template. The board does not have a serial EEPROM or equivalent to hold a unique ethernet MAC address, so that has to be provided in software instead. For RedBoot or applications run on top of RedBoot the MAC address will typically be supplied by an **fconfig** setting. Otherwise the address will be set by a configuration option in the ethernet driver. Care should be taken that no two boards on the same network segment accidentally use the same MAC address.

The I²C bus is supported by the generic package `CYGPKG_IO_I2C` and the device driver `CYGPKG_DEVS_I2C_MCFxxxx`. Both of these will be included automatically in any configuration for the Cobra5329, but will be eliminated at link-time if the application does not use any I²C functionality. The I²C bus instance is called `hal_mcfxxxx_i2c_bus`, and the platform HAL also instantiates I²C device objects `hal_cobra5329_lm73`, `hal_cobra5329_max3353`, `cyg_i2c_wallclock_isl12028` and `cyg_i2c_wallclock_isl12028_eeprom` for the various devices attached to the I²C bus. These devices are not used by eCos, but example code for how to access the LM73 can be found in the platform testcase `cobra5329.c`.

The QSPI bus is supported by the generic package `CYGPKG_IO_SPI` and the device driver `CYGPKG_DEVS_SPI_MCFxxxx_QSPI`. Both of these will be included automatically in any configuration for the Cobra5329, but will be eliminated at link-time if the application does not use any SPI functionality. The SPI bus instance is called `hal_mcfxxxx_qspi_bus`, and the platform HAL also instances SPI device objects `cyg_spi_mmc_dev0` and `hal_cobra5329_tsc2200` for the two devices attached to the bus. The MMC device can be used with the eCos MMC disk driver. The TSC2200 is not used by eCos, but example code for how to access it can be found in the platform testcase `cobra5329.c`.

Support for USB peripheral mode on the OTG controller is supported by the EHCI peripheral controller driver (CYGPKG_DEVS_USB_PCD_EHCI). A configuration package (CYGPKG_DEVS_USB_COBRA) enables the charge pump. Support is also present for a CDC/ACM USB serial interface.

All eCos configurations for the Cobra5329 also include a watchdog device driver CYGPKG_DEVS_WATCHDOG_MCF532x. That driver is inactive unless the generic watchdog support CYGPKG_IO_WATCHDOG has been added to the configuration, and should be accessed via the API provided by that package.

All eCos configurations for the Cobra5329 also include a wallclock device driver CYGPKG_DEVICES_WALLCLOCK_INTERSIL_ISL12028. This will be used automatically by the C library's time-related functions, for example time and asctime, and can be changed by an eCos-specific function cyg_libc_time_settime. In addition when using RedBoot the **data** command can be used to examine and change the current clock setting.

The platform HAL contains a utility function for manipulating the four LEDs:

```
void hal_cobra5329_led_set(which, on);
```

which should be a number between 1 and 4, and on should be 1 or 0. Example code for driving the LEDs can be found in the platform testcase cobra5329.c.

When using the Robust Bootloader package CYGPKG_RBL, switch 8 on the configuration dipswitch controls the **rbl condboot** functionality.

eCos also manages the interrupt controllers, the FlexBus settings for chip selects 0 and 5, and the SDRAM controller. The Crossbar switch is set to favour I/O rather than the cpu, avoiding problems with DMA underruns. Timer PIT3 is normally used for the eCos system clock, and when using the profiling package CYGPKG_PROFILE_GPROF PIT2 will be used for the profiling timer. Bit 7 of the edge port module is set up for use with the board's IRQ7 button. The remaining hardware is available for use by the application.

Tools

The Cobra5329 port is intended to work with GNU tools configured for an m68k-elf target. The original port was done using m68k-elf-gcc version 3.4.4, m68k-elf-gdb version 6.4, and binutils version 2.16.

By default eCos is built using the compiler flag -fomit-frame-pointer. Omitting the frame pointer eliminates some work on every function call and makes another register available, so the code should be smaller and faster. However without a frame pointer m68k-elf-gdb is not always able to identify stack frames, so it may be unable to provide accurate backtrace information. Removing this compiler flag from the configuration option CYGBLD_GLOBAL_CFLAGS avoids such debug problems.

Name

Setup — Preparing the Cobra5329 board for eCos Development

Overview

In a typical development environment the Cobra5329 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run via either ethernet or serial using the m68k-elf-gdb debugger. Preparing the board therefore involves programming a suitable RedBoot image into flash memory, replacing the existing dBUG monitor. Four different approaches can be used for this:

1. The board can be booted into its existing dBUG ROM monitor, which is then used to load and execute a dBUG startup build of RedBoot into RAM. The RAM-resident version of RedBoot can then be used to initialize the hardware, including uploading a ROM startup version of RedBoot and programming it into flash. If anything goes wrong during this procedure then the dBUG ROM monitor may have been wiped already, leaving the board unusable unless a hardware debug solution is available.
2. A BDM hardware debug module can be used in conjunction with a suitable debugger to load and run a RAM startup build of RedBoot. Again this can then be used to initialize the hardware, including programming a ROM startup version of RedBoot into flash.
3. The ecoflash flash programming utility can be used. Again this depends on a BDM hardware debug module and a suitable debugger. ecoflash can only be used to program a ROM startup version of RedBoot into flash, it cannot perform other tasks such as initializing the **fconfig** board settings. However those other tasks can be performed from inside RedBoot.
4. A third party flash programming utility may be available.

The following RedBoot configurations are supported:

Startup	Description	Use	Files
ROM	Runs from the board's flash	`redboot_ROM.ecm`	`redboot.elf`, `redboot.bin`
dBUG	Used for initial setup	`redboot_DBUG.ecm`	`redboot.elf`, `redboot.bin`, `redboot.srec`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot.elf`, `redboot.bin`

The RAM startup version of RedBoot can be run either via BDM or on top of an already installed ROM RedBoot. Full eCos releases may come with prebuilt RedBoot images renamed to incorporate the startup type, for example `redboot_ROM.bin`.

For serial communications all versions run with 8 bits, no parity, and 1 stop bit. The dBUG version runs at 115200 baud. The ROM and RAM versions run at 38400 baud. These baud rates can be changed via the configuration option `CYGNUM_HAL_M68K_MCFxxxx_DIAGNOSTICS_BAUD` and rebuilding RedBoot. By default uart0 will be used for the diagnostics/debug channel.

Setting Up BDM

The recommended BDM debug solution is the Ronetix PEEDI. Other solutions such as the P&E USBMultilink device have proved unreliable on this board, so if a PEEDI is not available then it is recommended that application developers should debug their applications on top of RedBoot's gdb stubs.

The PEEDI requires a configuration file `peedi.cfg` which can be found in the platform HAL's `misc` directory. The configuration file will initialize the hardware in the same way as standard eCos applications, so applications can be loaded into RAM and run as normal. The configuration file will need minor edits, for example to specify the correct license keys. For full details see the Ronetix documentation. Once the PEEDI is correctly set up m68k-elf-gdb can then connect to it in the usual way:

```
$ m68k-elf-gdb install/tests/kernel/current/tests/tm_basic
GNU gdb 6.4.50.20060226-cvs (eCosCentric)
```

```

(gdb) quit
The program is running.  Exit anyway? (y or n) y
$
```

A P&E USBMultilink BDM device can be used in conjunction with CodeSourcery's m68k-elf-cfpe-stub server. Inside the device is a jumper which should be set to the `NO CLK` position. The server requires a configuration file `cobra5329.cfg` which can be found in the platform HAL's `misc` directory. It is recommended that the m68k-elf-cfpe-stub be restarted for every debug session to ensure that the board is properly reset. Power cycling the boards between debug sessions may also help to improve reliability.

```
$ m68k-elf-cfpe-stub -d USBMultilink -l 9000 -t <path>/cobra5329.cfg
```

It is also possible to use a P&E parallel port module or a senTec CobraConnect module with m68k-elf-cfpe-stub. The command line invocation for the later changes to:

```
$ m68k-elf-cfpe-stub -d ParallelPortCable -l 9000 -t <path>/cobra5329.cfg
```

For Linux hosts there is also an alternative to using m68k-elf-cfpe-stub. Cobra5329 boards come with a CD, including a toolchain build in the `install/linux` subdirectory. One of the tools is m68k-bdm-elf-gdb, a variant of m68k-elf-gdb which can access parallel port BDM modules directly. Unlike the PEEDI or m68k-elf-cfpe-stub, m68k-bdm-elf-gdb will not automatically initialize the hardware. Instead this can be achieved using a set of gdb macros which can be found in the `bdm.gdb` file in the platform HAL's `misc` subdirectory. A typical debug session would look like:

```
$ m68k-bdm-elf-gdb install/tests/kernel/current/tests/tm_basic
GNU gdb 6.3
Copyright 2004 Free Software Foundation, Inc.
GDB is free software, covered by the GNU General Public License, and you are

(gdb) c
Continuing.
```

Initial Installation Using dBUG

This process assumes that the board still has its original dBUG ROM monitor and does not require any special debug hardware. Programming the RedBoot rom monitor into flash memory requires an application that can manage flash blocks. RedBoot itself has this capability. Rather than have a separate application that is used only for flash management during the initial installation, a special RAM-resident version of RedBoot is loaded into memory and run. This version can then be used to load the normal flash-resident version of RedBoot and program it into the flash.

It should be noted that some Cobra5329 boards have been shipped with a broken version of dBUG. This section describes two different ways of loading RedBoot into RAM, over a serial line or over the network.

The first step is to connect an RS232 cable between the Cobra5329 uart0 serial port and the host PC. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 115200 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Apply power to the board and you should see a `dBUG>` prompt. Once dBUG is up and running the RAM-resident version of RedBoot can be downloaded:

```
dBUG> dl
Escape to local host and send S-records now...
```

The required S-records file is the dBUG startup build of `redboot.srec`, which is normally supplied with the eCos release in the `loaders` directory. If it needs to be rebuilt then instructions for this are supplied below. The file should be sent to the target as raw text using the terminal emulator:

```
S-record download successful!
dBUG>
```

If instead dBUG complained about the S-record addresses during the download then your board has the broken version of dBUG. Instead it will be necessary to run a tftp server on the local network and place the dBUG startup build of `redboot.bin` in the tftp server's directory. The details of this will depend on the tftp server being used. Once this has been accomplished, dBUG's network settings must be set appropriately using the **set** command. The dBUG documentation should be consulted for more information on this. Once networking is functional the RedBoot image can be downloaded:

```
dBUG> dn -i redboot.bin
Address:  0x40020000
Downloading Image 'redboot.bin' from 10.1.1.251
TFTP transfer completed
Read 93972 bytes (184 blocks)
dBUG>
```

When RedBoot has been loaded into RAM, either over serial or via the network, it can be run with the **go** command:

```
dBUG> go 0x40020000
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 40:01:3b:e0:00:00
IP: 10.1.1.181/255.255.255.0, Gateway: 10.1.1.241
Default server: 0.0.0.0, DNS server IP: 10.1.1.240

RedBoot(tm) bootstrap and debug environment [DBUG]
Non-certified release, version UNKNOWN - built 21:15:30, Mar  5 2008

Platform: Cobra5329 (Freescale MCF5329)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited
```

```
RAM: 0x40000000-0x41000000, [0x4004204c-0x40fed000] available
FLASH: 0x00000000-0x00ffffff, 256 x 0x10000 blocks
RedBoot>
```

At this stage the RedBoot flash management initialization has not yet happended so the warning about the configuration checksum error is expected. In this example RedBoot is using a default MAC address and has contacted a local bootp server to get the address information. To perform the flash initialization use the **fis init** command.

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x00ff0000-0x00ffffff: .
... Program from 0x40ff0000-0x41000000 to 0x00ff0000: .
RedBoot>
```

At this stage the block of flash at location 0x00FF0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address:
DNS server IP address:
GDB connection port: 9000
Force console for special debug messages: false
Network hardware address [MAC]: 0x00:0xff:0x12:0x34:0x01:0x13
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x00ff0000-0x00ffffff: .
... Program from 0x40ff0000-0x41000000 to 0x00ff0000: .
RedBoot>
```

For most of these configuration variables the default value will be acceptable, at least initially. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server. The other exception is the network hardware address, also known as MAC address. All boards should be given a unique MAC address, not the one in the above example. If there are two boards on the same network trying to use the same MAC address then the resulting behaviour is undefined.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The ROM startup build of `redboot.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
Raw file loaded 0x40042400-0x4005936b, assumed entry at 0x40042400
xyzModem - CRC mode, 737(SOH)/0(STX)/0(CAN) packets, 3 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x00000000-0x0001ffff: ..
... Program from 0x40042400-0x4005936c to 0x00000000: ..
... Erase from 0x00ff0000-0x00ffffff: .
... Program from 0x40ff0000-0x41000000 to 0x00ff0000: .
RedBoot>
```

The flash-resident version of RedBoot has now been programmed at location 0x00000000, and the flash info block at 0x00FF0000 has been updated. The initial setup is now complete. Power off the board, set the terminal emulator to run at 38400 baud (the usual baud rate for RedBoot), and power up the board again.

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 00:ff:12:34:01:13
IP: 10.1.1.182/255.255.255.0, Gateway: 10.1.1.241
Default server: 0.0.0.0, DNS server IP: 10.1.1.240

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 17:42:36, Mar 18 2008

Platform: Cobra5329 (Freescale MCF5329)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited

RAM: 0x40000000-0x41000000, [0x4000c030-0x40fed000] available
FLASH: 0x00000000-0x00ffffff, 256 x 0x10000 blocks
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from m68k-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done using the RAM startup build of `redboot.bin` rather than the dBUG version of RedBoot used above. It should be loaded using the ROM RedBoot's **load -r -m ymodem -b 0x40010000** and started with the **go** command. The ROM version can then be loaded into memory and programmed into flash as before.

Initial Installation Using BDM

Given a functional BDM setup, it is possible to run a RAM-resident version of RedBoot directly. This involves either m68k-elf-gdb or m68k-bdm-elf-gdb, together with the RAM build of `redboot.elf`, for example:

```
$ m68k-elf-gdb install/bin/redboot.elf

RedBoot's output will be sent out of uart0 at 38400 baud, so an RS232 cable should be connected and a suitable terminal emulation application should be run. Once at the RedBoot prompt the procedure is the same as for the dBUG setup: initializing the flash, loading the ROM build of `redboot.bin` into memory, and then writing it to flash using **fis create**.

Initial Installation Using ecoflash

Given a functional BDM setup, the ecoflash utility can be used to program a RedBoot image directly into flash. Full information on ecoflash can be found elsewhere. It uses environment variables to determine the target hardware and how to access it. When using a PEEDI:

```
$ export ECOFLASH_BOARD=cobra5329
$ export ECOFLASH_TARGET='remote peedi:9000'
```

For m68k-elf-cfpe-stub a different remote address will need to be specified. When using m68k-bdm-elf-gdb:

```
$ export ECOFLASH_BOARD=cobra5329
$ export ECOFLASH_TARGET='bdm /dev/bdmcf0'
$ export ECOFLASH_GDB=m68k-bdm-elf-gdb
```

The **ecoflash info** can be used to verify that everything is working:

```
$ ecoflash info
Target board is cobra5329.
  gdb is "m68k-elf-gdb", gdb target is "remote localhost:9000".
  Target-side executable is version 1.
  Detected 1 bank of flash.
    Start 0x00000000, end 0x00ffffff -> 16384K.
      256 blocks of 64K.
  Flash block locking is not supported.
  Default program location for executables is 0x00000000.
  Target-side buffer for read and write operation is 64K.
```

If anything goes wrong then **ecoflash -v info** will run the same command in verbose mode, possibly providing additional information as to what is going wrong. Once everything is working a ROM startup build of RedBoot can be programmed into flash:

```
$ ecoflash program <path>/redboot.elf
Erasing 0x00000000 - 0x00016f6b
Writing 0x00000000 - 0x0000ffff (65536 bytes) from file "/tmp/redboot.elf.719", offset 0
Writing 0x00010000 - 0x00016f6b (28524 bytes) from file "/tmp/redboot.elf.719", offset 65536
```

When the board is next reset it should boot into RedBoot, with the output sent out of uart 0 at 38400 baud. A terminal emulator can then be used to connect to RedBoot and perform the **fis init** and **fconfig -i** initialization steps.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the dBUG version of RedBoot are:

```
$ mkdir redboot_dbug
$ cd redboot_dbug
$ ecosconfig new cobra5329 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/m68k/mcf52xx/mcf532x/cobra5329/<vsn>/misc/redboot_DBUG.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required files `redboot.srec` and `redboot.bin`, as well as the ELF executable `redboot.elf`.

Rebuilding the RAM and ROM versions involves basically the same process. The RAM version uses the file `redboot_RAM.ecm` and generates a file `redboot_ram.bin`. The ROM version uses the file `redboot_ROM.ecm` and generates a file `redboot_rom.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The Cobra5329 platform HAL package is loaded automatically when eCos is configured for a Cobra5329 target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The platform HAL is complemented by the M68K architectural HAL `CYGPKG_HAL_M68K`, the MCFxxxx variant HAL `CYGPKG_HAL_M68K_MCFxxxx`, and the MCF532x processor HAL `CYGPKG_HAL_M68K_MCF532x`.

Startup

The Cobra5329 platform HAL package supports three separate startup types: RAM, RAMBDM, DBUG and ROM. The configuration option `CYG_HAL_STARTUP`: controls which startup type is being used. For typical application development RAM startup should be used, and the application will be run via m68k-elf-gdb interacting with RedBoot using either serial or ethernet. It is assumed that the low-level hardware initialization, including setting up the memory map, has already been performed by RedBoot. By default the application will use certain services provided by RedBoot via the virtual vector mechanism, including diagnostic output, but that can be disabled via `CYGSEM_HAL_USE_ROM_MONITOR`. RAMBDM startup is a variant of RAM startup which has `CYGSEM_HAL_USE_ROM_MONITOR` disabled by default, and may be useful when debugging over BDM.

ROM startup can be used for applications which boot directly from flash. All the hardware will be initialized, and the application is self-contained. This startup type is used by the flash-resident version of RedBoot, and can also be used for finished applications.

DBUG startup can be used for applications which will be loaded via the dBUG ROM monitor rather than RedBoot. As with RAM startup it is assumed that the memory map has already been set up, but the application will not use any services provided by the ROM monitor. Typically this startup type is only used when setting up a board, as part of the process of replacing dBUG with RedBoot.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via BDM.

Diagnostics

Diagnostics support is provided by the MCFxxxx variant HAL. For RAM startup the application will inherit its diagnostics channel from RedBoot: when debugging over ethernet diagnostics will travel over the TCP connection between **m68k-elf-gdb** and RedBoot; if RedBoot is set to discard its diagnostics then application diagnostics will be discarded as well; otherwise diagnostics will be sent over one of the uarts, typically uart0.

For other startup types the default diagnostics channel can be set to either of the uarts, or eCos can be configured to discard all diagnostics. The relevant configuration option is `CYGHWR_HAL_M68K_MCFxxxx_DIAGNOSTICS_PORT`.

Optional Hardware

The MCF532x processor HAL provides configuration options for the GPIO pin assignment registers, effectively controlling which of the on-chip peripherals are connected to the outside board. These settings are used in term to set the defaults for various devices, for example which uarts are available and whether or not the hardware handshake lines are connected. The platform HAL provides default setttings for all these registers appropriate for a Cobra5329 cpu module plugged into a standard carrier board, with no additional hardware. If the cpu module is plugged into a different carrier board or if extra hardware is hooked up to the various expansion sockets, the pin assignments can be changed as appropriate. Alternatively application can manipulate the processor's GPIO unit directly.

Cache and On-Chip RAM

The platform HAL contains configuration options for the values of the RAMBAR, CACR, ACR0 and ACR1 control registers. The first of these determines the location of on-chip RAM and does not usually need to be changed by application developers. The other three registers determine the caching behaviour. The default settings have the external flash cached in write-through mode, the external SDRAM cached in copyback mode, and everything else uncached. Normally it should be necessary to change these settings, and for a processor that can run at 240MHz it is important to make the best possible use of the cache. However, when debugging over BDM using hardware other than a Ronetix PEEDI it has been found that debug reliability could be improved somewhat when the cache was disabled, i.e. when the top bit of the CACR register was cleared. Obviously this is at the cost of greatly reduced performance.

System Clock

By default the platform HAL assumes a system clock running at 240/80MHz, 240MHz for the CPU and 80MHz for the peripherals. `CYGHWR_HAL_SYSTEM_CLOCK_HZ` corresponds to the peripheral clock speed. It is possible to run the board at a slower 180/60MHz by changing one of the switches in the configuration dip switch. If so then the configuration option must be changed for both RedBoot and the application, since it affects various I/O settings such as uart baud rates.

The port uses programmable interrupt timer PIT3 to implement the eCos system clock. By default this is set to tick once every 10ms, corresponding to a 100Hz clock. The frequency can be changed via the configuration option `CYGNUM_HAL_RTC_PERIOD`, which is used to program the timer's PIT Modulus Register (PMR3). Other clock-related settings are recalculated automatically if the period is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are three flags specific to this port:

`-m528x`

The m68k-elf-gcc compiler supports many variants of the M68K architecture, from the original 68000 onwards. A `-m` option should be used to select the specific variant in use, and with current tools `-m528x` is the closest match for an MCF532x processor.

`-malign-int`

This option forces m68k-elf-gcc to align integer and floating point data to a 32-bit boundary rather than a 16-bit boundary. It should improve performance. However the resulting code is incompatible with most published application binary interface specifications for M68K processors, so it is possible that this option causes problems with existing third-party object code.

`-fomit-frame-pointer`

Traditionally the `%A6` register was used as a dedicated frame pointer, and the compiler was expected to generate link and unlink instructions on procedure entry and exit. These days the compiler is perfectly capable of generating working code without a frame pointer, so omitting the frame pointer often saves some work during procedure entry and exit and makes another register available for optimization. However without a frame pointer register the m68k-elf-gdb debugger is not always able to interpret a thread stack, so it cannot reliably give a backtrace. Removing `-fomit-frame-pointer` from the default flags will make debugging easier, but the generated code may be worse.

Chapter 331. Motorola MCF520x Processor Support

Name

CYGPKG_HAL_M68K_MCF520x — eCos Support for Freescale MCF520x Processors

Description

The Freescale MCF5207 and MCF5208 processors are part of the larger family of ColdFire processors. The two processors differ in the peripheral support: the MCF5208 has on-chip ethernet, the MCF5207 does not. The processor HAL package CYGPKG_HAL_M68K_MCF520x provides support for both processors, although at the time of writing it has only been tested on an MCF5208. It complements the M68K architectural HAL package CYGPKG_HAL_M68K and the variant HAL package CYGPKG_HAL_M68K_MCFxxxx. An eCos configuration should also include a platform HAL package to support board-level details like how the on-chip peripherals are connected to the outside world.

The package contains very little code. Instead it consists mainly of definitions, enabling appropriate code in the MCFxxxx variant HAL and in the various device drivers.

Configuration

The MCF520x processor HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Most of the package's configuration options relate to hardware. The settings are generally determined by the platform HAL and there is little need for application developers to change them. The first hardware option is CYGHWR_HAL_MCF520x_PROCESSOR, identifying the specific MCF520x processor being used. Legal values are MCF5207 and MCF5208. Typically the platform HAL will set this option via a CDL constraint.

Component CYGHWR_HAL_M68K_MCF520x_GPIO contains various options related to pin-connectivity. This gives full control over the PAR pin assignment registers, and for those pins configured as GPIO it is also possible to control the pin direction and data settings. These options are used to initialize the processor's GPIO module early on during system initialization, but applications may change settings later on as necessary.

The GPIO settings are used to determine default settings for the three on-chip uarts, the I²C bus and the QSPI bus. For example if none of the relevant GPIO pins are assigned to uart2 then component CYGHWR_HAL_M68K_MCFxxxx_UART2 will be disabled by default, and that uart cannot be used for HAL diagnostics nor accessed via the serial device driver. It is possible to override these settings if desired, for example if a uart is connected but will be manipulated directly by application code instead of via a device driver.

1. For each of the three on-chip uarts there will be a component, e.g. CYGHWR_HAL_M68K_MCFxxxx_UART0, determining whether or not the uart is usable on the target hardware. There are additional options CYGHWR_HAL_M68K_MCFxxxx_UART0_RTS and CYGHWR_HAL_M68K_MCFxxxx_UART0_CTS indicating whether or not the hardware handshake lines are connected, and CYGHWR_HAL_M68K_MCFxxxx_UART0_RS485_RTS to indicate that the RTS line controls an RS485 transceiver.

2. Component CYGHWR_HAL_M68K_MCF520x_I2C determines whether or not the processor HAL will instantiate an I²C bus device hal_mcfxxxx_i2c_bus. There are also options to control the interrupt priority and to set the FDR register which controls the bus speed. The default bus speed will be the standard I²C bus speed of 100KHz, or as close as can be achieved given hardware limitations.

3. Component CYGHWR_HAL_M68K_MCF520x_SPI determines whether or not the processor HAL will instantiate an SPI bus device hal_mcfxxxx_qspi_bus. It contains an additional configuration option for the interrupt priority.

For configurations which include the eCos kernel, CYGIMP_HAL_M68K_MCF520x_IDLE determines what happens when the idle thread runs. It should be noted that there are hardware errata associated with this functionality, and when systems were configured to use WAIT or DOZE mode problems were observed where the processor appeared to fail to wake up even though there were pending interrupts.

The HAL Port

This section describes how the MCF520x processor HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

HAL I/O

The header file `cyg/hal/proc_io.h` provides definitions of MCF520x-specific on-chip peripherals. Many of the on-chip peripherals are compatible with those on the MCF5282 or other ColdFire processors, and for those peripherals it is the `var_io.h` header provided by the MCFxxxx variant HAL which provides the appropriate definitions. Both headers are automatically included by the architectural header `cyg/hal/hal_io.h`, so typically application code and other packages will just include the latter.

Interrupt Handling

MCF520x processors implement standard ColdFire interrupt and exception handling, and come with one MCF5282-compatible interrupt controller and an edge port module. Therefore all interrupt and exception handling is left to the architectural and MCFxxxx variant HAL. The interrupt controllers are slightly enhanced relative to the MCF5282, with extra registers to facilitate masking and unmasking interrupts. These enhancements are supported. Unlike the MCF5282 interrupt priorities do not have to be unique, so valid interrupt priorities are in the range 1 to 6 corresponding to M68K IPL levels.

The processor's `cyg/hal/proc_intr.h` serves mainly to define symbols such as `CYGNUM_HAL_ISR_UART0`, mapping the MCF520x on-chip interrupt sources to the interrupt vectors.

Clock

Typically hardware timer PIT0 will be used for the eCos system clock, and that timer should not be manipulated directly by application code. If gprof-based profiling is enabled then that will use hardware timer PIT1. Some of the configuration options related to the system clock, for example `CYGNUM_HAL_RTC_PERIOD`, are actually contained in the platform HAL rather than the processor HAL. These options need to take into account the processor clock speed, a characteristic of the platform rather than the processor.

Caching

Support for the cache is provided via the generic HAL macros in the MCFxxxx variant HAL cache. The HAL also defines a macro `HAL_MEMORY_BARRIER()` which acts to synchronize the pipeline, delaying execution until all previous operations including all pending writes are complete. This will usually be necessary when interacting with devices that access memory directly.

Other Issues

The MCF520x processor HAL does not affect the implementation of data types, stack size definitions, SMP support, system startup, or debug support. The MCFxxxx variant HAL versions of `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` are used since the processor supports the `ff1.l` and `bitrev.l` instructions. `HAL_DELAY_US` is implemented as a simple counting loop. `HAL_IDLE_THREAD_ACTION` may be defined depending on configuration option `CYGIMP_HAL_M68K_MCF520x_IDLE`.

Other Functionality

The processor HAL will instantiate a cyg_i2c_bus structure `hal_mcfxxxx_i2c_bus` when the configuration option `CYGHWR_HAL_M68K_MCFxxxx_I2C` is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the `CYGPKG_DEVS_I2C_MCFxxxx` device driver. The processor HAL does not know what I²C devices may be attached to the bus so that is left to the platform HAL.

The processor HAL will instantiate a cyg_spi_bus structure `hal_mcfxxxx_qspi_bus` when the configuration option `CYGHWR_HAL_M68K_MCFxxxx_SPI` is enabled. That option is enabled by default if various GPIO pins are configured appropriately. The implementation is provided by the `CYGPKG_DEVS_SPI_MCFxxxx_QSPI` device driver. The processor HAL does not know what SPI devices may be attached to the bus so that is left to the platform HAL. All SPI device structures should be placed in the table `mcfxxxx_qspi`.

Part LXXXII. MIPS Architecture

Table of Contents

Chapter 332. MIPS Architectural HAL

Name

`CYGPKG_HAL_MIPS` — eCos Support for the MIPS Architecture

Description

The MIPS architecture HAL provides support for all MIPS base processors. This includes both legacy devices, MIPS32 based devices, and Release 2 devices. Support is included for MIP16 and microMIPS instruction sets in addition to the MIPS32 instruction set.

This HAL contains support for CPU initialization, exception and interrupt entry and exit, thread context switching, interrupt masking, timer management, cache management and debugging.

Name

Options — Configuring the MIPS Architectural HAL Package

Description

The MIPS architectural HAL is included in all ecos.db entries for MIPS targets, so the package will be loaded automatically when creating a configuration. It should never be necessary to load the package explicitly or to unload it.

The MIPS architectural HAL contains a number of configuration points. Few of these should be altered by the user, they are mainly present for the variant and platform HALs to select different architectural features.

`CYGINT_HAL_MIPS_VARIANT`

This interface is implemented by each variant HAL and acts as a check on the number of variants included in the configuration.

`CYGPKG_HAL_MIPS_MIPS16_SUPPORT`

This option is usually set with a requires statement by the variant or platform HAL to enable support for MIPS16 applications. The eCos operating system and library remains in the MIPS32 instruction set.

`CYGINT_HAL_MIPS_MICROMIPS_SUPPORT`

This interface is implemented by the variant or platform HAL to enable support for the microMIPS instruction set.

`CYGPKG_HAL_MIPS_MICROMIPS_SUPPORT`

This option is usually enabled implicitly by the variant or platform HAL implementing `CYGINT_HAL_MIPS_MICROMIPS_SUPPORT`. Its value controls the level of support for the microMIPS instruction set. If set to `APP` then only application code may be compiled in the microMIPS instruction set, eCos remains in the MIPS32 instruction set. If set to `ECOS` then the whole of eCos is also compiled to the microMIPS instruction set, although those parts of the HAL involved in startup and exception handling remain in MIPS32 instructions. If set to `FULL` then all code is compiled or assembled to microMIPS. This latter option is only applicable to CPU variants that only execute microMIPS instructions and is not currently supported.

`CYGNUM_HAL_MIPS_RELEASE`

This option defines the architecture release that the processor supports. It is usually set by the variant or platform HAL to enable various configuration changes in the architecture HAL.

`CYGINT_HAL_MIPS_DEBUG_MODE`

This interface is implemented by the variant or platform HAL to enable support for Debug Mode. Debug Mode is only available on Release 2 devices that have EJTAG support. It is used primarily to support single step and breakpoints.

`CYGHWR_HAL_MIPS_CPU_FREQ`

This option contains the frequency of the CPU in MegaHertz. This will usually be set from the variant or platform HAL, which may define additional clock related options. This may affect thing like serial device, interval clock and memory access speed settings.

`CYGSEM_HAL_MIPS_EMULATE_UNIMPLEMENTED_FPU_OPS`

Enabling this option will include a hook in the exception processing so that Unimplemented Operation FPU exceptions may be handled. This option has no effect if there is no hardware floating-point unit. Note that not all situations in which an exception is raised may be handled. If not, the exception will be passed on as normal through the standard exception delivery mechanism.

`CYGINT_HAL_MIPS_STUB_REPRESENT_32BIT_AS_64BIT`

This interface may be implemented by MIPS variant or platform HALs to instruct the MIPS stub to interwork correctly with GDB which expects 64-bit register values, even in application code which has been compiled as 32-bit. Do not use this for real 64-bit code.

`CYGINT_HAL_MIPS_INTERRUPT_RETURN_KEEP_SR_IM`

On some MIPS variants, the status register (SR) contains a number of interrupt mask bits (IM\[0..7\]). Default behaviour is to restore the whole SR over an interrupt. This means that if the ISR modifies those bits, the change is lost when the interrupt returns. If this interface is implemented, changes made to the SR IM bits by an ISR will instead be preserved. Variants whose HAL_INTERRUPT_MASK() routines (et al) modify the IM bits in the SR should implement this interface to get the necessary preserving behaviour.

Redefinable Macros

In addition to the CDL configuration points above, there are a number of assembler macros that may be redefined. The assembler header `cyg/hal/arch.inc` contains default implementations of most of these. Variant or platform HALs may supply alternative definitions of these and define the matching preprocessor macro. For example, the default implementation of the `hal_intc_init` macro sets up the default interrupt mechanism using the Status register. By defining `CYGPKG_HAL_MIPS_INTC_INIT_DEFINED`, this macro may be redefined. Defining `CYGPKG_HAL_MIPS_INTC_DEFINED` allows all the `hal_intc_*` macros to be redefined. This same approach is applicable to most other macros or macro groups in `arch.inc`.

The same approach is also applicable to C-level macros for controlling interrupts, the timer, caches, bit indexing. A `..._DEFINED` macro is tested to determine whether a macro, or group of macros, have been defined in the variant or platform and if not then a default implementation is defined.

Compiler Flags

It is normally the responsibility of the platform HAL to define the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

Linker Scripts

The linker script, supplied by either the variant or platform HALs, must define some symbols that the architecture HAL depends on:

hal_vsr_table

This defines the location of the VSR table. First level interrupt and exception trampolines use the value of the Cause register ExcCode field to index this table and vector to a VSR routine. Generally this table should be placed in RAM close to the vector trampolines. This table should be 64 entries in length, although not all will be used.

hal_virtual_vector_table

This defines the location of the virtual vector table used to communicate between a ROM monitor and an eCos application. This table needs to be word aligned. It is usually placed in internal SRAM just after the VSR table, perhaps aligned to a convenient boundary. This table should be 64 entries in length.

Name

HAL Port — Implementation Details

Description

This documentation explains how the eCos HAL specification has been mapped onto the MIPS hardware and should be read in conjunction with the manuals for the processor in use. It should be noted that the architectural HAL is usually complemented by a variant HAL and a platform HAL, and those may affect or redefine some parts of the implementation.

Exports

The architectural HAL provides header files `cyg/hal/hal_arch.h`, `cyg/hal/hal_intr.h` and `cyg/hal/hal_io.h`. These header files export the functionality provided by all the MIPS HALs for a given target, automatically including headers from the lower-level HALs as appropriate. For example the platform HAL may provide a header `cyg/hal/plf_io.h` containing additional I/O functionality, but that header will be automatically included by `cyg/hal/hal_io.h` so there is no need to include it directly.

Additionally, the architecture HAL provides the `cyg/hal/basetype.h` header, which defines the basic properties of the architecture, including endianness, data type sizes and alignment constraints.

Startup

The conventional bootstrap mechanism involves the CPU starting execution at 0xBFC00000. Normally ROM or flash will be mapped here and a ROM startup RedBoot or application will be linked to start at this address. Some variants have an on-board boot ROM that runs at this address, and RedBoot or applications must be placed elsewhere in memory. In either case, execution must normally start at the `reset_vector` location in `vectors.S`.

The architectural HAL provides a default implementation of the low-level startup code which will be appropriate in nearly all scenarios. For a ROM startup this includes copying initialized data from flash to RAM. For all startup types it will involve zeroing bss regions and setting up the general C environment. It may also set up the exception trampolines in low memory, initializing CP0 registers, the memory controller, interrupt controller caches, timers, MMU and FPU, mostly by invoking variant or platform HAL defined macros. Depending on the variant and platform, some of these things are initialized in assembly code during startup, others may be initialized in later C code.

In addition to the setup it does itself, the initialization code calls out to the variant and platform HALs to perform their own initialization. Full initialization is handled by `hal_variant_init` and `hal_platform_init`. The former should handle any further initialization of the CPU variant and on-chip devices. The platform initialization routine will complete any initialization needed for devices external to the microprocessor.

The architectural HAL also initializes the VSR and virtual vector tables, sets up HAL diagnostics, and invokes C++ static constructors, prior to calling the first application entry point `cyg_start`. This code resides in `src/hal_misc.c`.

Interrupts and Exceptions

The eCos interrupt and exception architecture is built around a table of pointers to Vector Service Routines that translate hardware exceptions and interrupts into the function calls expected by eCos.

The vector table is either constructed at runtime or is part of the initialized data of the executable. For ROM, ROMRAM and JTAG startup all entries are initialized. For RAM startup only the interrupt VSR table entry is (re-)initialized to point to the VSR in the loaded code, the exception vectors are left pointing to the VSRs of the loading software, usually RedBoot or GDB stubs.

When an exception occurs it is delivered to a shared trampoline routine, `other_vector` which reads the Cause register, isolates the ExcCode field and uses it to index the VSR table and jump to the routine at the given offset. VSR table entries usually point to either `__default_exception_vsr` or `__default_interrupt_vsr`, which are responsible for delivering the exception or interrupt to the kernel.

The exception VSR, `__default_exception_vsr`, saves the CPU state on the thread stack, optionally switches to the interrupt stack and calls `cyg_hal_exception_handler()` to pass the exception on. Depending on the configuration, this routine then partly decodes the exception and passes it on for FPU emulation or exception handling, limited memory access errors, GDB stub exception handling or application level handling. When it finally returns the VSR jumps to code common with the interrupt VSR to restore the interrupted state and resume execution.

The interrupt VSR, `__default_interrupt_vsr`, saves the CPU state in the same way as the exception VSR, increments the scheduler lock and switches to the interrupt stack. It then calls two variant or platform supplied macros, `hal_intc_decode` and `hal_intc_translate` to query the interrupt controller for an interrupt number and then translate the interrupt number into an interrupt table offset. This offset is used to fetch an ISR from the interrupt handler table, and a data pointer from the interrupt data table, and the ISR is called to handle the interrupt. When the ISR returns, the stack pointer is switched back to the thread stack and `interrupt_end()` called. This may result in a thread context switch and the current thread may not resume for some time. When it does, the interrupted CPU state is restored from the thread stack and execution resumed from where it was interrupted.

The architectural HAL provides default implementations of `HAL_DISABLE_INTERRUPTS`, `HAL_RESTORE_INTERRUPTS`, `HAL_ENABLE_INTERRUPTS` and `HAL_QUERY_INTERRUPTS`. These involve manipulation of the Status register IE bit. Similarly there are default implementations of the interrupt controller macros `HAL_INTERRUPT_MASK`, `HAL_INTERRUPT_UNMASK` and `HAL_INTERRUPT_ACKNOWLEDGE` macros that manipulate the Status register IM bits. `HAL_INTERRUPT_SET_LEVEL` and `HAL_INTERRUPT_CONFIGURE` are no-ops at the architectural level. If a variant or platform contains an external interrupt controller, then it should redefine these macros to manipulate it.

Stacks and Stack Sizes

`cyg/hal/hal_arch.h` defines values for minimal and recommended thread stack sizes, `CYGNUM_HAL_STACK_SIZE_MINIMUM` and `CYGNUM_HAL_STACK_SIZE_TYPICAL`. These values depend on a number of configuration options.

The MIPS architecture HAL has the option of either using thread stacks for all exception and interrupt processing or implementing a separate interrupt stack. The default is to use an interrupt stack, since not doing so would require significantly larger per-thread stacks. This can be changed with the configuration option `CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK`.

Thread Contexts and setjmp/longjmp

`cyg/hal/hal_arch.h` defines a thread context data structure, the context-related macros, and the `setjmp`/`longjmp` support. The implementations can be found in `src/context.S`. The context structure is defined as a single structure used for all purposes: thread context, exceptions and interrupts. However, not all fields will be stored in all cases.

Bit Indexing

The architectural HAL provides inline assembler implementations of `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` which use algorithmic methods to extract a bit index in constant time. Variant HALs for later versions of the architecture can replace these with macros that use inline assembly to use CLZ or other instructions.

Idle Thread Processing

The architecture HAL provides a default `HAL_IDLE_THREAD_ACTION` implementation that simply spins. Variant and platform HALs can provide a replacement if required.

Clock Support

The architectural HAL provides a default implementation of the various system clock macros such as `HAL_CLOCK_INITIALIZE`. These macros use the architecture defined CP0 Count and Compare registers to implement the eCos system clock. The variant or platform HAL needs to define `CYGNUM_HAL_RTC_PERIOD` in terms of the frequency supplied to the Count register.

HAL I/O

The MIPS architecture does not have a separate I/O bus. Instead all hardware is assumed to be memory-mapped. Further it is assumed that all peripherals on the memory bus will switch endianness with the processor and that there is no need for any byte swapping. Hence the various HAL macros for performing I/O simply involve pointers to volatile memory.

The variant and platform files included by the `cyg/hal/hal_io.h` header will typically also provide details of some or all of the peripherals, for example register offsets and the meaning of various bits in those registers.

Cache Handling

The architecture HAL provides standard macros for dealing with both data and instruction caches. These macros make use of the CACHE instruction to affect cache contents. The architecture HAL does not provide support for enabling and disabling the caches, since there is no common mechanism for doing this; these must be implemented by the variant HAL.

Linker Scripts

The architecture HAL does not provide the main linker script, this must be supplied by the variant HAL and the makefile rules to generate the final `target.ld` must be included in the variant's CDL file.

Diagnostic Support

The architectural HAL does not implement diagnostic support. Instead this is left to the variant or platform HAL, depending on whether suitable peripherals are available on-chip or off-chip.

SMP Support

The MIPS architectural HAL does not provide any SMP support.

Debug Support

The architectural HAL provides basic support for gdb stubs using the debug monitor exceptions. Breakpoints may be implemented using a fixed-size list of breakpoints, as per the configuration option `CYGNUM_HAL_BREAKPOINT_LIST_SIZE`. When a JTAG device is connected to a MIPS device, it will steal breakpoints and other exceptions from the running code. Therefore debugging from RedBoot or the GDB stubs can only be done after detaching any JTAG debugger and power-cycling the board.

Debug support depends on the exact CPU model. Older parts, pre MIPS32R2, use the BREAK instruction for breakpoints and rely on instruction analysis to plant a breakpoint for single step for both MIPS32 and MIPS16 instruction sets. CPUs with debug mode use the SDBBP instructions for breakpoints and the Debug register SSt bit to implement single step for both MIPS32 and microMIPS instruction sets.

HAL_DELAY_US() Macro

`cyg/hal/hal_intr.h` provides a simple implementation of the `HAL_DELAY_US` macro based around reading the system timer. The timer must therefore be initialized before this macro is used, from either the variant or platform HAL initialization routines.

Profiling Support

The MIPS architectural HAL implements the `mcount` function, allowing profiling tools like gprof to determine the application's call graph. It does not implement the profiling timer. Instead that functionality needs to be provided by the variant or platform HAL.

Chapter 333. MIPS32 Variant HAL

Name

`CYGPKG_HAL_MIPS_MIPS32` — eCos Support for the MIPS32 Architecture Variant

Description

The MIPS32 variant HAL provides support for all MIPS32 base processors. This includes both legacy devices and Release 2 devices. It extends and modifies the generic architecture support provided by the architecture HAL to work with processors that conform to the MIPS32 specification.

Name

Options — Configuring the MIPS32 Variant HAL Package

Description

The MIPS32 variant HAL is included in all ecos.db entries for MIPS32-based targets, so the package will be loaded automatically when creating a configuration. It should never be necessary to load the package explicitly or to unload it.

The MIPS32 variant HAL contains a number of configuration points. Few of these should be altered by the user, they are mainly present for the platform HAL to select different features.

`CYGHWR_HAL_MIPS_MIPS32_CORE`

> This defines the CPU core on the target hardware. It is usually set by the platform HAL and may change the configuration of this HAL and of any changes it makes to the architecture HAL.

`CYGHWR_HAL_MIPS_MIPS32_ENDIAN`

> The MIPS32 core can use either a big or little endian mode. Platforms with a fixed endianness should set this to `Little` or `Big` as appropriate. Bi-endian platforms may allow this to be set by the user, or implicitly by supplying a platform configuration option to control endianness.

Compiler Flags

It is normally the responsibility of the platform HAL to define the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. The endianness flags, `-EL` and `-EB` are controlled here by the `CYGHWR_HAL_MIPS_MIPS32_ENDIAN` option. The selection of the instruction set for eCos: MIPS32 or microMIPS, is also selected here based on various architecture options.

Name

MIPS32 HAL Port — Implementation Details

Description

This documentation explains how the eCos HAL specification has been mapped onto the MIPS hardware and should be read in conjunction with the manuals for the processor in use. It should be noted that the variant HAL is usually complemented by an architecture HAL and a platform HAL, and those may affect or redefine some parts of the implementation.

Exports

The variant HAL provides header files `cyg/hal/var_arch.h`, `cyg/hal/var_intr.h` and `cyg/hal/var_cache.h`. These header files export the functionality of this HAL to the architecture HAL, and are included automatically by the architecture HAL where needed.

Additionally, the variant HAL provides the `cyg/hal/variant.inc` header, which is included into the architecture assembly code and redefines some macros used there, to configure the architecture to the MIPS32 variant.

Startup

The MIPS32 HAL does no additional initialization beyond the redefined assembly macros mentioned above. As a purely CPU-based variant there are no additional variant-specific devices to be initialized.

Interrupts and Exceptions

The MIPS32 HAL defines some additional exception vectors that are present in MIPS32 variants. Otherwise it takes no part in interrupt or exception delivery.

Bit Indexing

The MIPS32 HAL provides replacement implementations of the `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` macros that use inline assembly CLZ instructions.

Cache Handling

The main contribution that the MIPS32 HAL makes is in cache handling. It provides cache handling macros that extend and modify those supplied in the architecture HAL. It also implements cache enable and disable support via the K0 field of the Config0 register. It also provides default cache dimension declarations, as well as a mechanism for these to be defined by the platform HAL.

Linker Scripts

The MIPS32 HAL provides the main linker script for use by all platforms. The MIPS32 HAL will generate the linker script for eCos applications. This involves the file `src/mips_mips32.ld` and a `.ldi` memory layout file, typically provided by the platform HAL. It is the `.ldi` file which places code and data in the appropriate places for the startup type, but most of the hard work is done via macros in the `mips_mips32.ld` file.

Chapter 334. MIPS SEAD3 Board Support

Name

eCos Support for the MIPS SEAD3 Board — Overview

Description

The MIPS SEAD3 board comes in three variants. The LX50 is fitted with a M14K processor and no SDRAM. The LX110 is fitted with a M14Kc processor and 512MiB of SDRAM. The LX155 is virtually identical to the LX110, but is fitted with a larger FPGA. From the point of view of eCos, it is considered identical to the LX110 and all references in this documentation and in eCos to the LX110 should be considered to include the LX155. All boards have 4MiB of SRAM and 32MiB of NOR flash, a dual 16550 compatible UART, and a SMSC LAN9211 ethernet controller. A two line LCD display and LEDs are also present. For typical eCos development a RedBoot image is programmed into the external flash. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet. It is also possible to debug applications using the JTAG interface.

Supported Hardware

The memory map used by both eCos and RedBoot is as follows:

Memory	Base	Length
SDRAM	0x80000000	0x20000000
SRAM	0x80000000	0x00400000
User Flash	0x9c000000	0x02000000
SRAM Shadow	0x8E000000	0x00400000
Interrupt Controller (if present)	0xBB1C0000	0x00020000
Peripherals	0xBF000000	0x00010000
SMSC LAN9211	0xBF010000	0x00010000
Boot Flash	0xBFC00000	0x00600000

On the LX110/LX155 SDRAM is mapped to physical address 0x00000000 and SRAM is visible only at the shadow location. On the LX50 SRAM is mapped to physical location 0x00000000 as well as the shadow location. SDRAM, SRAM and flash are normally accessed via the kseg0 segment and hence via the cache. The peripherals are normally accessed via kseg1 and hence uncached.

eCos can be configured for one of three startup types:

RAM

> This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. mip-sde-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output. The bottom 1MB of RAM is used for RedBoot code and data so the application will start at 0x80100000.

ROM

> This startup type can be used for finished applications which will be programmed into the start of external flash at location 0xbfc00000. On power-up the processor will automatically execute the contents of flash from 0xbfc00000. The application will initialize the system, copy its data to RAM and zero its BSS. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

ROMRAM

This startup type can be used for finished applications which will be programmed into the start of external flash at location 0xbfc00000. On power-up the processor automatically execute the contents of flash from 0xbfc00000. The application will initialize the system, copy itself from flash to RAM, and zero its BSS. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

JTAG

This can be used to run applications via JTAG rather than RedBoot. The application will be loaded at location 0x80000000 and it will take over all the hardware. Uart0 will be used for all HAL diagnostics and standard output. A JTAG application build may prove useful for debugging certain problems, especially ones related to interrupts and exceptions. However the JTAG software may not fully cope with the executables and debug information generated by the GNU tools, so the user experience may be poor compared with using the GNU mips-sde-elf-gdb debugger.

In a typical setup RedBoot is programmed into the boot flash, which eCos does not manage. The last 256KiB of User flash is used for managing the flash and holding the RedBoot fconfig values. The remaining blocks from 0x9c000000 to 0x9dfbffff can be used by application code.

RedBoot can communicate with the host using either uart0 or ethernet.

All configurations for the SEAD3 target include an ethernet driver package `CYGPKG_DEVS_ETH_SMSC_LAN9118`. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package `CYGPKG_IO_ETH_DRIVERS`. Typically the choice of eCos template causes the right thing to happen. For example, the default template does not include any TCP/IP stack so `CYGPKG_IO_ETH_DRIVERS` is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver. The ethernet device can be shared by RedBoot and the application, so it is possible to debug a networked application over ethernet.

The SEAD3 board has a serial EPROM providing a unique network MAC address.

All configurations for the SEAD3 target include serial device driver packages `CYGPKG_IO_SERIAL_GENERIC_16X5X` and `CYGPKG_IO_SERIAL_MIPS_SEAD3`. The `16X5X` driver provided generic support for 16X5X compatible UARTs while the `SEAD3` package provides configuration to adapt that driver to the SEAD3 board. The driver as a whole is inactive unless the generic serial support, `CYGPKG_IO_SERIAL_DEVICES` is enabled. Both UART0 and UART1 are connected, and both have hardware flow control lines routed to the connector. UART0 is routed to a standard 9-pin RS232 connector and UART1 is connected to an FTDI USB adaptor. If a UART is needed by the application then it cannot also be used by RedBoot for gdb traffic, so care should be exercised in selecting which UART to use for these purposes. Alternatively another communication channel such as ethernet should be used instead.

The GIC interrupt controller is managed by eCos using macros provided by the SEAD3 platform HAL. The architecture COUNTER/COMPARE timer is used to implement the eCos system clock. If gprof-based profiling is enabled then that will use the GIC compare register and its associated interrupt. If the core does not include a GIC, then the configuration option `CYGHWR_HAL_SEAD3_HAS_GIC` must be disabled, and gprof profiling will not be possible. At the moment, without a GIC additional interrupt decoding is performed to indicate which of the two UART devices generated an interrupt, as these are multiplexed in the same interrupt vector (2). However decoding is not performed on the multiplexed peripherals on interrupt vector 0: PIC32 GPIO, SPI or USB as these peripherals are as yet not supported in eCosPro.

Tools

The SEAD3 port is intended to work with GNU tools configured for an mips-sde-elf target. The original port was done using mips-sde-elf-gcc version 4.4 mips-sde-elf-gdb version 6.8, and binutils version 2.19.

Name

Setup — Preparing the SEAD3 board for eCos Development

Overview

In a typical development environment the SEAD3 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run on the board via the debugger mips-sde-elf-gdb. Preparing the board therefore involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROMRAM	RedBoot loaded from boot flash, running in RAM	`redboot_ROMRAM.ecm`	`redboot_romram.bin`
ROM	RedBoot running from boot flash	`redboot_ROM.ecm`	`redboot_rom.bin`
JTAG	RedBoot debug	`redboot_JTAG.ecm`	`redboot.elf`

For serial communications all versions run at 115200 baud with 8 bits, no parity, and 1 stop bit. The baud rates can be changed via the **baud** RedBoot command. RedBoot will support communication on both UARTs. Ethernet communication and flash management are also supported.

Switch Setting

The LX50, LX110 and LX155 boards need the SW1 and SW2 switch banks set in order to execute code properly. These are mostly to overcome problems in the hardware or FPGA firmware.

The LX50 needs to run at 50MHz, and the SDRAM must be mapped to zero, so the switches are set as follows:

Switch	Setting
SW1[1]	ON
SW1[2]	OFF
SW1[3]	OFF
SW1[4]	ON
SW1[5]	OFF
SW1[6]	OFF
SW1[7]	OFF
SW1[8]	OFF
SW2[1]	OFF
SW2[2]	OFF
SW2[3]	ON
SW2[4]	OFF

The LX110 and LX155 also need to run at 50MHz, but the SDRAM does not need to be mapped to zero, so the switches are set as follows:

Switch	Setting
SW1[1]	ON

Switch	Setting
SW1[2]	OFF
SW1[3]	OFF
SW1[4]	ON
SW1[5]	OFF
SW1[6]	OFF
SW1[7]	OFF
SW1[8]	OFF
SW2[1]	OFF
SW2[2]	OFF
SW2[3]	OFF
SW2[4]	OFF

These settings are the defaults for the boards as delivered from MIPS and should generally not be altered.

Initial Installation

RedBoot is installed using the USB download mechanism available on the board. The reader is referred to the SEAD3 documentation for a full description; however, the following steps should suffice to install RedBoot.

Connect a USB cable between your host machine and the SEAD3 board's USB download connector.

If your host system is Windows based open "Printers and Faxes" in the Start Menu. Click on "Add a printer". Then click "Next". Select "Local printer attached to this computer". Uncheck the box that says "Automatically detect and install my Plug and Play printer". Click "Next". Select a printer port. Click on "Use the following port", and select USB001 (virtual printer port for USB). If you have previously installed a USB printer, you may see more than one USBxxx choice. You must choose the one associated with the port connected to your USB cable. If necessary, use trial and error. When you have finished click "Next". Under "Manufacturers", select "Generic". Under "Printers", select "Generic/Text Only". Click "Next".

Locate the file `redboot_ROMRAM.fl` and load into **WordPad**; make sure "Word Wrap" is turned OFF and that "Print page numbers" is unchecked in "Print Setup". Print the document to the printer set up above.

For Linux users the file can be copied to the printer using a command similar to either of the following:

-
  ```
      % cat redboot_ROMRAM.fl >/dev/usblp0
  ```

-
  ```
      % cat redboot_ROMRAM.fl >/dev/usb/lp0
  ```

It may be necessary to execute this as root, depending on the permissions on the printer device.

Disconnect the USB cable and either connect a serial cable between the board and your host or plug the USB cable into the UART1 USB adaptor socket. Run a terminal emulator (HyperTerminal, TeraTerm or minicom) at 115200 baud attached to the serial port. Power cycle the SEAD3 board and you should see output similar to this:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 00:d0:a0:00:08:1c
IP: 10.0.2.4/255.0.0.0, Gateway: 10.0.0.3
Default server: 0.0.0.0
DNS server IP: 10.0.0.1, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 14:40:05, Apr 23 2010
```

```

Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: LX110 (M14Kc) LE
RAM: 0x80000000-0x9b000000 [0x8000b8b0-0x9afbd000 available]
FLASH: 0x9c000000-0x9dffffff, 128 x 0x40000 blocks
RedBoot>
```

The exact details may vary slightly, depending on whether or not the ethernet is plugged in yet. If no ethernet cable in plugged in there may be a delay before this output completes. At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. To perform the flash initialization use the **fis init -f** command:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Unlocking from 0x9dfc0000-0x9dffffff: .
... Erase from 0x9dfc0000-0x9dffffff: .
... Program from 0x9afc0000-0x9b000000 to 0x9dfc0000: .
... Locking from 0x9dfc0000-0x9dffffff: .
RedBoot>
```

At this stage the block of flash at location 0x9dFc0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 10.0.1.1
Console baud rate: 115200
DNS domain name: xxxxxxx.com
DNS server IP address: 10.0.0.1
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlocking from 0x9dfc0000-0x9dffffff: .
... Erase from 0x9dfc0000-0x9dffffff: .
... Program from 0x9afc0000-0x9b000000 to 0x9dfc0000: .
... Locking from 0x9dfc0000-0x9dffffff: .
RedBoot>
```

For most of these configuration variables the default value is correct. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server.

Initialization is now complete. Press the board reset button and the following output should be seen:

```
+Ethernet eth0: MAC address 00:d0:a0:00:08:1c
IP: 10.0.2.4/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.1
DNS server IP: 10.0.0.1, DNS domain name: <null>

FLASH: 0x9c000000-0x9dffffff, 128 x 0x40000 blocks
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from **mips-sde-elf-gdb**, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done by repeating this process.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROMRAM version of RedBoot are:

```
$ mkdir redboot_romram
$ cd redboot_romran
$ ecosconfig new sead3_14kc redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/mips/sead3/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot_romram.fl`. This builds RedBoot for the LX155/M14Kc or LX110/M14Kc boards; to build for the LX50/M14K board substitute sead3_14k for sead3_14kc in the above.

Rebuilding the ROM and JTAG versions involves basically the same process. The ROM version uses the file `redboot_ROM.ecm` and generates an ELF executable `redboot.elf`, which will be automatically converted to `redboot_romram.fl` for flash programming. The JTAG version uses the file `redboot_JTAG.ecm` and generates an ELF executable `redboot.elf`, which may need to be converted to another format before it can be used with the JTAG software.

Note

The program that creates the `redboot_romram.fl` file is a perl script, `srecconv.pl`, that requires the `perl` command to be in your path. While this is normally available under Linux, Windows users may be required to install perl on their machine to create `redboot_romram.fl`.

Name

Configuration — Platform-specific Configuration Options

Overview

The SEAD3 platform HAL package is loaded automatically when eCos is configured for an SEAD3 target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The SEAD3 platform HAL package supports four separate startup types: RAM, ROM, ROMRAM and JTAG. The configuration option `CYG_HAL_STARTUP` controls which startup type is being used. For typical application development RAM startup should be used, and the application will be run via mips-sde-elf-gdb interacting with RedBoot using either serial or ethernet. It is assumed that the low-level hardware initialization, including setting up the memory map, has already been performed by RedBoot. By default the application will use certain services provided by RedBoot via the virtual vector mechanism, including diagnostic output, but that can be disabled via `CYGSEM_HAL_USE_ROM_MONITOR`.

ROM startup can be used for applications which are programmed into the boot flash at 0xbfc00000. On power up the processor will jump to this location and execute the code that is there. The startup code will copy the applications data segment from ROM to RAM at 0x80000000 and zero the BSS. Code execution will continue from ROM. All the hardware will be initialized, and the application is self-contained. This startup type can be used by the flash-resident version of RedBoot, and can also be used for finished applications that run stand-alone.

ROMRAM startup can be used for applications which are programmed into the boot flash at 0xbfc00000. On power up the processor will jump to this location and execute the code that is there. The startup code will copy the applications taxt and data segments from ROM to RAM at 0x80000000 and zero the BSS. Code execution will continue from RAM. All the hardware will be initialized, and the application is self-contained. This startup type can be used by the flash-resident version of RedBoot, and can also be used for finished applications that run stand-alone.

JTAG startup can be used for applications which will be debugged via JTAG instead of RedBoot. The behaviour is a combination of ROM and RAM startup: the application is loaded at 0x80000000 and initializes all the hardware, with no dependencies on services provided by a ROM monitor.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via JTAG.

If the application does not rely on a ROM monitor for diagnostic services then UART0 will be used for HAL diagnostics and standard output. The default baud rate is controlled by `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD`. If UART0 is needed by the HAL diagnostics code it cannot be accessed via the serial driver and applications should be loaded via ethernet. Diagnostic output can also be switched to using UART1 by setting `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` to 1.

System Clock

The coprocessor 0 COUNTER/COMPARE timer is used for the eCos system clock. The configuration option `CYGNUM_HAL_RTC_PERIOD` controls the value programmed into the compare register. The value of this is calculated from the CPU frequency and the value of `CYGNUM_HAL_RTC_DENOMINATOR`. The calculations are arranged so that

CYGNUM_HAL_RTC_DENOMINATOR effectively defines the clock frequency and it the only configuration option that need to be changed to select a different clock rate.

Board Type Selection

The option CYGHWR_HAL_MIPS_SEAD3 selects the SEAD3 board variant. It may be set to either LX50 or LX110. Normally this will be set automatically when selecting for the sead3_14k or sead3_14kc targets.

Endian Mode Selection

The option CYGHWR_HAL_MIPS_SEAD3_ENDIAN selects the CPU and peripheral endian mode. It may be set to either Little or Big. The default is Little. The BIGEND switch, SW2[1], needs to be set to match and if RAM applications are to be used a matching RedBoot must also be installed. Note also that the RedBoot flash directory and configuration are not stored in an endian-independent manner and would need to be reinitialized.

Instruction Set Selection

The option CYGPKG_HAL_MIPS_MICROMIPS_SUPPORT selects instruction set support. It may be set to either APP, ECOS or FULL. The default is APP which causes eCos and RedBoot to be compiled in the MIPS32 instruction set, but allows user code to be compiled in the microMIPS instruction set. When set to ECOS then all eCos/RedBoot C and C++ code is compiled into microMIPS instructions; however assembly level startup and exception handling code remains in MIPS32 instructions, as it must since the CPU starts in this instruction set, and switches to it for all exceptions. The FULL option is present for future devices that operate entirely in microMIPS mode, and is not currently supported.

Unlike endian mode, the instruction set selection of RedBoot and eCos applications need not match. A MIPS32 RedBoot can load and run microMIPS eCos applications and a microMIPS RedBoot can load and run MIPS32 applications.

To compile applications into microMIPS the standard flags that are used in eCos and exported to the ecos.mak file should be used except that the -mips32r2 flag should be replaced by -mmicromips and the options -mno-jals -minterlink-mips16 added.

Flash Driver

The platform HAL package contains flash driver support for the user flash device. By default this is inactive, and it can be made active by loading the generic flash package CYGPKG_IO_FLASH. The boot flash is not programmable at runtime.

Ethernet Support

The platform HAL provides the platform-specific support for a single SMSC LAN9211 ethernet device, if the generic ethernet support is enabled. The MAC address is stored in an EEPROM connected to the LAN9211 and will be loaded into the MAC automatically on reset.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are some flags specific to this port:

-mips32r2

> The mips-sde-elf-gcc toolchain defaults to supporting the mips32 release 2 architecture, so this option is not strictly necessary. However, it is good practice to include it.

`-mmicromips`

To compile code in the microMIPS instruction set, this option must be substituted for `-mips32r2`.

`-mno-jals` `-minterlink-mips16`

These options are necessary to link MIPS32 code with microMIPS code. They both restrict the compiler to generating instructions for calls and other control transfers that can be converted to instructions that switch the instruction set. Without these options some instructions either cannot be converted, or will be converted incorrectly.

`-G0`

MIPS calling conventions reserve one register for use as a global pointer register. In theory this allows static variables in one 64K area of memory to be accessed using just one instruction instead of two, and the `-G` option provides some control over this. However due to limitations within the current linker all modules have to be compiled with the same `-G` setting, and the compiler support libraries are built with `-G0`. Therefore all eCos and application modules also have to be built with `-G0` and this optimization is not available.

`-EB, EL`

The eCos port supports both big-endian and little-endian modes.

`-msoft-float`

The M14K family does not have a hardware floating point unit so software floating point has to be used instead.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the SEAD3 hardware, and should be read in conjunction with that specification. The SEAD3 platform HAL package complements the MIPS architectural HAL, the MIPS32 variant HAL It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will set up some of the peripherals (UART, GIC, LCD etc.) appropriately for eCos, but other peripherals (USB, PIC32) are left to their default settings. Full details of this initialization can be found in the function `hal_platform_init` in `sead3.c`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

On the LX110/LX155 this is 512MiB in size and mapped to location 0x80000000. The first four kilobytes are reserved for exception vectors and for data which needs to be shared between RAM startup applications and the ROM monitor. For JTAG startup, code will be loaded from 0x80001000 onwards. For ROM startup data will be loaded from 0x80001000 onwards. For ROMRAM startup, the text and data of the applications will be loaded from 0x80001000 onwards. For RAM startup, code will start at 0x80040000, reserving the bottom 256KiB for RedBoot's code and data. This memory is not present on the LX50.

SRAM

On the LX50 this is 4MiB in size and is mapped to location 0x80000000. The first four kilobytes are reserved for exception vectors and for data which needs to be shared between RAM startup applications and the ROM monitor. For JTAG startup, code will be loaded from 0x80001000 onwards. For ROM startup data will be loaded from 0x80001000 onwards. For ROMRAM startup, the text and data of the applications will be loaded from 0x80001000 onwards. For RAM startup, code will start at 0x80040000, reserving the bottom 256KiB for RedBoot's code and data. This memory is present on the LX110/LX155, where it is mapped to 0x1E000000 and is unused by eCos.

On-chip Peripherals

These are accessible at location 0xBF000000 onwards.

Flash

The user flash device is located at 0x9C000000 onwards. CFI is used at run-time to query the flash chip and adapt to it. Redboot is not held in this flash device, but in a separate boot flash that is not accessible at run time. The last user flash block at location 0x9DFC0000 is used to hold flash management data and the RedBoot **fconfig** variables. The remaining blocks can be used by application code.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the architectural COUNTER/COMPARE registers accessed via coprocessor 0. The actual HAL macros for managing the clock are provided by the MIPS architectural HAL. The specific numbers used are a characteristic of the platform because they depend on the processor speed. If the interrupt controller is present, its compare register and interrupt is used for profiling.

Other Issues

The SEAD3 platform HAL does not affect the implementation of other parts of the eCos HAL specification.

Name

JTAG Debugging — Using System Navigator

Overview

The SEAD 3 board can be debugged using the System Navigator JTAG probe. This consists of the probe itself plus the Navigator Console software. The Navigator Console should be installed onto your host system according to the "MIPS Navigator Console Getting Started Guide". To do this you need to obtain a license from MIPS. For Linux users, the Navigator Console version 4.0.16 currently only installs on RedHat Enterprises Linux. Once the console software is installed, connect the System Navigator to the host.

Setup for standard eCosPro GNU tools

To use the System Navigator from GDB, the Navigator Console must be started independently. The Navigator Console must be supplied with a startup script which can be chosen at startup, or supplied on the command line. Choose either `mips_m14k.tcl` for the LX150, or `mips_m14kc.tcl` for the LX110/LX155. When started correctly, the console window will appear and show something similar to the following:

```
Main console display active (Tcl8.5.6 / Tk8.5.6)
mips_m14k initialization successful.
(scripts) 1 %
```

In addition, for Linux you should add the path to the Navigator Console binaries directory to your library load path. For example, add the following line to your `.bashrc`:

```
export LD_LIBRARY_PATH=~/MIPS/NavigatorConsole/bin:$LD_LIBRARY_PATH
```

Download and install the Sourcery CodeBench Lite tools for MIPS ELF. It is sufficient to just download the TAR archive as this download is solely required to obtain the **mips-sde-elf-sprite** tool. Place the "bin" directory for those tools (containing **mips-sde-elf-sprite**) in your shell's PATH environment variable, making sure it comes *after* the PATH component for the eCosPro GNU tools so that the eCosPro tools are still preferred.

Connect to the target from GDB by using the following connection command at the GDB console:

```
(gdb) target remote | mips-sde-elf-sprite -q -a 'mdi:/1/1?rst=5&lib=/home/USER/MIPS/NavigatorConsole/bin/libsysnav_mdi
```

Substitute in the correct location for the `libsysnav_mdi.so` as required.

Consult the Navigator Console documentation `NavConGdbGuide.pdf` for further guidance on use with GDB.

Setup for CodeSourcery tools

While eCosCentric no longer recommend using the CodeSourcery tools (other than to obtain the **mips-sde-elf-sprite** tool), this documentation has been preserved in case some users decide they do wish to use those tools.

To use the System Navigator from GDB, the Navigator Console must be started independently. The Navigator Console must be supplied with a startup script which can be chosen at startup, or supplied on the command line. Choose either `mips_m14k.tcl` or `mips_m14kc.tcl` for the LX50 and LX110 respectively. When started correctly, the console window will appear and show something similar to the following:

```
Main console display active (Tcl8.5.6 / Tk8.5.6)
mips_m14k initialization successful.
(scripts) 1 %
```

To use the System Navigator from GDB, GDB must be supplied with the name of a dynamic library to load, and the location to load it from. This is best done from a `.gdbinit` file. For Window this should contain:

```
set mdi library C:\MIPS\NavigatorConsole\bin\sysnav_mdi.dll
set mdi target 1
set mdi connectreset 7
```

And for Linux:

```
set mdi library libsysnav_mdi.so
set mdi connectreset 7
set mdi target 1
```

In addition, for Linux you should add the path to the Navigator Console binaries directory to your library load path. For example, add the following line to your `.bashrc`:

```
export LD_LIBRARY_PATH=~/MIPS/NavigatorConsole/bin:$LD_LIBRARY_PATH
```

With these files set up it should be possible to start GDB and connect by giving the following command:

```
(gdb) target mdi 1:1
Selected device jtagindex-0 on MIPS mips_m14k
Connected to MDI target
(gdb)
```

GDB should now be ready to download and debug a JTAG startup application.

Chapter 335. MIPS Malta Board Support

Name

eCos Support for the Malta Board — Overview

Description

This document covers the MIPS Malta single board computer based on the MIPS 4Kc, 4KEc and 5Kc processors. Suport for the 5Kc is restricted to RedBoot only, however, all 4Kc configurations of eCos and RedBoot will also function on a 5Kc.

The Malta board contains the processor, 32Mb of RAM, 4MB of flash memory, an AMD Am79C973 PCnet ethernet MAC, connections for two serial channels and the various other peripherals on the board.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of two Intel 28F160 devices in parallel, giving 32 blocks of 128k bytes each. In a typical setup, the first two flash blocks are used for the ROM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining 29 blocks between 0xbe040000 and 0xbe3dffff can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_GENERIC_16X5X` which supports the two UART serial devices on the Malta board. This is configured for the Malta by the `CYGPKG_IO_SERIAL_MIPS_MALTA` package. These devices can be used by RedBoot for communication with the host. If either of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the Malta target.

There is an ethernet driver `CYGPKG_DEVS_ETH_AMD_PCNET` for the AMD Am79C973 PCnet ethernet device. A second package `CYGPKG_DEVS_ETH_MIPS_MIPS32_MALTA` is responsible for configuring this generic driver to the Malta hardware. These drivers are also loaded automatically when configuring for the Malta target.

eCos manages the on-chip interrupt controller. The MIPS32 architectural Count and Compare registers are used to implement the eCos system clock and the microsecond delay function. Other devices (Caches, PCI, UARTs, memory and interrupt controllers) are initialized only as far as is necessary for eCos to run. Other devices are not touched.

Tools

The Malta port is intended to work with GNU tools configured for an mipsisa32-elf target. The original port was undertaken using mipsisa32-elf-gcc version 3.2.1, mipsisa32-elf-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing the Malta board for eCos Development

Overview

In a typical development environment, the Malta board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **mipsisa32-elf-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
RAM	RedBoot running from RAM, usually loaded by another version of RedBoot	`redboot_RAM.ecm`	`redboot_RAM.bin`
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. RedBoot also supports ethernet communication and flash management.

Initial Installation

Installing RedBoot is a matter of downloading a new binary image and overwriting the existing Boot monitor ROM image.

RedBoot is installed using the code download facility built into the Malta board. See the Malta User manual for details.

Quick Download Instructions

Here are quick start instructions for downloading the prebuilt RedBoot image.

1. Locate the prebuilt files in the bin directory: `deleteall.fl` and `redboot_ROM.fl`.
2. Make sure switch S5-1 is ON. Reset the board and verify that the LED display reads `Flash DL`.
3. Make sure your parallel port is connected between the 1284 port of the Malta board and the parallel port of your host system.
4. Send the `deleteall.fl` file to the parallel port to erase previous images:

   ```
   $ cat deleteall.fl >/dev/lp0
   ```

   When this is complete, the LED display should read `Deleted`.
5. Send the RedBoot image to the board:

   ```
   $ cat redboot_ROM.fl >/dev/lp0
   ```

   When this is complete, the LED display should show the last address programmed. This will be something like: `1fc17000`.
6. Connect a serial cable between one of the Malta board serial ports and a serial port on your host. Use a terminal emulator to monitor the serial port (HyperTerminal on Windows or minicom on Linux).
7. Change switch S5-1 to OFF and reset the board. The LED display should read `RedBoot` and something similar to the following should be output on the serial port:

   ```
   No devices on IDE controller 0
   ```

```
No devices on IDE controller 1
... waiting for BOOTP information
Ethernet eth0: MAC address 00:d0:a0:00:01:cb
IP: 10.0.0.203/255.255.255.0, Gateway: 10.0.0.3
Default server: 10.0.0.1, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 15:01:37, Oct 20 2004

Platform: Malta (MIPS32 4Kc)

Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x80000400-0x82000000, [0x8000cc40-0x81ed1000] available
FLASH: 0xbe000000 - 0xbe400000, 32 blocks of 0x00020000 bytes each.
RedBoot>
```

8. Run the RedBoot **fis init** and **fconfig** commands to initialize the flash.

Malta Download Format

In order to download RedBoot to the Malta board, it must be converted to the Malta download format.

The *Atlas/Malta Developer's Kit* CD contains an srecconv.pl utility which requires Perl. This utility is part of the `yamon/yamon-src-02.00.tar.gz` tarball on the Dev Kit CD. The path in the expanded tarball is `yamon/bin/tools`. To use srecconv to convert the S-record file:

```
$ cp redboot_ROM.srec redboot_ROM.rec
$ srecconv.pl -ES L -A 29 redboot_ROM
```

The resulting file is named `redboot_ROM.fl`.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot for the Malta are:

```
$ mkdir redboot_malta_rom
$ cd redboot_malta_rom
$ ecosconfig new malta redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/mips/malta/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.srec`. This can then be converted into the download format by using the srecconv program as described above.

Additional commands

The **exec** command which allows the loading and execution of Linux kernels, is supported for this architecture. The **exec** parameters used for MIPS boards are:

-b *<addr>*	Location to store command line and environment passed to kernel
-w *<time>*	Wait time in seconds before starting kernel
-c *"params"*	Parameters passed to kernel
<addr>	Kernel entry point, defaulting to the entry point of the last image loaded

Linux kernels on MIPS platforms expect the entry point to be called with arguments in the registers equivalent to a C call with prototype:

```
void Linux(int argc, char **argv, char **envp);
```

RedBoot will place the appropriate data at the offset specified by the *-b* parameter, or by default at address 0x80080000, and will set the arguments accordingly when calling into the kernel.

The default entry point, if no image with explicit entry point has been loaded and none is specified, is 0x80000750.

Other Issues

The Malta platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MIPS32 variant HAL, and the MIPS architectural HAL documentation should be consulted for further details.

Name

Configuration — Platform-specific Configuration Options

Overview

The Malta platform HAL package is loaded automatically when eCos is configured for a `malta` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Target Selection

The exact processor type is determined by the target selected during configuration. The following targets are currently supported:

malta_mips32_4kc	Board fitted with 4Kc core card.
malta_mips32_4kec	Board fitted with 4KEc core card.
malta_mips32_5kc	Board fitted with 5Kc core card. This will only support a RedBoot configuration.

Startup

The Malta platform HAL package supports two startup types:

RAM

> This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. mipsisa32-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM

> This startup type can be used for finished applications which will be programmed into flash at physical address 0xbe000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The Malta board contains two 16 bit Intel 28F160 flash devices arranged in parallel to form a 32 bit wide interface. The `CYGPKG_DEVS_FLASH_INTEL_28FXXX` package contains all the code necessary to support these parts and the `CYGPKG_DEVS_FLASH_MALTA` package contains definitions that customize the driver to the Malta board.

Ethernet Driver

The Malta board contains an AMD Am79C973 PCnet ethernet MAC. The `CYGPKG_DEVS_ETH_AMD_PCNET` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_MIPS_MIPS32_MALTA` package contains definitions that customize the driver to the Malta board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

`-mips32`

The mipsisa32-elf-gcc compiler supports many variants of the MIPS architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mips32` is the correct option for the 4Kc and 4KEc processors.

`-mips64`

If the board is populated with a 5Kc processor, then RedBoot may be built with 64 bit support. In that case, stand-alone applications may be built with the `-mips64` option. This option is not currently supported by eCos applications.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Malta hardware, and should be read in conjunction with that specification. The Malta platform HAL package complements the MIPS architectural HAL and the MIPS32 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize the peripherals that it uses. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the memory controller and PCI bridge and programming the various internal registers. This is done in the assembler macros defined in the `arch.inc`, `variant.inc` and `platform.inc` headers and in the `hal_platform_init()` function in `plf_misc.c`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The MMU is not enabled for this platform, however, the normal MIPS segment address translations are present. The key memory locations are as follows.

NOTE

The virtual memory maps in this section use a C and B column to indicate whether or not the region is cached (C) or buffered (B).

```
Virtual Address Range   C B  Description
----------------------- - -  -----------
0x80000000 - 0x81ffffff Y Y  SDRAM
0x9e000000 - 0x9e3fffff Y N  System flash (cached)
0x9fc00000 - 0x9fffffff Y N  System flash (mirrored)
0xa8000000 - 0xb7ffffff N N  PCI Memory Space
0xb4000000 - 0xb40fffff N N  Galileo System Controller
0xb8000000 - 0xb80fffff N N  Southbridge / ISA
0xb8100000 - 0xbbdfffff N N  PCI I/O Space
0xbe000000 - 0xbe3fffff N N  System flash (noncached)
0xbf000000 - 0xbfffffff N N  Board logic FPGA
```

MIPS16 Support

The Malta platform HAL enables MIPS16 support in the architecture HAL for those Core boards that contain capable processors. This allows *application* code to be compiled using MIPS16 options and linked against the 32 bit mode eCos library.

To compile for MIPS16 the standard flags that are used in eCos and exported to the `ecos.mak` file should be used except that the `-mips32` flag should be replaced by `-mips16 -fwritable-strings`. The `-mips16` option enables MIPS16 compilation and the `-fwritable-strings` option is a work-around for a bug in the compiler.

Chapter 336. NXP PNX83xx Common Support

Name

`CYGPKG_HAL_MIPS_PNX83xx` — eCos Support for NXP PNX83xx Processors

Description

The NXP PNX83xx family is a range of processors including the PNX8310 and PNX8330. This package provides support for features that are common across the range. For example the PNX8310 and PNX8330 use similar UARTs, so the device definitions are provided by this package rather than duplicated in the two processor HAL packages. Similarly HAL diagnostics support using these UARTs is provided here.

Configuration

The PNX83xx common HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The package does not contain any configuration options.

Chapter 337. NXP PNX8310 Processor Support

Name

CYGPKG_HAL_MIPS_PNX8310 — eCos Support for the NXP PNX8310 Processor

Description

The NXP PNX8310 processor is based around a PR1910 MIPS core, complemented by a range of on-chip peripherals. The HAL package CYGPKG_HAL_MIPS_PNX8310 provides the processor-specific support, combining the functionality of an eCos variant HAL and processor HAL. It complements the MIPS architectural HAL package CYGPKG_HAL_MIPS, and the PNX83xx support package CYGPKG_HAL_MIPS_PNX83xx which contains support for features common to several members of the PNX83xx family. An eCos configuration should also include a platform HAL package to support board-level details like the memory chips and off-chip peripherals.

Configuration

The PNX8310 HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The package does not contain any user-settable options.

The HAL Port

This section describes how the PNX8310 HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

HAL I/O

The header file cyg/hal/var_io.h provides definitions of all on-chip peripherals, except for some UART definitions which are provided by the PNX83xx support HAL instead. This header file is automatically included by the architectural header cyg/hal/hal_io.h, so typically application code and other packages will just include the latter. The register addresses are all in kseg1 so will be accessed uncached.

Interrupt Handling

The header file cyg/hal/var_intr.h provides ISR vector numbers for all interrupt sources, for example CYGNUM_HAL_ISR_I2C0 and CYGNUM_HAL_ISR_PIO_1. These vector numbers should be used for calls like cyg_interrupt_create. The header file is automatically included by the architectural header cyg/hal/hal_intr.h, and other packages and application code will normally just include the latter.

The interrupt vectors come in three groups. There are three vectors for the timers implemented by the PR1910 core's coprocessor 0. There are 20 vectors for the other on-chip peripherals, managed by the priority interrupt controller. One of these, CYGNUM_HAL_ISR_PIO is reserved for use by the HAL's interrupt decoding code to detect PIO interrupts. Finally there are 16 vectors for interrupts on the PIO pins.

The eCos HAL macros HAL_INTERRUPT_MASK, HAL_INTERRUPT_UNMASK, HAL_INTERRUPT_ACKNOWLEDGE, HAL_INTERRUPT_CONFIGURE and HAL_INTERRUPT_SET_LEVEL are implemented by the processor HAL. The implementations depend on the interrupt vector. HAL_INTERRUPT_ACKNOWLEDGE is only needed for PIO interrupts, otherwise it is a no-op. HAL_INTERRUPT_CONFIGURE is also only relevant for PIO interrupts.

Interrupt priorities should be in the range 1 to 14, and correspond to the *int_priority* fields in the pic_int_reg registers. 1 is the lowest priority and 14 the highest. Interrupt priorities are ignored for the three timer interrupts. All PIO interrupt sources operate at the same priority, which is the highest priority assigned to any of the PIO vectors.

Interrupt chaining via the common HAL's configuration option CYGIMP_HAL_COMMON_INTERRUPTS_CHAIN is supported for PIO interrupts only. This makes it possible to connect several external peripherals' interrupt lines to a single PIO pin if desired.

Clock Support

The PR1910 core provides three timers, TMR1, TMR2 and TMR3. TMR1 is used for the eCos system clock. TMR2 is used for gprof-based profiling if enabled, otherwise it can be used by the application. TMR3 is normally used only for the watchdog device driver.

Cache Handling

The PNX8310 has an 8K unified cache, which is automatically initialized and enabled by the eCos startup code. The standard macros `HAL_UCACHE_INVALIDATE_ALL` and `HAL_UCACHE_SYNC` are supported, and both the DCACHE and ICACHE variants are just mapped on to these. Working ENABLE, DISABLE and IS_ENABLED macros are provided as well but these are not generally useful on a MIPS processor.

Profiling Support

The PNX8310 HAL provides a profiling timer for use with the gprof profiling package. This uses the PR1910 coprocessor 0 timer TMR2, so application code should not manipulate this timer if profiling is enabled. The MIPS architectural HAL implements the `mcount` function so profiling is fully supported on all PNX8310-based platforms.

Linker Script

During a build the PNX8310 HAL provides a linker script suitable for use with all C and C++ applications. This also allows parts of the application code and data to be placed in the on-chip deeply embedded memory, using ELF linker sections `.dem_text` for code, `.dem_data` for statically initialized data, and `.dem_bss` for uninitialized data. The `dem1.c` testcase in this package illustrates how to use this functionality.

Other Issues

The `HAL_PLATFORM_RESET` is implemented via the PNX8310's system reset unit, and involves a full reset of the core and all peripherals. Hence, whenever a soft reset is performed by the application or via a gdb command, the system should start up again in a clean state, and there is no need for the system to reinitialize all the peripherals.

The PNX8310 HAL does not affect the implementation of data types, stack size definitions, bit indexing, idle thread processing, SMP support, system startup, or debug support.

Other Functionality

The PNX8310 processor HAL only implements functionality defined in the eCos HAL specification and does not export any additional functions.

Chapter 338. NXP STB200 Board Support

Name

eCos Support for the NXP STB200 Board — Overview

Description

The NXP STB200 board has a PNX8310 processor, 16MB of external SDRAM, 4MB of external flash, an SMSC LAN9118 ethernet chip, and connectors plus required support chips for various on-chip peripherals. For typical eCos development a RedBoot image is programmed into the external flash. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The memory map used by both eCos and RedBoot is as follows:

Memory	Base	Length
External SDRAM	0x80000000	0x01000000
External Flash	0x98000000	0x00400000
Internal RAM	0xA4000000	0x00001000
On-chip Peripherals	0xB7000000	0x00200000
SMSC LAN9118	0xBA000000	0x02000000

External SDRAM and flash are normally accessed via the kseg0 segment and hence via the cache. The internal RAM and the peripherals are normally accessed via kseg1 and hence uncached. Accesses to the on-chip RAM are as fast as cache accesses so there is no point in going through the cache for those.

eCos can be configured for one of three startup types:

RAM

> This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. mipsisa32-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output. The bottom 256K of RAM is used for RedBoot code and data so the application will start at 0x80040000.

ROMRAM

> This startup type can be used for finished applications which will be programmed into the start of external flash at location 0xB8000000. On power-up the chip's bootloader will automatically load the application into RAM at location 0x80001000 and start it. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

JTAG

> This can be used to run applications via JTAG rather than RedBoot. As with ROMRAM startup, the application will be loaded at location 0x80001000 and it will take over all the hardware. Uart1 will be used for all HAL diagnostics and standard output. A JTAG build of RedBoot can be used during hardware setup to program the ROMRAM version into flash. A JTAG application build may prove useful for debugging certain problems, especially ones related to interrupts and exceptions. However the JTAG software may not fully cope with the executables and debug information generated by the GNU tools, so the user experience may be poor compared with using the GNU mipsisa32-elf-gdb debugger.

In a typical setup the first 128K of flash is used for holding the RedBoot image, and the last 64K is used for managing the flash and holding the RedBoot fconfig values. The remaining blocks from 0x98020000 to 0x983EFFFF can be used by application code.

RedBoot can communicate with the host using either uart1 or ethernet. The PNX8310's uart0 is not connected on this board.

All configurations for the STB200 target include an ethernet driver package `CYGPKG_DEVS_ETH_SMSC_LAN9118`. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package `CYGPKG_IO_ETH_DRIVERS`. Typically the choice of eCos template causes the right thing to happen. For example, the default template does not include any TCP/IP stack so `CYGPKG_IO_ETH_DRIVERS` is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver. The ethernet device can be shared by RedBoot and the application, so it is possible to debug a networked application over ethernet.

The STB200 board does not have a serial EPROM or similar hardware providing a unique network MAC address. Instead a suitable address has to be programmed into flash via RedBoot's **fconfig** command.

All configurations for the STB200 target include a serial device driver package `CYGPKG_DEVS_SERIAL_MIPS_PNX8310`. The driver as a whole is inactive unless the generic serial support, `CYGPKG_IO_SERIAL_DEVICES` is enabled. Only uart1 has a suitable connector so that is the only device which can be accessed through the serial driver. The hardware flow control lines are not connected so only software flow control is available. If the UART is needed by the application then it cannot also be used by RedBoot for gdb traffic, so another communication channel such as ethernet should be used instead.

All configurations for the STB200 target include a watchdog device driver package `CYGPKG_DEVS_WATCHDOG_MIPS_PNX8310`. This is inactive unless the generic watchdog support, `CYGPKG_IO_WATCHDOG` is loaded.

The on-chip interrupt controller is managed by eCos using macros provided by the PNX8310 processor HAL. The on-chip timer TMR1 is used to implement the eCos system clock. If gprof-based profiling is enabled then that will use TMR2, otherwise that timer can be used by the application. TMR3 is normally used only by the watchdog device driver. GPIO pins 17 and 18 are used for uart1, and pin 14 is used for ethernet interrupts. The remaining GPIO pins are not used by eCos. Other on-chip peripherals are left to their initial settings and not manipulated by eCos.

Tools

The STB200 port is intended to work with GNU tools configured for an mipsisa32-elf target. The original port was done using mipsisa32-elf-gcc version 3.4.4 mipsisa32-elf-gdb version 6.3, and binutils version 2.16. The PNX8310's PR1910 core does not implement the full mips32 functionality so all application code should be compiled with `-mips2`.

Name

Setup — Preparing the STB200 board for eCos Development

Overview

In a typical development environment the STB200 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run on the board via the debugger mipsisa32-elf-gdb. Preparing the board therefore involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	**Description**	**Use**	**File**
ROM	RedBoot running from the board's flash	`redboot_ROMRAM.ecm`	`redboot_romram.bin`
JTAG	Used for initial setup	`redboot_JTAG.ecm`	`redboot.elf`
RAM	For debugging RedBoot	`redboot_RAM.ecm`	`redboot_ram.bin`

For serial communications all versions run at 384000 baud with 8 bits, no parity, and 1 stop bit. The baud rates can be changed via the configuration option `CYGNUM_HAL_MIPS_STB200_DIAG_BAUD` and rebuilding RedBoot. Only uart1 has a serial connector so RedBoot will use that. Ethernet communication and flash management are also supported.

Initial Installation

This process assumes that RedBoot has not yet been installed into flash, so JTAG has to be used to program the `redboot_romram.bin` file into flash. This can be done either via a flash programming utility or by first running a JTAG version of RedBoot and using that to initialize and program the flash. This second approach is described here.

The first step is to set up a suitable JTAG module and associated debug software, as per the instructions supplied with the JTAG kit. Next connect a straight-throught RS232 cable between the STB200's serial port and the host PC, and start a terminal emulation application such as HyperTerminal or minicom on the host PC. The serial communication parameters should be 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking).

It is now necessary to load and run a JTAG build of RedBoot. A prebuilt image `redboot_JTAG.elf` is supplied with eCos, or can be rebuilt as described below. This file is an ELF executable complete with relocation and debug information, and may need to be converted to another format for use with the JTAG software. For example, when using an Ashling Opella unit, the SymFinder utility sfdwarf should be used to convert the ELF executable to a `.CSO` file. This utility may give numerous warnings which can be ignored. The `.CSO` file can be loaded via the JTAG debugger, and it can be started running at location 0x80001000. At this point RedBoot will output text similar to the following on the serial port:

```
+FLASH configuration checksum error or invalid key
Ethernet eth0: MAC address 00:FF:12:34:56:78
... waiting for BOOTP information
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [JTAG]
Non-certified release, version UNKNOWN - built 20:35:11, Sep 29 2005

Platform: STB200 (Philips PNX8310)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005 eCosCentric Limited

RAM: 0x80000000-0x81000000, [0x80028720-0x80fed000] available
FLASH: 0x98000000 - 0x983fffff 8 x 0x2000 blocks 63 x 0x10000 blocks
RedBoot>
```

The exact details may vary slightly, depending on the flash chip present and whether or not the ethernet is plugged in yet. At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. There will also be a delay while RedBoot tries to contact a local BOOTP server. To perform the flash initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x983f0000-0x983fffff: .
... Program from 0x80ff0000-0x81000000 to 0x983f0000: .
RedBoot>
```

At this stage the block of flash at location 0x983F0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 10.1.1.1
GDB connection port: 9000
Force console for special debug messages: false
Network hardware address [MAC]: 0x00:0xff:0x12:0x34:0x01:0x0C
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x983f0000-0x983fffff: .
... Program from 0x80ff0000-0x81000000 to 0x983f0000: .
RedBoot>
```

For most of these configuration variables the default value is correct. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled, and instead RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server. The other exception is the network hardware address, also known as MAC address. All boards should be given a unique MAC address, not the one in the above example. If there are two boards on the same network trying to use the same MAC address then the resulting behaviour is undefined.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The file `redboot_romram.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
CRaw file loaded 0x80028800-0x8004568f, assumed entry at 0x80028800
xyzModem - CRC mode, 930(SOH)/0(STX)/0(CAN) packets, 5 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x98000000-0x9801ffff: .........
... Program from 0x80028800-0x80048800 to 0x98000000: .........
... Erase from 0x983f0000-0x983fffff: .
... Program from 0x80ff0000-0x81000000 to 0x983f0000: .
RedBoot>
```

The flash-resident version of RedBoot has now been programmed at location 0x98000000, and the flash info block at 0x983F0000 has been updated. The initial setup is now complete and the board can now boot from flash. This can be done either by powering the board down and back up, or simply by using RedBoot's **reset** command:

```
RedBoot> reset
... Resetting.+... waiting for BOOTP information
```

```
Ethernet eth0: MAC address 00:ff:12:34:01:0c
IP: 10.1.1.153/255.255.255.0, Gateway: 10.1.1.241
Default server: 10.1.1.1

RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 12:46:19, Oct  2 2005

Platform: STB200 (Philips PNX8310)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005 eCosCentric Limited

RAM: 0x80000000-0x81000000, [0x800288e0-0x80fed000] available
FLASH: 0x98000000 - 0x983fffff 8 x 0x2000 blocks 63 x 0x10000 blocks
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from mipsisa32-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done at the ROMRAM RedBoot prompt - there is no need to run the JTAG version again unless the version already installed has been corrupted. It involves loading the new image into RAM using RedBoot's **load** command, and then programming it into flash using **fis create RedBoot**

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROMRAM version of RedBoot are:

```
$ mkdir redboot_romram
$ cd redboot_romram
$ ecosconfig new stb200 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/mips/pnx83xx/pnx8310/stb200/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot_romram.bin`.

Rebuilding the JTAG and RAM versions involves basically the same process. The JTAG version uses the file `redboot_JTAG.ecm` and generates an ELF executable `redboot.elf`, which may need to be converted to another format before it can be used with the JTAG software. The RAM version uses the file `redboot_RAM.ecm` and generates a raw binary `redboot.ram.bin` which can be loaded into memory at 0x80040000 and executed from there.

Name

Configuration — Platform-specific Configuration Options

Overview

The STB200 platform HAL package is loaded automatically when eCos is configured for an STB200 target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STB200 platform HAL package supports three separate startup types: RAM, ROMRAM and JTAG. The configuration option `CYG_HAL_STARTUP` controls which startup type is being used. For typical application development RAM startup should be used, and the application will be run via mipsisa32-elf-gdb interacting with RedBoot using either serial or ethernet. It is assumed that the low-level hardware initialization, including setting up the memory map, has already been performed by RedBoot. By default the application will use certain services provided by RedBoot via the virtual vector mechanism, including diagnostic output, but that can be disabled via `CYGSEM_HAL_USE_ROM_MONITOR`.

ROMRAM startup can be used for applications which are programmed into the base of flash at 0x98000000. On power up the chip's boot loader will load the first 8K of code from flash to RAM at 0x80001000 and branch to that location. The startup code will copy the remainder of the application from flash to RAM, and subsequently the flash will not be used for executing any code. All the hardware will be initialized, and the application is self-contained. This startup type is used by the flash-resident version of RedBoot, and can also be used for finished applications.

JTAG startup can be used for applications which will be debugged via JTAG instead of RedBoot. The behaviour is mostly the same as for ROMRAM startup: the application is loaded at 0x80001000 and initializes all the hardware, with no dependencies on services provided by a ROM monitor. There are some minor differences in the startup code, for example it is not necessary to copy the remainder of the application from flash to RAM.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via BDM.

If the application does not rely on a ROM monitor for diagnostic services then uart1 will be used for HAL diagnostics and standard output. The default baud rate is controlled by `CYGNUM_HAL_MIPS_STB200_DIAG_BAUD`. The board does not have a connector for uart0 so that cannot be used instead. Since uart1 is needed by the HAL diagnostics code it cannot be accessed via the serial driver.

System Clock

The coprocessor 0 TMR1 timer is used for the eCos system clock. The configuration option `CYGNUM_HAL_RTC_PERIOD` controls the value programmed into the compare register. TMR1 ticks at 120MHz so the default value of 1200000 corresponds to a 100Hz system clock or one tick per 10ms. Other clock-related settings are recalculated automatically if the period is changed.

Flash Driver

The platform HAL package contains flash driver support for the external flash device. By default this is inactive, and it can be made active by loading the generic flash package `CYGPKG_IO_FLASH`. The board may use one of a variety of flash chips. The exact type present is determined at run-time using CFI and the system will adjust accordingly.

Ethernet Support

The platform HAL provides the platform-specific support for a single SMSC LAN9118 ethernet device, if the generic ethernet support is enabled. The configuration `CYGNUM_HAL_MIPS_STB200_ETH_ISR_PRIORITY` provides control over the interrupt priority used for this device. The board does not have a suitable EEPROM so the MAC address is provided via a RedBoot fconfig option.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are four flags specific to this port:

`-mips2`

The mipsisa32-elf-gcc toolchain defaults to supporting the mips32 architecture, and the PNX8310's PR1910 core does not fully implement this. Specifying `-mips2` restricts the compiler to using a subset of the mips32 instruction set appropriate for the PR1910.

`-G0`

MIPS calling conventions reserve one register for use as a global pointer register. In theory this allows static variables in one 64K area of memory to be accessed using just one instruction instead of two, and the `-G` option provides some control over this. However due to limitations within the current linker all modules have to be compiled with the same `-G` setting, and the compiler support libraries are built with `-G0`. Therefore all eCos and application modules also have to be built with `-G0` and this optimization is not available.

`-EB`

The eCos port only supports big-endian mode so `-EB` must be specified.

`-msoft-float`

The PR1910 does not have a hardware floating point unit so software floating point has to be used instead.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STB200 hardware, and should be read in conjunction with that specification. The STB200 platform HAL package complements the MIPS architectural HAL, the PNX8310 variant HAL, and the PNX83xx support HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will set up some of the on-chip peripherals appropriately for eCos, but most peripherals are left to their default settings. Full details of this initialization can be found in the function `hal_platform_init` in `stb200.c`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External SDRAM
: This is mapped to location 0x80000000. The first four kilobytes are reserved for exception vectors and for some data which needs to be shared between RAM startup applications and the ROM monitor. For ROMRAM or JTAG startup, code will be loaded from 0x80001000 onwards. For RAM startup, code will start at 0x80040000, reserving the bottom 256K for RedBoot's code and data.

Internal RAM
: The 4K of deeply-embedded internal RAM is mapped at location 0xA4000000. Neither eCos nor RedBoot use this so all of it is available to the application. The PNX8310 variant HAL documentation explains how to map code or data into this memory.

On-chip Peripherals
: These are accessible at location 0xB7000000 onwards.

External Flash
: This is located at location 0x98000000 onwards. Different STB200 boards may come with different flash chips so CFI is used at run-time to query the flash chip and adapt. Typically the first 128K of flash at location 0x98000000 is used to hold RedBoot, and the last flash block at location 0x983F0000 is used to hold flash management data and the RedBoot **fconfig** variables. The remaining blocks can be used by application code.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer TMR1, part of the PR1910 core and is accessed via coprocessor 0. The actual HAL macros for managing the clock are provided by the PNX8310 variant HAL. The specific numbers used are a characteristic of the platform because they depend on the processor speed. TMR2 is used by the gprof-based profiling code, or is available for application use when profiling is not enabled. TMR3 is normally used only for the watchdog.

MIPS16 Support

The STB200 platform HAL enables MIPS16 support in the architecture HAL. This allows *application* code to be compiled using MIPS16 options and linked against the 32 bit mode eCos library.

To compile for MIPS16 the standard flags that are used in eCos and exported to the `ecos.mak` file should be used except that the `-mips2` flag should be replaced by `-mips16 -fwritable-strings`. The `-mips16` option enables MIPS16 compilation and the `-fwritable-strings` option is a work-around for a bug in the compiler.

Other Issues

The STB200 platform HAL does not affect the implementation of other parts of the eCos HAL specification.

Chapter 339. NXP PNX8330 Processor Support

Name

CYGPKG_HAL_MIPS_PNX8330 — eCos Support for the NXP PNX8330 Processor

Description

The NXP PNX8330 processor is based around a 4KEc MIPS32 core, complemented by a range of on-chip peripherals. The HAL package CYGPKG_HAL_MIPS_PNX8330 provides the processor-specific support. It complements the MIPS architectural HAL package CYGPKG_HAL_MIPS, the MIPS32 variant package CYGPKG_HAL_MIPS_MIPS32 and the PNX83xx support package CYGPKG_HAL_MIPS_PNX83xx which contains support for features common to several members of the PNX83xx family. An eCos configuration should also include a platform HAL package to support board-level details like the memory chips and off-chip peripherals.

Configuration

The PNX8330 HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The package does not contain any user-settable options.

The HAL Port

This section describes how the PNX8330 HAL package implements parts of the eCos HAL specification. It should be read in conjunction with similar sections from the architectural and variant HAL documentation.

HAL I/O

The header file cyg/hal/pnx8330_io.h provides definitions of the on-chip peripherals used by eCos, except for some UART definitions which are provided by the PNX83xx support HAL instead. This header file is automatically included by the architectural header cyg/hal/hal_io.h, so typically application code and other packages will just include the latter. The register addresses are all in kseg1 so will be accessed uncached.

Interrupt Handling

The header file cyg/hal/pnx8330_intr.h provides ISR vector numbers for all interrupt sources, for example CYGNUM_HAL_ISR_I2C0 and CYGNUM_HAL_ISR_PIO_1. These vector numbers should be used for calls like cyg_interrupt_create. The header file is automatically included by the architectural header cyg/hal/hal_intr.h, and other packages and application code will normally just include the latter.

The interrupt vectors come in four groups. There are six vectors corresponding to the external interrupts available in the CPU SR and CAUSE registers. Of these, interrupt number 2 is attached to the on-chip interrupt controller, and interrupt number 5 is attached to the internal COMPARE register, which is used to supply system time interrupts. There are 37 vectors for the on-chip peripherals, managed by the priority interrupt controller. One of these, CYGNUM_HAL_ISR_PIO is reserved for use by the HAL's interrupt decoding code to detect PIO interrupts and decode them into the next 16 vectors. Another peripheral interrupt, CYGNUM_HAL_ISR_CONFIG is decoded into the final seven interrupt vectors, which correspond to the interrupt sources available from the CONFIG unit.

The eCos HAL macros HAL_INTERRUPT_MASK, HAL_INTERRUPT_UNMASK, HAL_INTERRUPT_ACKNOWLEDGE, HAL_INTERRUPT_CONFIGURE and HAL_INTERRUPT_SET_LEVEL are implemented by the processor HAL. The implementations depend on the interrupt vector. HAL_INTERRUPT_ACKNOWLEDGE is only needed for PIO and CONFIG interrupts, otherwise it is a no-op. HAL_INTERRUPT_CONFIGURE is only relevant for PIO interrupts.

Interrupt priorities should be in the range 1 to 14, and correspond to the *int_priority* fields in the pic_int_reg registers. 1 is the lowest priority and 14 the highest. Interrupt priorities are ignored for the COMPARE interrupt. All PIO and CONFIG interrupt sources operate at the same priority, which is the highest priority assigned to any of the PIO or CONFIG vectors.

Interrupt chaining via the common HAL's configuration option CYGIMP_HAL_COMMON_INTERRUPTS_CHAIN is supported for PIO interrupts only. This makes it possible to connect several external peripherals' interrupt lines to a single PIO pin if desired.

Clock Support

The 4kEc core provides standard COUNTER and COMPARE registers which are used for the eCos system clock. The CONFIG unit timer 0 is used for gprof-based profiling if enabled, otherwise it can be used by the application. The CONFIG unit watchdog timer is supported by a watchdog driver.

Cache Handling

The PNX8330 has an 8K data cache and a 16k instruction cache, which are automatically initialized and enabled by the eCos startup code. All the standard cache control macros are supported through the cache instruction. However, since all memory is always available both cached and uncached as part of the architecture, these are not always necessary.

Profiling Support

The PNX8330 HAL provides a profiling timer for use with the gprof profiling package. This uses the PNX8330 configuration timer 0, so application code should not manipulate this timer if profiling is enabled. The MIPS architectural HAL implements the mcount function so profiling is fully supported on all PNX8330-based platforms.

Other Issues

The macro HAL_PLATFORM_RESET is implemented via the PNX8330's system reset unit, and involves a full reset of the core and all peripherals. Hence, whenever a soft reset is performed by the application or via a gdb command, the system should start up again in a clean state, and there is no need for the system to reinitialize all the peripherals.

The PNX8330 HAL does not affect the implementation of data types, stack size definitions, bit indexing, idle thread processing, SMP support, system startup, or debug support.

Other Functionality

The PNX8330 processor HAL only implements functionality defined in the eCos HAL specification and does not export any additional functions.

Chapter 340. NXP STB220 Board Support

Name

eCos Support for the NXP STB220 Board — Overview

Description

The NXP STB220 board has a PNX8330 processor, 32MB of external SDRAM, 16MB of external flash, an SMSC LAN9118 ethernet chip, and connectors plus required support chips for various on-chip peripherals. For typical eCos development a RedBoot image is programmed into the external flash. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The memory map used by both eCos and RedBoot is as follows:

Memory	Base	Length
External SDRAM	0x80000000	0x04000000
External Flash	0x98000000	0x01000000
On-chip Peripherals	0xB7000000	0x00200000

External SDRAM and flash are normally accessed via the kseg0 segment and hence via the cache. The peripherals are normally accessed via kseg1 and hence uncached.

eCos can be configured for one of four startup types:

RAM

> This is the startup type normally used during application development. RedBoot is programmed into flash and performs the initial bootstrap. mipsisa32-elf-gdb is then used to load a RAM startup application into memory and debug it. By default the application will use eCos' virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output. The bottom 1MB of RAM is used for RedBoot code and data so the application will start at 0x80100000.

ROM

> This startup type can be used for finished applications which will be programmed into the start of external flash at location 0xB8000000. On power-up the chip's bootloader will automatically execute the contents of flash from 0xB8000000. The application will initialize SDRAM, copy its data to RAM and zero its BSS. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

ROMRAM

> This startup type can be used for finished applications which will be programmed into the start of external flash at location 0xB8000000. On power-up the chip's bootloader will automatically execute the contents of flash from 0xB8000000. The application will initialize SDRAM, copy itself from flash to RAM, and zero its BSS. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type is used for building the flash-resident version of RedBoot but can also be used for application code.

JTAG

> This can be used to run applications via JTAG rather than RedBoot. The application will be loaded at location 0x80000000 and it will take over all the hardware. Uart0 will be used for all HAL diagnostics and standard output. A JTAG build of RedBoot can be used during hardware setup to program the ROM or ROMRAM versions into flash. A JTAG application build may prove useful for debugging certain problems, especially ones related to interrupts and exceptions. However the JTAG software

may not fully cope with the executables and debug information generated by the GNU tools, so the user experience may be poor compared with using the GNU mipsisa32-elf-gdb debugger.

In a typical setup the first 128KB of flash is used for holding the RedBoot image, and the last 128KB is used for managing the flash and holding the RedBoot fconfig values. The remaining blocks from 0x98020000 to 0x98FEFFFF can be used by application code.

RedBoot can communicate with the host using either uart0 or uart1.

All configurations for the STB220 target include an ethernet driver package `CYGPKG_DEVS_ETH_SMSC_LAN9118`. If the application does not actually require ethernet functionality then the package is inactive and the final executable will not suffer any overheads from unused functionality. This is determined by the presence of the generic ethernet I/O package `CYGPKG_IO_ETH_DRIVERS`. Typically the choice of eCos template causes the right thing to happen. For example, the default template does not include any TCP/IP stack so `CYGPKG_IO_ETH_DRIVERS` is not included, but both the net and redboot templates do include a TCP/IP stack so will specify that package and hence enable the ethernet driver. The ethernet device can be shared by RedBoot and the application, so it is possible to debug a networked application over ethernet.

The STB220 board does not have a serial EPROM or similar hardware providing a unique network MAC address. Instead a suitable address has to be programmed into flash via RedBoot's **fconfig** command.

All configurations for the STB220 target include a serial device driver package `CYGPKG_DEVS_SERIAL_MIPS_PNX8310` (this driver is shared with PNX8310 based targets, and for historical reasons it is named for them, however it it applicable to both). The driver as a whole is inactive unless the generic serial support, `CYGPKG_IO_SERIAL_DEVICES` is enabled. Both Uart0 and uart1 are connected, however, only Uart0 has hardware flow control lines routed to the connector. If a UART is needed by the application then it cannot also be used by RedBoot for gdb traffic, so care should be exercised in selecting which UART to use for these purposes. Alternatively another communication channel such as ethernet chould be used instead.

All configurations for the STB220 target include a watchdog device driver package `CYGPKG_DEVS_WATCHDOG_MIPS_PNX8330`. This is inactive unless the generic watchdog support, `CYGPKG_IO_WATCHDOG` is loaded.

The on-chip interrupt controller is managed by eCos using macros provided by the PNX8330 processor HAL. The architecture COUNTER/COMPARE timer is used to implement the eCos system clock. If gprof-based profiling is enabled then that will use CONFIG unit timer 0, otherwise that timer can be used by the application. GPIO pins 4 to 7 are used for UART1 and pins 10 to 13 may be used for ethernet interrupts. The remaining GPIO pins are not used by eCos. Other on-chip peripherals are left to their initial settings and not manipulated by eCos.

Tools

The STB220 port is intended to work with GNU tools configured for an mipsisa32-elf target. The original port was done using mipsisa32-elf-gcc version 3.4.4 mipsisa32-elf-gdb version 6.3, and binutils version 2.16.

Name

Setup — Preparing the STB220 board for eCos Development

Overview

In a typical development environment the STB220 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for a RAM startup, and then downloaded and run on the board via the debugger mipsisa32-elf-gdb. Preparing the board therefore involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from parallel flash	`redboot_ROM.ecm`	`redboot_rom.bin`
ROMRAM	RedBoot copied from flash into RAM	`redboot_ROMRAM.ecm`	`redboot_romram.bin`
JTAG	Used for initial setup	`redboot_JTAG.ecm`	`redboot.elf`
RAM	For debugging RedBoot	`redboot_RAM.ecm`	`redboot_ram.bin`

For serial communications all versions run at 384000 baud with 8 bits, no parity, and 1 stop bit. The baud rates can be changed via the configuration option `CYGNUM_HAL_MIPS_STB220_DIAG_BAUD` and rebuilding RedBoot. RedBoot will support communication on either UART. Flash management is supported. Ethernet communication and flash management are also supported.

For EV8330 boards with DDR RAM there are alternative configuration files for the ROM and ROMRAM configurations. These have the same names as the files given above, with `_DDR` added giving `redboot_ROM_DDR.ecm` and `redboot_ROMRAM_DDR.ecm`.

Initial Installation

This process assumes that RedBoot has not yet been installed into flash, so JTAG has to be used to program the `redboot_romram.bin` file into flash. This can be done either via a flash programming utility or by first running a JTAG version of RedBoot and using that to initialize and program the flash. This second approach is described here.

The first step is to set up a suitable JTAG module and associated debug software, as per the instructions supplied with the JTAG kit. Next connect a straight-throught RS232 cable between the STB220's serial port and the host PC, and start a terminal emulation application such as HyperTerminal or minicom on the host PC. The serial communication parameters should be 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking).

Ensure that SW801 is set to the CSn0 position, SW802 is set to OFF and that SW803 is set to 16b. It will also be necessary to configure the JTAG software to make both the FLASH and SDRAM accessible.

It is now necessary to load and run a JTAG build of RedBoot. A prebuilt image `redboot_JTAG.elf` is supplied with eCos, or can be rebuilt as described below. This file is an ELF executable complete with relocation and debug information, and may need to be converted to another format for use with the JTAG software. For example, when using an Ashling Opella unit, the SymFinder utility sfdwarf should be used to convert the ELF executable to a `.CSO` file. This utility may give numerous warnings which can be ignored. The `.CSO` file can be loaded via the JTAG debugger, and it can be started running at location 0x80001000. At this point RedBoot will output text similar to the following on the serial port:

```
**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database

RedBoot(tm) bootstrap and debug environment [JTAG]
```

```
Non-certified release, version UNKNOWN - built 15:19:46, Dec  1 2005

Platform: STB220 (Philips PNX8330)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005 eCosCentric Limited

RAM: 0x80000000-0x84000000, [0x8001aec0-0x83fdd000] available
FLASH: 0x98000000 - 0x98ffffff 128 x 0x20000 blocks
RedBoot>
```

The exact details may vary slightly, depending on the flash chip present and whether or not the ethernet is plugged in yet. At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. To perform the flash initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x98020000-0x98fdffff: ...............................................................................
...............................................
... Unlocking from 0x98fe0000-0x98ffffff: .
... Erase from 0x98fe0000-0x98ffffff: .
... Program from 0x83fe0000-0x84000000 to 0x98fe0000: .
... Locking from 0x98fe0000-0x98ffffff: .
RedBoot>
```

At this stage the block of flash at location 0x98FE0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlocking from 0x98fe0000-0x98ffffff: .
... Erase from 0x98fe0000-0x98ffffff: .
... Program from 0x83fe0000-0x84000000 to 0x98fe0000: .
... Locking from 0x98fe0000-0x98ffffff: .
RedBoot>
```

For most of these configuration variables the default value is correct.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The file `redboot_romram.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the Y-modem protocol.

```
CRaw file loaded 0x8001b000-0x80031887, assumed entry at 0x8001b000
xyzModem - CRC mode, 724(SOH)/0(STX)/0(CAN) packets, 4 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Unlocking from 0x98000000-0x9801ffff: .
... Erase from 0x98000000-0x9801ffff: .
... Program from 0x8001b000-0x8003b000 to 0x98000000: .
... Locking from 0x98000000-0x9801ffff: .
... Unlocking from 0x98fe0000-0x98ffffff: .
... Erase from 0x98fe0000-0x98ffffff: .
... Program from 0x83fe0000-0x84000000 to 0x98fe0000: .
... Locking from 0x98fe0000-0x98ffffff: .
RedBoot>
```

The flash-resident version of RedBoot has now been programmed at location 0x98000000, and the flash info block at 0x98FE0000 has been updated. The initial setup is now complete and the board can now boot from flash. To do this, power the board down, detach the JTAG module and power the board up. It should produce the following output:

```
+
RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 14:37:14, Dec  1 2005

Platform: STB220 (Philips PNX8330)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005 eCosCentric Limited

RAM: 0x80000000-0x84000000, [0x8001b350-0x83fdd000] available
FLASH: 0x98000000 - 0x98ffffff 128 x 0x20000 blocks
RedBoot>
```

When RedBoot issues its prompt it is also ready to accept connections from mipsisa32-elf-gdb, allowing eCos applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done at the ROMRAM RedBoot prompt - there is no need to run the JTAG version again unless the version already installed has been corrupted. It involves loading the new image into RAM using RedBoot's **load** command, and then programming it into flash using **fis create RedBoot**

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROMRAM version of RedBoot are:

```
$ mkdir redboot_romram
$ cd redboot_romram
$ ecosconfig new stb220 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/mips/pnx83xx/pnx8330/stb220/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the required file `redboot_romram.bin`.

Rebuilding the JTAG and RAM versions involves basically the same process. The JTAG version uses the file `redboot_JTAG.ecm` and generates an ELF executable `redboot.elf`, which may need to be converted to another format before it can be used with the JTAG software. The RAM version uses the file `redboot_RAM.ecm` and generates a raw binary `redboot.ram.bin` which can be loaded into memory at 0x80100000 and executed from there.

Name

Configuration — Platform-specific Configuration Options

Overview

The STB220 platform HAL package is loaded automatically when eCos is configured for an STB220 target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STB220 platform HAL package supports four separate startup types: RAM, ROM, ROMRAM and JTAG. The configuration option `CYG_HAL_STARTUP` controls which startup type is being used. For typical application development RAM startup should be used, and the application will be run via mipsisa32-elf-gdb interacting with RedBoot using either serial or ethernet. It is assumed that the low-level hardware initialization, including setting up the memory map, has already been performed by RedBoot. By default the application will use certain services provided by RedBoot via the virtual vector mechanism, including diagnostic output, but that can be disabled via `CYGSEM_HAL_USE_ROM_MONITOR`.

ROM startup can be used for applications which are programmed into the base of a parallel flash device at 0x98000000. On power up the chip's boot loader will jump to this location and execute the code that is there. The startup code will copy the applications data segment from ROM to RAM at 0x80000000 and zero the BSS. Code execution will continue from ROM. All the hardware will be initialized, and the application is self-contained. This startup type can be used by the flash-resident version of RedBoot, and can also be used for finished applications.

ROMRAM startup can be used for applications which are programmed into the base of flash at 0x98000000. On power up the chip's boot loader will jump to this location and execute the code that is there. The startup code will copy the application from flash to RAM at 0x80000000, and subsequently the flash will not be used for executing any code. All the hardware will be initialized, and the application is self-contained. This startup type is used by the flash-resident version of RedBoot, and can also be used for finished applications.

JTAG startup can be used for applications which will be debugged via JTAG instead of RedBoot. The behaviour is mostly the same as for ROMRAM startup: the application is loaded at 0x80000000 and initializes all the hardware, with no dependencies on services provided by a ROM monitor. There are some minor differences in the startup code, for example it is not necessary to copy the remainder of the application from flash to RAM.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained. That is useful as a testing step before switching to ROM startup. It also allows applications to be run and debugged via JTAG.

If the application does not rely on a ROM monitor for diagnostic services then uart0 will be used for HAL diagnostics and standard output. The default baud rate is controlled by `CYGNUM_HAL_MIPS_PNX83XX_DIAG_BAUD`. Since uart0 is needed by the HAL diagnostics code it cannot be accessed via the serial driver and uart1 should be used for this purpose.

System Clock

The coprocessor 0 COUNTER/COMPARE timer is used for the eCos system clock. The configuration option `CYGNUM_HAL_RTC_PERIOD` controls the value programmed into the compare register. The value of this is calculated from the CPU frequency and the value of `CYGNUM_HAL_RTC_DENOMINATOR`. The calculations are arranged so that

`CYGNUM_HAL_RTC_DENOMINATOR` effectively defines the clock frequency and it the only configuration option that need to be changed to select a different clock rate.

DRAM Type Selection

EV8330 boards can be fitted with either DDR RAM or SDRAM. These require different initialization of the the SDRAM interface controller. This is selected by setting `CYGHWR_HAL_PNX8330_DRAM` to either `SDRAM` or `DDR`. The default is to select SDRAM.

Flash Driver

The platform HAL package contains flash driver support for the external flash device. By default this is inactive, and it can be made active by loading the generic flash package `CYGPKG_IO_FLASH`. The board may use one of a variety of flash chips. The exact type present is determined at run-time using CFI and the system will adjust accordingly.

Ethernet Support

The platform HAL provides the platform-specific support for a single SMSC LAN9118 ethernet device, if the generic ethernet support is enabled. The configuration `CYGNUM_HAL_MIPS_STB220_ETH_ISR_PRIORITY` provides control over the interrupt priority used for this device. The option `CYGNUM_HAL_MIPS_STB220_ETH_ISR_PIO` controls which PIO pin the ethernet interrupt is connected to and `CYGNUM_HAL_MIPS_STB220_ETH_CS` controls which chip select is used to access the ethernet device. These options must match the setting of the jumpers on the board. The board does not have a suitable EEPROM so the MAC address is provided via a RedBoot fconfig option.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are four flags specific to this port:

`-mips32`
: The mipsisa32-elf-gcc toolchain defaults to supporting the mips32 architecture, so this option is not strictly necessary. However, it is good practice to include it.

`-G0`
: MIPS calling conventions reserve one register for use as a global pointer register. In theory this allows static variables in one 64K area of memory to be accessed using just one instruction instead of two, and the `-G` option provides some control over this. However due to limitations within the current linker all modules have to be compiled with the same `-G` setting, and the compiler support libraries are built with `-G0`. Therefore all eCos and application modules also have to be built with `-G0` and this optimization is not available.

`-EB`
: The eCos port only supports big-endian mode so `-EB` must be specified.

`-msoft-float`
: The PNX8330 does not have a hardware floating point unit so software floating point has to be used instead.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STB220 hardware, and should be read in conjunction with that specification. The STB220 platform HAL package complements the MIPS architectural HAL, the PNX8330 variant HAL, and the PNX83xx support HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will set up some of the on-chip peripherals appropriately for eCos, but most peripherals are left to their default settings. Full details of this initialization can be found in the function `hal_platform_init` in `stb220.c`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External SDRAM
: This is mapped to location 0x80000000. The first four kilobytes are reserved for exception vectors and for some data which needs to be shared between RAM startup applications and the ROM monitor. For ROMRAM or JTAG startup, code will be loaded from 0x80001000 onwards. For ROM startup data will be loaded from 0x80001000 onwards. For RAM startup, code will start at 0x80100000, reserving the bottom 1MB for RedBoot's code and data.

On-chip Peripherals
: These are accessible at location 0xB7000000 onwards.

External Flash
: This is located at location 0x98000000 onwards. Different STB220 boards may come with different flash chips so CFI is used at run-time to query the flash chip and adapt. Typically the first 128K of flash at location 0x98000000 is used to hold RedBoot, and the last flash block at location 0x98DE0000 is used to hold flash management data and the RedBoot **fconfig** variables. The remaining blocks can be used by application code.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the 4kEc COUNTER/COMPARE registers accessed via coprocessor 0. The actual HAL macros for managing the clock are provided by the MIPS architectural HAL. The specific numbers used are a characteristic of the platform because they depend on the processor speed. The CONFIG unit's timer 0 is used for profiling and its watchdog timer is supported by a watchdog driver.

MIPS16 Support

The STB220 platform HAL enables MIPS16 support in the architecture HAL. This allows *application* code to be compiled using MIPS16 options and linked against the 32 bit mode eCos library.

To compile for MIPS16 the standard flags that are used in eCos and exported to the `ecos.mak` file should be used except that the `-mips32` flag should be replaced by `-mips16 -fwritable-strings`. The `-mips16` option enables MIPS16 compilation and the `-fwritable-strings` option is a work-around for a bug in the compiler.

Other Issues

The STB220 platform HAL does not affect the implementation of other parts of the eCos HAL specification.

Part LXXXIII. NIOS2 Architecture

Table of Contents

Chapter 341. Nios II Architectural Support

Name

CYGPKG_HAL_NIOS2 — eCos Support for the Nios II Architecture

Description

The Altera Nios II is a configurable processor. Using the Altera design suite a system designer can build a custom hardware design. This will involve a Nios II cpu, possibly fine-tuned as appropriate for the application with e.g. appropriate amounts of cache and custom instructions. Next those peripherals needed by the application are added. The resulting design is compiled and programmed into a suitably-sized FPGA. This FPGA will be the heart of a larger circuit containing other devices such as external flash and RAM memories and support chips such as RS232 transceivers. A number of reference hardware designs are included with the design suite. The eCos Nios II architectural HAL package together with supporting HAL packages and device drivers allow eCos to be configured and built for a hardware design. Complete applications can then be built with eCos.

The configurable nature of the Nios II architecture means that the eCos port is implemented somewhat differently from ports to other architectures, although the same basic functionality is available. A conventional eCos port involves an architectural HAL package, a variant HAL, possibly a processor HAL, and a platform HAL. Typically the architectural HAL provides a framework for the lower HALs, interrupt and exception processing, context switch support, and gdb stub debug support. The variant HAL deals with cpu issues which are not common to all members of the basic architecture, for example caches and optional FPU and MMU support. The processor HAL deals with the specific set of devices on one specific chip that implements the basic architecture, for example timers, a uart for diagnostics, and interrupt controllers. Base address for the various devices and their interrupt vectors are also defined here. The platform HAL deals with devices that are off-chip. This includes external flash and RAM, as well as specialized I/O chips on an I²C or SPI bus. Typically the external memory will determine how the system boots up so issues like different startup types are largely handled by the platform HAL.

Exactly what work is done where depends very much on the specific processor, for example an interrupt controller may be supported by the variant HAL instead of the processor HAL if it is expected that all processors implementing that variant will use the same interrupt controller. Typically lower HALs are able to extend or override the behaviour of higher ones as appropriate, for example a platform HAL could redefine the interrupt controller support if the platform includes an external interrupt controller as well as an on-chip one.

The Nios II port still involves an architectural HAL and a platform HAL. The architectural HAL tends to do more of the work than other architectural HALs. For example it provides default implementations of system clock support using an Avalon timer and diagnostics using an Avalon uart. The platform HAL still deals with the off-chip devices such as external flash and RAM. For example the devkit platform HAL CYGPKG_HAL_NIOS2_DEVKIT provides the appropriate support for the Stratix II/2s60_RoHS and the Cyclone II/2c35 boards and compatibles.

There is also a new type of HAL, the hardware design HAL. Typically this does not contain any code, only definitions and eCos configuration support. It contains the information needed by the other HALs and by device drivers to adapt themselves to a specific hardware design, for example the presence of certain cpu instructions, the existence and size of cache, and the base addresses and interrupt vectors assigned to the various on-chip and off-chip devices. Essentially this corresponds to the information manipulated within the SOPC Builder component of the Altera Design Suite. An example of a hardware design HAL is CYGPKG_HAL_NIOS2_CYCLONE2_2C35_TSEPLUS, corresponding to the eCosPro TSEplus hardware design for a Cyclone II/2c35 board.

An eCos target, as defined by an entry in the toplevel ecos.db database, consists of the Nios II architectural HAL, a hardware design HAL, a platform HAL, and a set of device drivers. Typically each target will have its own hardware design HAL, although in some cases multiple targets may use the same hardware design HAL to allow for incompatible device drivers. If a platform HAL is fairly generic then it may be shared between several targets, otherwise a target will need its own platform HAL. Porting eCos to a new Nios II design will typically involve creating a new hardware design HAL, usually by cloning an existing one, and either reusing or cloning an existing platform HAL, followed by creating the appropriate entries in ecos.db.

Note

At the time of writing hardware design HALs are manually written or cloned. It is expected that in a future release these HALs will be generated automatically from the output of SOPC Builder, with little or no need for manual intervention. For simple hardware the need for a separate platform HAL may also be eliminated at that time.

Name

Installation — Generic Instructions

Overview

Typical Nios II hardware for use with eCos will include an FPGA to run the hardware design, a bank each of external parallel NOR flash and SDRAM, an rs232 transceiver plus a uart in the hardware design to act as the diagnostics and debug channel, support logic to initialize the hardware following power up, and any other peripherals appropriate to the application. The external flash is needed to hold the hardware design as well as code and persistent data, and external SDRAM is needed because a typical FPGA cannot provide enough RAM for the system's requirements. Relative to the FPGA and the SDRAM the external flash is usually somewhat slow.

In a self-contained production system both the hardware design and all code will reside in the flash, and the FPGA will start executing code from flash shortly after power up once the hardware design has been loaded. This code will be linked against a build of eCos configured to use a ROM startup. The code can be the actual application, which means that the entire application will execute in place from flash and all hardware resources are available to it. However because of flash speed issues the resulting performance may be poor. An alternative approach is to have a two-stage boot process: the code that runs from flash is the RedBoot ROM monitor, linked using a ROM startup; following system initialization RedBoot then loads the application from flash into RAM and starts it running; this load can be done using either the **fis load** and **go** commands in a boot script, or alternatives such as the Robust Boot Loader `CYGPKG_RBL`. The application is linked against a separate eCos build configured for RAM startup, and can access some facilities provided by RedBoot such as the fconfig persistent data database. However some flash and RAM needs to be reserved for RedBoot.

An alternative available on some platforms is a ROMRAM startup. Here the application starts up as per a ROM startup, but then copies itself into RAM and continues executing from there, avoiding the performance problems of executing from flash. There is no RedBoot in the system so no resources need be reserved for it, but on the other hand its facilities are not available.

Another alternative is to use an EPCS serial flash chip instead of or in addition to the parallel flash. The hardware design and the boot code both reside in the EPCS chip, and the FPGA will load the design on power up. The design automatically includes a very simple bootloader provided by Altera which runs, copies the main boot code from the EPCS chip to RAM, and then jumps to the entry point.

Obviously during software development it is undesirable to reprogram the parallel flash or the EPCS chip following every build. Instead the nios2-elf-gdb debugger will load the application into RAM and run it under debugger control, complete with facilities such as breakpoints and single stepping. The debugger can be run either directly from the command line or from inside an integrated development environment, depending on the user's preferences and the tools available.

nios2-elf-gdb can interact with the target in two ways. It can use dedicated debug hardware such as the jtag-based Altera USB Blaster. Alternatively it can communicate with the RedBoot ROM monitor over either an rs232 connection or an ethernet network. Both approaches have advantages and disadvantages. Debugging via jtag can be less intrusive on the application's behaviour, but some functionality such as RedBoot's fconfig data will not be available. If the hardware design incorporates hardware breakpoints then jtag also offers limited capabilities for debugging code that executes from flash. RedBoot has some knowledge of eCos internals so debugging via RedBoot also provides some advanced functionality such as thread-aware debugging. Applications that will be debugged via RedBoot should be linked against an eCos built configured for RAM startup. Note that this means that exactly same application image can later be programmed into flash in a production system. Applications that will be debugged via jtag should be linked against an eCos built configured for RAMJTAG startup.

Preparing a board for debugging via jtag simply involves setting up the hardware and software in accordance with the appropriate Altera documentation. If the gdb hwdebug diagnostics channel is used then it will also be necessary to run the gdb command **set hwdebug** to activate that channel. Debugging via RedBoot is more complicated because it means installing RedBoot and initializing the **fis** and **fconfig** persistent data. This is covered in more detail below. Typically the RedBoot image resides in the first 128K of flash, the last 64K of flash is used for RedBoot's persistent data, and the first 64K of external SDRAM is reserved for use by RedBoot.

Embedded hardware varies widely and eCos is itself a highly configurable operation system, so many variations of the above setup are possible. Hence some platforms will have their own installation instructions and the platform HAL documentation should be consulted first before proceeding with the instructions below. In addition some of the information such as the location of RedBoot depend on the hardware design and possibly the platform HAL, so again the appropriate documentation should be consulted for details.

Installing RedBoot

Typically the hardware design, specifically the `.sof` file that is the final result of compilation, needs to be programmed into flash alongside RedBoot and everything else. This can be done either using the graphical tools provided with Quartus and the Altera IDE, or using command line tools like sof2flash and nios2-flash-programmer. These tools require a jtag connection to the target, and the Altera documentation should be consulted for further details. The location of the hardware design within the flash is determined by the board's reset logic so that information can be found in the hardware design and platform HAL documentation.

The next step is to program a ROM-startup build of RedBoot into flash at the reset location. Typically the external flash is placed at location 0x00000000 within the address map and execution will start from that address, but this may be changed within the hardware design. eCosPro releases for a supported target will come with prebuilts of RedBoot in a variety of file formats (usually the ELF executable, raw binary, and S-records). Alternatively RedBoot can be rebuilt for the target as per the standard RedBoot documentation. This may either generate the various file formats automatically or it may be necessary to use nios2-elf-objcopy to convert from the ELF executable to other formats.

There are two main ways of getting RedBoot into flash. The first is to use the Altera utilities, either the graphical ones or the command-line tools. For example nios2-flash-programmer can be used together with the S-record version of the RedBoot build. When the board is reset afterwards RedBoot will start running, sending output out of the board's first serial port and providing a prompt. Starting up a terminal emulator program on the host will allow the user to see this output and to invoke RedBoot commands. The rs232 parameters will depend on the hardware design, but typically RedBoot will communicate at 115200 baud, 8 bits, no parity, 1 stop bit. At this stage there will be a number of warnings from RedBoot about uninitialized **fis** and **fconfig** settings, which is to be expected since the relevant initialization commands have not been run yet. These commands are **fis init** and **fconfig -i**, and the RedBoot documentation should be consulted for further information.

If the hardware design image is held in flash then it is usually a good idea at this stage to create one or more **fis** entries, marking the relevant part of the flash as in use and preventing RedBoot from overwriting the image by accident. In theory this will also allow RedBoot commands to be used to update the hardware design image if needed, although the jtag flash utilities are generally more convenient for this. For example, on a Stratix II/2s60_RoHS board the current hardware design resides at offset 0x00800000 within the flash and for safety there is also a factory fallback design at 0x00C00000.

```
RedBoot> fis create -f 0x00800000 -l 0x00400000 -n hwdesign_user
RedBoot> fis create -f 0x00C00000 -l 0x003F0000 -n hwdesign_bak
```

Here the `-f` specifies the address, `-l` the length, and `-n` prevents RedBoot from initializing the relevant parts of flash and thus overwriting the hardware designs already programmed.

If the hardware design includes a system id register then during initialization RedBoot will check the current value of that register with the setting defined in the hardware design HAL. A mismatch indicates that the RedBoot build does not correspond to the hardware design being used, so RedBoot may not be fully functional and may even fail before getting as far as providing a prompt. Sometimes this warning is innocuous because, even though a custom hardware design is being used, it is fully compatible with the one RedBoot was built for (same memory map, same interrupt vector assignments, same settings for those peripherals used by RedBoot). If so the warning can either be ignored or RedBoot can be rebuilt with an updated system id value.

The alternative approach to installing RedBoot via the jtag flash programming utilities is to go via a RAM build of RedBoot. This has the advantage of supplying the user with more information as the installation process proceeds. For example if there is a problem with the way the hardware design attempts to access flash then a RAM build of RedBoot may still function to some extent but report errors whenever attempting to access the flash, whereas a ROM build of RedBoot trying to execute from that flash may fail silently.

The file that is needed is an RedBoot ELF executable for a RAM startup build (RedBoot is not a typical eCos application and for it there is no difference between the RAM and RAMJTAG startup types). Again eCosPro releases for a supported target will come with prebuilts, alternatively Redboot can be rebuilt in the usual way. The RedBoot build will be run via nios2-elf-gdb over jtag, so typically this will first involve starting up nios2-gdb-server:

```
$ nios2-gdb-server --tcpport 9000
```

And then at a separate shell prompt:

```
$ nios2-elf-gdb <path>/redboot.elf
(gdb) target remote localhost:9000
(gdb) set $status=0
(gdb) load
(gdb) continue
```

Setting `$status` to 0 has the effect of disabling interrupts, useful if the board was previously used to run an application and that run left interrupts enabled. If an interrupt is pending then as soon as the **continue** command is executed and RedBoot starts running, before it has a chance to run a single instruction let alone initialize the system appropriately for interrupt handling, an interrupt exception will occur. Disabling interrupts before the **continue** avoids any such problems.

Once the RAM RedBoot starts running it should send output out of the board's first serial port and provide a prompt, as before. If this does not happen it indicates a mismatch between the RedBoot build and the hardware design, for example the RedBoot build being used may be for a different target or the hardware design currently running on the board may not be the one that RedBoot was built for. If the discrepancy is minor then the RAM RedBoot may still provide some diagnostics indicating what is wrong, for example it may warn about a system id mismatch.

Once the RAM RedBoot is up and running the **fis init** and **fconfig -i** commands can be run as before, and fis entries for any hardware design(s) in reserved areas of flash can be created. Finally a ROM version of RedBoot can be uploaded:

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The raw binary version of the RedBoot build, typically `redboot.rom.bin` should now be uploaded via the host's terminal emulator program using a ymodem transfer. Once this has finished the ROM RedBoot can be installed into flash, and a **reset** command will restart the processor from the reset vector which should now be RedBoot code.

```
RedBoot> fis create RedBoot -b %{freememlo}
…
RedBoot> reset
```

Updating RedBoot

Sometimes it may be necessary or desirable to install a new version of RedBoot, either because the hardware design has changed or because of a software update. The new version can be installed using the above instructions, usually skipping the **fis** and **fconfig** initializations because there is no need to repeat these. Alternatively it is also possible to use an existing still-functional ROM RedBoot to run up a RAM RedBoot and then use the latter to install a new ROM RedBoot - obviously it is not possible for a ROM RedBoot to update itself because it would be overwriting its own code. This has the advantage of not requiring jtag unless something goes badly wrong and major recovery is needed, but it will take somewhat longer. At the ROM RedBoot prompt:

```
RedBoot> load -r -m ymodem -b <address>
RedBoot> go
```

Again this involves a ymodem transfer from the host to the target, this time using the raw binary file `redboot.ram.bin`. The address should be the execution address for RAM applications, typically 64K into external RAM but the details will depend on the hardware design and the platform. It is also possible to skip the `-r` option and the address and transfer an ELF executable, but this involves a larger transfer so will take more time. The **go** command transfers control to the RAM RedBoot, and the ROM RedBoot binary can then be uploaded and programmed into flash as before.

Name

Options — Configuring the Nios II Architectural HAL Package

Description

The Nios II architectural HAL is included in all ecos.db entries for Nios II targets, so the package will be loaded automatically when creating a configuration. It should never be necessary to load the package explicitly or to unload it.

The architectural HAL contains a number of configuration options, although relatively few compared with many other architectures. This is because many aspects of the system that would normally be handled at compile-time by eCos configuration options can instead be controlled during the hardware design process. For example, the uart used for the diagnostics and debug channel can be hardwired to a particular baud rate, eliminating the need to control this via an eCos configuration option.

The most important configuration options in the architectural HAL are `CYGBLD_GLOBAL_CFLAGS` and `CYGBLD_GLOBAL_LDFLAGS`, the default compiler flags for building eCos and for linking testcases. The flags are exported in the file `install/include/pkgconf/ecos.mak` in the eCos build tree and are usually used for building application code as well, either as is or after any appropriate changes. Users may wish to change these flags, for example to build eCos with different compiler optimization settings. The default values of these options adapt to information provided by the hardware design HAL about the cpu's capabilities, for example the availability of the various multiply and divide instructions.

`CYGSEM_HAL_COMMON_INTERRUPTS_FIXED_GP` affects the way eCos interacts with the global pointer register or gp. The Nios II ABI uses gp to access certain variables, allowing up to 64K worth of data to be accessed via a single instruction rather than two separate instructions. The gp register is initialized during application startup. The use of a global pointer can cause problems. For example when the system involves a ROM RedBoot and a RAM application, both are built independently and have their own area for small variables and hence their own gp values. Whenever the system switches between code running in the application and code running in RedBoot the gp register must be switched as well. That means when an interrupt or exception occurs the gp register may have the wrong value for the interrupt or exception handler, and hence the gp register must be saved, updated, and restored alongside other parts of the cpu state. This adds to the interrupt latency. If it is known that there will only be one application running in the system, e.g. when using ROM or RAMJTAG startup, then the system can assume a fixed global pointer register and there is no need for the interrupt and exception handlers to do anything with it. This configuration option controls the gp behaviour, and usually its default value determined from other configuration options will be appropriate.

A build of ROM RedBoot normally includes gdb stubs support, including breakpoints. Usually ordinary breakpoints involve inserting a special breakpoint into the image in memory, and hence debugging is generally limited to applications executing from RAM. On most architectures the host-side gdb will implement this via a memory write using the gdb remote protocol and no special stub support is needed for that. The Nios II architecture has two breakpoint instructions, one for use when debugging over jtag and one for use when debugging via a target-side gdb stub like the one in RedBoot. nios2-elf-gdb defaults to using the jtag version of the breakpoint instruction, which would break debugging via RedBoot. Hence the Nios II implementation of the gdb stubs code uses a different mechanism, involving a target-side list of the breakpoints that have been set and inserting the appropriate breakpoint instruction on the target-side rather than via memory writes initiated from the host. The gdb stubs code works without dynamic memory allocation so this list is a fixed size, and hence only a fixed number of breakpoints are supported. By default this limit is set to 25 breakpoints, which should suffice for all but the most complicated debug scenarios. If it should ever be necessary to have more breakpoints then the limit can be increased by changing the configuration option `CYGNUM_HAL_BREAKPOINT_LIST_SIZE` in a ROM Redboot configuration and rebuilding and installing the updated RedBoot.

Name

HAL Port — Implementation Details

Description

This documentation explains how the eCos HAL specification has been mapped onto Nios II hardware and should be read in conjunction with that specification. It should be noted that the architectural HAL is usually complemented by a hardware design HAL and a platform HAL, and those may affect or redefine some parts of the implementation.

Exports

The architectural HAL provides header files `cyg/hal/hal_arch.h`, `cyg/hal/hal_intr.h`, `cyg/hal/hal_cache.h`, `cyg/hal/hal_io.h` and `cyg/hal/arch.inc`. These header files export the functionality provided by all the Nios II HALs for a given target, automatically including headers from the lower-level HALs as appropriate. For example the platform HAL may provide a header `cyg/hal/plf_io.h` containing additional I/O functionality, but that header will be automatically included by `cyg/hal/hal_io.h` so there is no need to include it directly.

One header file is worth a special mention: `pkgconf/nios2_hwconfig.h`. This file is provided by the hardware design HAL and contains definitions such as base addresses and interrupt vectors. It is automatically included and used by the architectural HAL headers, but its contents may prove useful to application developers.

Data Types

The architectural HAL assumes that the Nios II cpu in the hardware design uses 32-bit arithmetic, little-endian byte ordering, and software floating point.

Startup

The architectural HAL provides a default implementation of the low-level startup code which will be appropriate in nearly all scenarios. For a ROM startup this includes clearing the instruction and data caches, if present, and copying initialized data from flash to RAM. For all startup types it will involve zeroing bss regions and setting up the stack and the general C environment. It may also include installing the exception vector code at the desired location as well as copying code and data to on-chip RAM or external SRAM as required. The platform HAL can override or extend this as required. The code assumes that all of flash is directly accessible. Platform HALs may override this as required, for example when booting from a serial flash rather more work is needed to copy data from flash to RAM. More information on the low-level startup code can be found in the source file `src/vectors.S`.

The architectural HAL also implements the next stage of the startup code, including initializing the VSR and virtual vector tables, setting up HAL diagnostics, and invoking C++ static constructors, prior to calling the first application entry point `cyg_start`. This code resides in `src/nios2.c`.

The current code assumes that there is no memory management or MMU and hence will not perform any MMU initialization.

Interrupts and Exceptions

The architectural HAL provides default implementations of `HAL_DISABLE_INTERRUPTS`, `HAL_RESTORE_INTERRUPTS`, `HAL_ENABLE_INTERRUPTS` and `HAL_QUERY_INTERRUPTS`. These just involve simple manipulation of the `status` control register. Similarly there are default implementations of the interrupt controller macros `HAL_INTERRUPT_MASK`, `HAL_INTERRUPT_UNMASK`, and `HAL_QUERY_INTERRUPT_MASKED` macros. These are slightly more complicated to cope with nested interrupt scenarios, involving a shadow mask as well as the `ienable` control register. `HAL_INTERRUPT_ACKNOWLEDGE` is a no-op because the hardware has no need for clearing an interrupt centrally. Instead interrupts must be acknowledged within each device as appropriate, using device-specific code.

`HAL_INTERRUPT_CONFIGURE` is a no-op. This macro is normally only relevant to GPIO interrupts, affecting level versus edge triggering, and on a Nios II an entire GPIO unit generates a single interrupt but the various inputs to that port can be controlled individually. Instead it is up to application code to set the various registers within each GPIO unit appropriately.

HAL_INTERRUPT_SET_LEVEL is also a no-op. However the architectural HAL does support prioritized nested interrupts when CYGSEM_HAL_COMMON_INTERRUPTS_ALLOW_NESTING is enabled. The implementation assumes that interrupt vector 0 has the highest priority, down to interrupt vector 31 as the lowest. In other words, assuming nested interrupt support is enabled, if the cpu is busy processing an interrupt from the device attached to interrupt vector 9 and an interrupt 0 occurs then the latter will be handled immediately and the processing of vector 9 resumes later. Since the assignment of interrupt vectors to devices in SOPC Builder is arbitrary this gives full flexibility without the overheads of managing priorities in software.

Interrupt handlers are managed by a simple table cyg_hal_interrupt_handlers so the implementation of HAL_INTERRUPT_ATTACH, HAL_INTERRUPT_DETACH, and HAL_INTERRUPT_IN_USE is straightforward.

By default interrupt handlers run on a separate interrupt stack. This saves memory because there is no need to allow for interrupt processing overhead on every thread stack. However switching to the interrupt stack requires a number of extra instructions so increases the interrupt latency. If the latter is more important than memory usage then CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK should be disabled.

That leaves VSR management and exceptions. On the Nios II interrupt and exception processing is somewhat simpler than on most other architectures. Typically the cpu indirects through a table in memory, the VSR table, with the table index depending on the interrupt vector or the exception being thrown. The eCos macro HAL_VSR_SET updates an entry in the table, allowing applications to take over completely certain interrupt sources and process them as quickly as possible, bypassing the overheads of the default general-purpose VSR handler used by eCos. For example a custom VSR written in assembler could save only a few registers before manipulating the hardware, whereas the general-purpose VSR handler needs to save much of the cpu state before calling the application's interrupt handler written in C. The net result is reduced interrupt latency for critical interrupts, at the cost of more complicated application code.

The Nios II implementation is very different. When an interrupt or exception occurs the cpu jumps to a fixed location in memory defined in the hardware design, the exception vector. The code at that location needs to determine whether it was invoked as the result of an interrupt or a processor exception. There is no hardware equivalent of the VSR table. eCos needs to provide the implementation of the code at the exception vector and there is no simple way for applications to provide a customized version. That makes it difficult for an application to handle critical interrupts with a minimum latency. It also causes other complications, for example it makes it difficult for a RAM startup eCos application to handle interrupts while the gdb stubs inside RedBoot handle exceptions including breakpoints.

To avoid these problems, the Nios II architectural HAL implements a VSR table in software. The code at the exception vector simply indirects through slot 0 of the VSR table, which involves a three instruction overhead compared with a more conventional implementation. Applications needing very fast handling of critical interrupts can use HAL_VSR_SET to install a custom handler in slot 0. That handler can check whether or not a critical interrupt is pending and process it immediately, Otherwise it can chain to the original VSR handler. The overall effect is to provide a mechanism for very fast handling of certain interrupts, at the cost of an extra three instructions for ordinary interrupts which are handled by interrupt handlers written in C.

The default handler for VSR 0 checks whether or not any interrupts are pending. If so then it saves the current cpu state, or the minimum subset thereof if CYGDBG_HAL_COMMON_INTERRUPTS_SAVE_MINIMUM_CONTEXT is enabled, switches to the interrupt stack if necessary, and invokes the appropriate interrupt handler installed via HAL_INTERRUPT_ATTACH or the higher-level functions like cyg_interrupt_create or cyg_drv_interrupt_create.

If the default handler for VSR 0 determines that no interrupt is pending then it must have been invoked as the result of a processor exception. The cpu provides only minimal support for detecting the nature of the exception. A breakpoint trap can be detected by examining the instruction that caused the exception. Anything else is treated as an illegal instruction. Both exceptions are processed by indirecting through further slots in the VSR table, thus allowing the gdb stubs code inside RedBoot to handle exceptions inside an eCos application. It should be noted that this mechanism is critically dependent on reliable interrupt reporting. If it is possible for an interrupt line to glitch, causing an interrupt but leaving the ipending register clear before the VSR 0 handler reads it, then this will be interpreted as an illegal instruction exception. Conceivably this can also affect device drivers if a write to a hardware register may result in an interrupt being cleared in a couple of cycles just as that interrupt is about to happen.

The full implementation of the interrupt and exception handling code can be found in src/nios2asm.S, and that code can be used as the starting point for custom application VSRs.

Stacks and Stack Sizes

cyg/hal/hal_arch.h defines values for minimal and recommended thread stack sizes, CYGNUM_HAL_STACK_SIZE_MINIMUM and CYGNUM_HAL_STACK_SIZE_TYPICAL. These values depend on a number of configuration options. Specifically if the use of a separate interrupt stack CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK is disabled to reduce interrupt latency then thread stacks have to be rather larger to cope with the interrupt processing overhead. If nested interrupts CYGSEM_HAL_COMMON_INTERRUPTS_ALLOW_NESTING are also enabled then thread stacks must be much larger.

The Nios II architectural HAL always provides a separate stack to run the startup code and for exception processing. This stack will also be used for interrupts if CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK is enabled, and its size is determined by CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE.

Thread Contexts and setjmp/longjmp

cyg/hal/hal_arch.h defines a thread context data structure, the context-related macros, and the setjmp/longjmp support. The implementations can be found in src/nios2asm.S. The context structure is straightforward, containing space for the integer registers and the status, ienable and ipending registers. Any floating point arithmetic is assumed to be implemented in software. A single data structure is used for the thread context in all eCos configurations. However some fields will only be used in certain configurations, for example when CYGDBG_HAL_COMMON_INTERRUPTS_SAVE_MINIMUM_CONTEXT is disabled. The use of a single data structure avoids complications when debugging a RAM startup application on top of a ROM RedBoot because both need to use the same structure.

Bit Indexing

The architectural HAL provides an assembler implementation of HAL_LSBIT_INDEX, optimized for faster context switching to higher priority threads. HAL_MSBIT_INDEX uses a straightforward C implementation since it is not performance-sensitive.

Idle Thread Processing

The Nios II instruction set does not include an idle instruction so the idle thread always simply spins, rather than suspend the cpu until an interrupt occurs.

Clock Support

The architectural HAL provides a default implementation of the various system clock macros such as HAL_CLOCK_INITIALIZE. These macros assume that the hardware design implements the system clock using a simple Avalon timer. A platform HAL can provide an alternative implementation if necessary but that is unlikely ever to be necessary because including an Avalon timer in the design is generally straightforward. The timer may be designed with either a fixed period, typically 10 milliseconds to give a 100Hz system clock, or with a variable period in which case there will a configuration option CYGNUM_HAL_RTC_PERIOD to control the clock frequency. Ideally the system clock should be designed with the readable snapshot option enabled. Otherwise the HAL will not be able to provide the HAL_CLOCK_READ macro and there will be no support for clock timings with a finer granularity than the interval between interrupts.

HAL I/O

The various I/O macros for accessing hardware registers such as HAL_READ_UINT8 are implemented using the **ldbuio** and related instructions. This ensures that all I/O accesses bypass any data cache that may be included the hardware design.

Cache Handling

The hardware design may include instruction and data caches, and there is some control over parameters such as the cache sizes and the line sizes. cyg/hal/hal_cache.h defines those cache macros which are appropriate for the current hardware design, typically the `INVALIDATE`, `INVALIDATE_ALL`, `FLUSH`, `STORE` and `SYNC` ones. The hardware does not allow the caches to be enabled or disabled so the `IS_ENABLED` macro always returns a 1 and the `ENABLE` and `DISABLE` macros are never defined. Note that this may confuse some existing code which assumes that these macros are always available.

In addition `cyg/hal/hal_arch.h` defines macros `CYGARC_CACHED_ADDRESS` and `CYGARC_UNCACHED_ADDRESS` which assume that the cpu only addresses 31 bits worth of address space, and that addresses with the top bit set access the same memory locations as those with the top bit clear, but bypassing the cache. This is the default behaviour for Nios II processors. The header file also provides a `HAL_MEMORY_BARRIER` macro which issues a **sync** instruction to cause pending memory operations to complete.

Linker Scripts

The architectural HAL will generate the linker script for eCos applications. This involves the architectural file `src/nios2.ld` and a `.ldi` memory layout file, typically provided by the platform HAL but using some definitions from the hardware design HAL. It is the `.ldi` file which places code and data in the appropriate places for the startup type, but most of the hard work is done via macros in the `nios2.ld` file. This includes macros for placing code and data in on-chip RAM as well as external flash and SDRAM, using linker sections `.iram_text`, `.iram_data` and `.iram_bss`. Code should only be placed in on-chip RAM if the hardware design includes a connection between the RAM and the cpu's instruction master port.

Diagnostic Support

By default the architectural HAL provides a diagnostics and debug channel using the first uart in the hardware design. If the design does not include any uarts then all diagnostics output will instead be discarded. The configuration option `CYGIMP_HAL_NIOS2_DIAGNOSTICS_PORT` can be used to select discard mode even when a uart is available. If the hardware includes an ethernet device then debugging is still possible over the network. Alternatively when debugging via JTAG it is possible to direct the diagnostics output to a gdb hwdebug file I/O channel. By default this will also discard diagnostics output. However if the application is running inside a gdb session and the gdb **set hwdebug** command has been used then the diagnostics will be output via gdb. Platform HALs may implement alternative diagnostics facilities.

SMP Support

The Nios II architectural HAL does not provide any SMP support.

Debug Support

The architectural HAL provides basic support for gdb stubs. Due to a conflict between jtag and stubs gdb support, breakpoints are always implemented using a fixed-size list of breakpoints, as per the configuration option `CYGNUM_HAL_BREAKPOINT_LIST_SIZE`. A hardware design may include hardware breakpoint support but these are not accessible to the gdb stubs code, only via jtag. Hence if a debug session requires the use of hardware breakpoints, for example when debugging code in flash, a jtag-based debug solution must be used instead of gdb stubs.

HAL_DELAY_US() Macro

`cyg/hal/hal_intr.h` provides a simple implementation of the `HAL_DELAY_US` macro using a busy loop. It requires that the hardware design HAL provides a count value `HAL_NIOS2_DELAY_US_LOOPS` appropriate to the cpu speed and the absence or presence of the instruction cache.

Other Functionality

If the hardware design includes a system id register then all RedBoot builds will include some extra initialization code checking the register's current value against the one specified by the hardware design HAL, reporting any mismatches. This helps to guard against accidentally running the wrong build of RedBoot or the wrong hardware design. Note that if there is a serious incompatibility between the two then system bootstrap may fail long before this check gets to run, or the diagnostics channel may be inoperable preventing the warning from reaching the user.

The architectural HAL provides the support needed by the gprof profiling package. This includes the `mcount` needed for callgraph profiling and `hal_enable_profile_timer` for timer-based profiling. The latter can be implemented in two ways. If the hardware design includes a dedicated Avalon timer labelled `“profiling”` then this will be used. Otherwise the sys_clk timer will be used for profiling as well as for the main system clock. Overloading the system clock in this way is less desirable because it means the profiling sampling is likely to miss any code that runs after clock events.

Otherwise the Nios II architectural HAL only implements the functionality provided by the eCos HAL specification and does not export anything extra.

Chapter 342. Nios II Stratix II/2s60_RoHS and Cyclone II/2c35 Platform HAL

Name

`CYGPKG_HAL_NIOS2_DEVKIT` — eCos Platform HAL Support for the Stratix II/2s60-RoHS and Cyclone II/2c35 Boards

Description

The package `CYGPKG_HAL_NIOS2_DEVKIT` provides platform HAL support for the Altera Stratix II/2s60-RoHS and Cyclone II/2c35 development boards, and may also be usable with various other boards depending on compatibility. It is always used in conjunction with the Nios II architectural HAL `CYGPKG_HAL_NIOS2` and with a hardware design HAL which provides details of the design that is programmed into the FPGA.

The main characteristics of both boards are as follows:

1. An FPGA which gets loaded on power up with a hardware design. The eCos Nios II HALs assume that this hardware design consists of a Nios II processor plus various peripherals. Different FPGAs are used on the different boards.

2. A 16MB AMD flash device or compatible. This is a 16-bit device but is attached to the FPGA via an 8-bit data bus. Part of the flash memory is used to hold the current hardware design and a factory default design. On the Stratix II board these reside at offsets 0x00800000 and 0x00C00000 respectively. On the Cyclone II board the offsets are 0x00C00000 and 0x00E00000. In a typical eCos setup this flash will also hold a RedBoot image and an area for RedBoot's **fconfig** and **fis** persistent data. It may also hold one or more application images which RedBoot can load into RAM, and any other persistent data that the application needs.

3. Reset circuitry which on power up loads the hardware design from the flash device into the FPGA. This happens before any code starts running so eCos does not interact with this circuitry in any way.

4. 32MB of SDRAM. In a typical setup the first 64K of this is reserved for RedBoot data and for special bits of code and data such as the Nios II exception vector, while the remainder holds the application code and data.

5. 2MB of SRAM. Typically eCos does not use any of this so all of it is available to the application, and there is linker script support for placing code and data there. Note that if the hardware design places the exception vector in SRAM then eCos will use a small amount of memory at the start of SRAM. Hardware designs can also include on-chip RAM or IRAM which applications can use in much the same way as SRAM.

6. A transceiver for a single uart. This is normally used by eCos as the diagnostics and debug channel so all hardware designs should include a uart connected to the transceiver.

7. A jtag connector, providing an alternative debug mechanism to RedBoot's gdb stubs. The jtag connector can also be used for programming the flash, for example when installing a new hardware design.

8. A lan91c111 ethernet chip. This can be used by one of the eCos TCP/IP stacks and for network debugging. Alternatively network connectivity can be provided by an ethernet device incorporated into the hardware design.

9. A row of LEDs and a dual seven-segment display.

10. Various other devices such as switches which are not directly supported by eCos, and which instead are left available for application use. The Stratix II and Cyclone II boards also come with expansion connectors so that additional hardware can be connected.

Installation

Generic instructions for setting up a board for use with eCos are provided by the Nios II architectural HAL documentation. The Stratix II and Cyclone II boards have no special requirements so the generic instructions should be followed. The address map depends on the hardware design so the documentation for the hardware design HAL should be consulted for details.

Configuration Options

The devkit platform HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The main configuration option in this package is `CYG_HAL_STARTUP`. This can take the following values:

`ROM`

This startup type should be used for code that should execute from flash. The executable will start executing from the Nios II reset vector and will contain all the low-level initialization code needed to bring up the system. Typically this startup type is only used for the RedBoot ROM monitor. On the Stratix II and Cyclone II boards the flash is accessed via an 8-bit data bus so executing code from flash will be slow, even with an instruction cache. Instead application code will normally execute in RAM. It will either be loaded during a gdb debug session, or it can be loaded from flash and started automatically by RedBoot using the **load** and **go** commands.

`RAM`

This startup type should be used for applications that should execute from RAM, either via a gdb debug session interacting with RedBoot's gdb stubs or loaded from flash by RedBoot. eCos will assume that certain services such as diagnostics channel support will be provided by RedBoot and can be accessed via the virtual vector mechanism.

`RAMJTAG`

This startup type is also for applications that should execute from RAM. However it is assumed that the application is not running on top of RedBoot and cannot access any services via the virtual vector mechanisms. Instead the HAL diagnostics channel will be implemented by direct access to the uart, and functionality like RedBoot's **fconfig** settings will not be available at all. This startup type is used primarily when debugging an application via jtag instead of via RedBoot's gdb stubs.

Builds of RedBoot are a special case. For a RAM-resident version of RedBoot there is no difference between the `RAM` and `RAMJTAG` startup types.

If the hardware design includes support for the lan91c111 ethernet chip and if the eCos configuration involves ethernet networking then there are two options related to the lan91c111 device. `CYGDAT_HAL_NIOS2_DEVKIT_ETH_LAN91C111_NAME` specifies the name of the ethernet device, defaulting to `“eth0”`. There should be no need to change this unless the hardware design includes other ethernet devices and their drivers use the same name for the device instances. `CYGDAT_HAL_NIOS2_DEVKIT_ETH_LAN91C111_MAC` specifies the fallback ethernet station address or MAC address. The Stratix II and Cyclone II boards do not have a serial eeprom or similar hardware to provide a unique MAC address, so instead this address has to be provided by software. Usually it will be held in flash as a RedBoot **fconfig** persistent variable. However if the **fconfig** entries have not been initialized, or if they are not accessible because the application is being debugged over jtag and uses the `RAMJTAG` startup type, then the lan91c111 ethernet device will instead use the fallback MAC address specified by this configuration option. No two boards on the same network should ever use the same MAC address so great care must be taken when debugging multiple boards over jtag using the same eCos configuration.

The devkit platform HAL contains a number of other configuration options but these are mainly for internal use by other packages and it should not normally be necessary to edit their values manually.

The HAL Port

The devkit platform HAL does not change the Nios II architectural HAL's implementation of the eCos HAL specification. It does provide the platform-specific linker script support. This takes into account the supported startup types, the locations of the Nios II reset and exception vectors, and the presence of SRAM and any on-chip IRAM.

eCos itself does not use any of the SRAM or the IRAM, except as necessary for exception processing. Instead these memories are available for use by the application. Any code that should end up running from SRAM should be placed in a `.sram_text` section.

Similarly initialized data should be placed in `.sram_data`, and uninitialized data should go in `.sram_bss`. All uninitialized data will be zeroed by the eCos startup code. The equivalent sections for on-chip IRAM are `.iram_text`, `.iram_data` and `.iram_bss`. The platform HAL comes with a testcase `tests/memories.c` which also serves as an example of how to use this functionality.

Other Functionality

If the hardware design includes GPIO units for the row of LEDs and for the dual seven-segment display then the platform HAL provides a number of utility functions for manipulating these.

```
#include <cyg/hal/hal_io.h>

externC void    hal_nios2_led_set(int /* which */, int /* on */);
externC void    hal_nios2_led_set_all(int /* settings */);
externC void    hal_nios2_set_7seg(int /* left */, int /* right */);
```

There is a testcase `tests/lights.c` which also serves as an example of how to use functions.

At the end of its initialization sequence RedBoot will switch all the LEDs off, thus setting them to a known state, and it will set the seven-segment display to `rb`, acting as a visual hint to the user that initialization is complete.

Reusing the Devkit Platform HAL

The devkit platform HAL is intended for use with the Stratix II/2s60_RoHS and Cyclone II/2c35 boards. However it should be usable as is with various other boards, or need only minor changes. The important points to note are as follows:

1. The devkit platform HAL assumes that there is an AMD-compatible flash device on the board, and that it is a 16-bit device attached to the FPGA via an 8-bit bus. The exact flash device and its size do not matter since a run-time CFI query is performed to determine the actual characteristics of the flash device. However if the flash device is not AMD-compatible, not a 16-bit device, or not attached via an 8-bit bus, then the file `src/devkit_flash.c` will have to be changed. With default configuration settings it is also assumed that the Nios II reset vector is at the start of the flash, that the first 128K of flash are available for RedBoot code, and that the last 64K of flash can be used for RedBoot's **fis** and **fconfig** persistent data.

2. The linker script assumes that there is a bank of SDRAM and that this will be used as the main location for application code and data. The size of the SDRAM is obtained from the hardware design HAL. Typically the first 64K is reserved for RedBoot's data area and for special bits of code such as the Nios II exception vector.

3. The SRAM and on-chip IRAM are optional. The devkit platform HAL checks whether or not the hardware design HAL provides base address and size definitions for these.

4. Usually at least one uart is essential to provide the diagnostics and debug channel.

5. The lan91c111 ethernet chip is optional. The devkit platform HAL will only instantiate the ethernet device if the hardware design HAL specifies that this chip is present.

6. Similarly the row of LEDs and the dual seven-segment display are optional and support for these is only provided if the hardware design includes GPIO units labelled “led” and “seven_seg”

Chapter 343. Nios II Cyclone II/2c35 Standard H/W Design HAL

Name

CYGPKG_HAL_NIOS2_CYCLONE2_2C35_STANDARD — eCos Support for the Standard Hardware Design on a Cyclone II/2c35 Board

Description

This package provides the hardware design HAL for the standard hardware design running on a Cyclone II/2c35 board. This design is provided with the Altera Nios II Embedded Design Suite in the directory `nios2eds/examples/vhdl/niosII_cycloneII_2c35/standard/`. It includes the following functionality:

CPU
: A Nios II/s processor running at 85MHz. This has 4K of instruction cache and no data cache. It has level 1 jtag support only with no hardware breakpoints. The reset vector is at address 0x00000000 in external flash and the exception vector is at address 0x02100020 in on-chip IRAM.

Flash
: 16MB of external AMD flash at 0x00000000 attached via an 8-bit data bus.

SDRAM
: 32MB of external SDRAM at 0x04000000.

SRAM
: 2MB of external SRAM at 0x01000000.

IRAM
: 4K of on-chip RAM at 0x02100000.

system clock
: An Avalon timer labelled `sys_clk` used to implement the main eCos system clock. This is hardwired to run at 100Hz.

uart
: An Avalon uart connected to the external transceiver on the board. This is hardwired at 115200 baud, 8 bits, no parity, 1 stop bit, and no RTS/CTS support. This uart is used by eCos for the HAL diagnostics and debug channel.

lan91c111
: An interface to the external lan91c111 ethernet chip on the board. This provides network communications for RedBoot and for eCos applications using one of the available TCP/IP stacks.

GPIO
: GPIO units connected to the row of LEDs, the dual seven-segment display, and the buttons. The devkit platform HAL provides some utility functions for the first two of these.

sysid
: A system id register. This is used by RedBoot to check that the current hardware design matches the RedBoot build.

Other
: A number of other hardware units including a second Avalon timer, a jtag uart, a character LCD controller, and an EPCS serial flash controller. These are not currently used by eCos so can be accessed directly by application code.

Configuration Options

This hardware design HAL package will be loaded automatically when creating an eCos configuration for the `nios2_cyclone2_2c35_standard` target, together with the Nios II architectural HAL and the devkit platform HAL. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The package does not contain any user configuration options.

Memory Map

For typical eCos usage the memory map is as follows:

Address	Purpose
0x00000000	16MB of flash

Address	**Purpose**
0x00000000	reset vector
0x00000000	128K for RedBoot code
0x00c00000	current hardware design
0x00e00000	factory hardware design
0x00FF0000	RedBoot fis and fconfig data
0x01000000	2MB of SRAM
0x02100000	4K of on-chip IRAM
0x02100020	exception vector
0x02120000	peripherals
0x04000000	32MB of SDRAM
0x04000000	64K for RedBoot data
0x04010000	application code and data

Chapter 344. Nios II Cyclone II/2c35 TSEplus H/W Configuration HAL

Name

Overview — eCos Support for the TSEplus Hardware Design on a Cyclone II/2c35 Board

Description

This package provides the hardware design HAL for the eCosPro TSEplus hardware design running on a Cyclone II/2c35 board. The design is based on the TSE_SGDMA design provided with the Altera Nios II Embedded Design Suite, with a number of extensions. It includes the following functionality:

CPU
A Nios II/f processor running at 85MHz. This has 4K of instruction cache and 2K of data cache. It has level 2 jtag support with two hardware breakpoints. The reset vector is at address 0x00000000 in external flash and the exception vector is at address 0x04000020 in external SDRAM.

Flash
16MB of external AMD flash at 0x00000000 attached via an 8-bit data bus.

SDRAM
32MB of external SDRAM at 0x04000000.

SRAM
2MB of external SRAM at 0x01200000.

IRAM
8K of on-chip RAM at 0x01400000. Some of this will used by the triple speed ethernet device driver to store DMA descriptors.

system clock
An Avalon timer labelled `sys_clk` used to implement the main eCos system clock. This defaults to 100Hz but can be changed via the `CYGNUM_HAL_RTC_PERIOD` eCos configuration option.

uart
An Avalon uart connected to the external transceiver on the board. This is hardwired to 8 bits, no parity, and 1 stop bit. The default baud rate is 115200 but can be changed at run-time. The RTS and CTS signals are supported. This uart is used by eCos for the HAL diagnostics and debug channel.

TSE
A triple speed ethernet tse_mac and associated rx_sgdma and tx_sgdma scatter-gather DMA controllers. This provides network communications for RedBoot and for eCos applications using one of the available TCP/IP stacks. Note that this device requires an external phy board to be plugged into one of the main board's expansion connectors.

lan91c111
An interface to the external lan91c111 ethernet chip on the board. This can be used for network communication instead of the triple speed ethernet device, useful if the external phy board is not available.

watchdog
An Avalon timer set up to act as a watchdog device with a 10-second timeout.

profiling
An additional Avalon timer used for gprof-based profiling.

GPIO
GPIO units connected to the row of LEDs, the dual seven-segment display, and the buttons. The devkit platform HAL provides some utility functions for the first two of these.

sysid
A system id register. This is used by RedBoot to check that the current hardware design matches the RedBoot build.

Other
A number of other hardware units including a second Avalon timer, a jtag uart, a character LCD controller, and an EPCS serial flash controller. These are not currently used by eCos so can be accessed directly by application code.

Configuration Options

The TSEplus hardware design HAL package is used with two different eCos targets. The `nios2_cyclone2_2c35_tseplus` target includes the TSE ethernet driver but not the lan91c111 ethernet driver, and can be used when the external phy board is present.

The `nios2_cyclone2_2c35_lan91c111` target includes the lan91c111 ethernet driver but no the TSE ethernet driver and can be used in the absence of the external phy board. When using a RAM startup configuration the same eCos target should be used for both RedBoot and the application.

The hardware design HAL package will be loaded automatically when creating an eCos configuration for either target, together with the Nios II architectural HAL and the devkit platform HAL. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The package does not contain any user configuration options.

The package contains a single configuration option, `CYGNUM_HAL_RTC_PERIOD`. This determines the period of the system clock. By default this operates at 100Hz but the value can be changed if a faster or slower clock is desired. The value is used to program the *`PERIODH`* and *`PERIODL`* registers of the `sys_clk` Avalon timer.

Memory Map

For typical eCos usage the memory map is as follows:

Address	Purpose
0x00000000	16MB of flash
0x00000000	reset vector
0x00000000	128K for RedBoot code
0x00800000	current hardware design
0x00c00000	factory hardware design
0x00FF0000	RedBoot fis and fconfig data
0x01200000	2MB of SRAM
0x01400000	8K of on-chip IRAM
0x01401E00	TSE DMA descriptors
0x01403000	peripherals
0x04000000	32MB of SDRAM
0x04000020	exception vector
0x04000100	~64K for RedBoot data
0x04010000	application code and data

Chapter 345. Nios II Stratix II/2s60_RoHS Standard H/W Design HAL

Name

`CYGPKG_HAL_NIOS2_STRATIX2_2S60_ROHS_STANDARD` — eCos Support for the Standard Hardware Design on a Stratix II/2s60-RoHS Board

Description

This package provides the hardware design HAL for the standard hardware design running on a Stratix II/2s60-RoHS board. This design is provided with the Altera Nios II Embedded Design Suite in the directory `nios2eds/examples/vhdl/niosII_stratixII_2s60_RoHS/standard/`. It includes the following functionality:

CPU
: A Nios II/s processor running at 100MHz. This has 4K of instruction cache and no data cache. It has level 1 jtag support only with no hardware breakpoints. The reset vector is at address 0x00000000 in external flash and the exception vector is at address 0x02100020 in on-chip IRAM.

Flash
: 16MB of external AMD flash at 0x00000000 attached via an 8-bit data bus.

SDRAM
: 32MB of external SDRAM at 0x04000000.

SRAM
: 2MB of external SRAM at 0x01000000.

IRAM
: 4K of on-chip RAM at 0x02100000.

system clock
: An Avalon timer labelled `sys_clk` used to implement the main eCos system clock. This is hardwired to run at 100Hz.

uart
: An Avalon uart connected to the external transceiver on the board. This is hardwired at 115200 baud, 8 bits, no parity, 1 stop bit, and no RTS/CTS support. This uart is used by eCos for the HAL diagnostics and debug channel.

lan91c111
: An interface to the external lan91c111 ethernet chip on the board. This provides network communications for RedBoot and for eCos applications using one of the available TCP/IP stacks.

GPIO
: GPIO units connected to the row of LEDs, the dual seven-segment display, and the buttons. The devkit platform HAL provides some utility functions for the first two of these.

sysid
: A system id register. This is used by RedBoot to check that the current hardware design matches the RedBoot build.

Other
: A number of other hardware units including a second Avalon timer, a jtag uart, a character LCD controller, and an EPCS serial flash controller. These are not currently used by eCos so can be accessed directly by application code.

Configuration Options

This hardware design HAL package will be loaded automatically when creating an eCos configuration for the `nios2_stratix2_2s60_rohs_standard` target, together with the Nios II architectural HAL and the devkit platform HAL. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The package does not contain any user configuration options.

Memory Map

For typical eCos usage the memory map is as follows:

Address	**Purpose**
0x00000000	16MB of flash

Address	**Purpose**
0x00000000	reset vector
0x00000000	128K for RedBoot code
0x00800000	current hardware design
0x00c00000	factory hardware design
0x00FF0000	RedBoot fis and fconfig data
0x01000000	2MB of SRAM
0x02100000	4K of on-chip IRAM
0x02100020	exception vector
0x02120000	peripherals
0x04000000	32MB of SDRAM
0x04000000	64K for RedBoot data
0x04010000	application code and data

Chapter 346. Nios II Stratix II/2s60_RoHS TSEplus H/W Design HAL

Name

— eCos Support for the TSEplus Hardware Design on a Stratix II/2s60-RoHS Board

Description

This package provides the hardware design HAL for the eCosPro TSEplus hardware design running on a Stratix II/2s60-RoHS board. The design is based on the TSE_SGDMA design provided with the Altera Nios II Embedded Design Suite, with a number of extensions. It includes the following functionality:

CPU
A Nios II/f processor running at 85MHz. This has 4K of instruction cache and 2K of data cache. It has level 2 jtag support with two hardware breakpoints. The reset vector is at address 0x00000000 in external flash and the exception vector is at address 0x04000020 in external SDRAM.

Flash
16MB of external AMD flash at 0x00000000 attached via an 8-bit data bus.

SDRAM
32MB of external SDRAM at 0x04000000.

SRAM
2MB of external SRAM at 0x01200000.

IRAM
8K of on-chip RAM at 0x01400000. Some of this will used by the triple speed ethernet device driver to store DMA descriptors.

system clock
An Avalon timer labelled `sys_clk` used to implement the main eCos system clock. This defaults to 100Hz but can be changed via the `CYGNUM_HAL_RTC_PERIOD` eCos configuration option.

uart
An Avalon uart connected to the external transceiver on the board. This is hardwired to 8 bits, no parity, and 1 stop bit. The default baud rate is 115200 but can be changed at run-time. The RTS and CTS signals are supported. This uart is used by eCos for the HAL diagnostics and debug channel.

TSE
A triple speed ethernet tse_mac and associated rx_sgdma and tx_sgdma scatter-gather DMA controllers. This provides network communications for RedBoot and for eCos applications using one of the available TCP/IP stacks. Note that this device requires an external phy board to be plugged into one of the main board's expansion connectors.

lan91c111
An interface to the external lan91c111 ethernet chip on the board. This can be used for network communication instead of the triple speed ethernet device, useful if the external phy board is not available.

watchdog
An Avalon timer set up to act as a watchdog device with a 10-second timeout.

profiling
An additional Avalon timer used for gprof-based profiling.

GPIO
GPIO units connected to the row of LEDs, the dual seven-segment display, and the buttons. The devkit platform HAL provides some utility functions for the first two of these.

sysid
A system id register. This is used by RedBoot to check that the current hardware design matches the RedBoot build.

Other
A number of other hardware units including a second Avalon timer, a jtag uart, a character LCD controller, and an EPCS serial flash controller. These are not currently used by eCos so can be accessed directly by application code.

Configuration Options

The TSEplus hardware design HAL package is used with two different eCos targets. The `nios2_stratix2_2s60_rohs_tseplus` target includes the TSE ethernet driver but not the lan91c111 ethernet driver, and can be used when the external phy board is present. The `nios2_stratix2_2s60_rohs_lan91c111` target includes the lan91c111 ethernet driver but no the TSE ethernet driver and can be used in the absence of the external phy board. When using a RAM startup configuration the same eCos target should be used for both RedBoot and the application.

The hardware design HAL package will be loaded automatically when creating an eCos configuration for either target, together with the Nios II architectural HAL and the devkit platform HAL. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware. The package does not contain any user configuration options.

The package contains a single configuration option, `CYGNUM_HAL_RTC_PERIOD`. This determines the period of the system clock. By default this operates at 100Hz but the value can be changed if a faster or slower clock is desired. The value is used to program the *`PERIODH`* and *`PERIODL`* registers of the `sys_clk` Avalon timer.

Memory Map

For typical eCos usage the memory map is as follows:

Address	**Purpose**
0x00000000	16MB of flash
0x00000000	reset vector
0x00000000	128K for RedBoot code
0x00800000	current hardware design
0x00c00000	factory hardware design
0x00FF0000	RedBoot fis and fconfig data
0x01200000	2MB of SRAM
0x01400000	8K of on-chip IRAM
0x01401E00	TSE DMA descriptors
0x01403000	peripherals
0x04000000	32MB of SDRAM
0x04000020	exception vector
0x04000100	~64K for RedBoot data
0x04010000	application code and data

Chapter 347. Board-level Support for the Nios II Embedded Evaluation Kit, Cyclone III edition

Name

CYGPKG_HAL_NIOS2_NEEK_CYCLONE3_BOARD — eCos Platform HAL Support for the Nios II Embedded Evaluation Kit, Cyclone III Edition

Description

This package provides platform HAL support for the Altera Nios II Embedded Evaluation Kit, Cyclone III Edition, also known as the NEEK board. Since this platform is based around an FPGA it can run a variety of hardware designs, and each design needs its own h/w design HAL to define the details of the hardware configured into the FPGA. The platform HAL contains support for some of the off-chip peripherals on the board, for example the external flash memory and the I²C device used to hold the ethernet MAC address. It also contains some code and configuration options which are likely to be reusable across many h/w designs, to avoid duplicating code unnecessarily.

The h/w design determines which peripherals are available, and that in turn affects how eCos can be used. Hence details of setting up a NEEK board for eCos development can be found in the h/w design HAL documentation. In addition the Nios II architectural HAL documentation contains some generic setup instructions which will be applicable to most h/w designs.

Configuration Options

This platform HAL package should be loaded automatically when eCos is configured for appropriate target hardware. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The main configuration option provided by this package is `CYG_HAL_STARTUP`. This can take either two or three values, depending on the h/w design:

`ROM`
: This startup type should be used for code that should execute from the external flash. The executable will start running from the Nios II reset vector defined in the h/w design and will contain all the low-level initialization code needed to bring up the system. ROM startup can be used for production systems. It can also be used for building the RedBoot ROM monitor on h/w designs that support RedBoot, and the application can then be loaded into RAM and run from there.

`RAMJTAG`
: This startup type will be used mainly for debugging via JTAG. The nios2-elf-gdb debugger will be used, directly or indirectly, to load the application into RAM and start it running.

`RAM`
: This startup type is only available if the h/w design incorporates a uart. It assumes that a ROM-startup RedBoot has been programmed into flash. JTAG is not used for debugging, only for the initial installation. For debugging, nios2-elf-gdb connects to the RedBoot ROM monitor over serial or ethernet and can then be used to load the application into RAM and run it. For production systems a RedBoot boot script can be used to load the application from flash to RAM and start it running.

For ROM and RAMJTAG startup, if the h/w design incorporates a uart then by default that will be used for the diagnostics channel. This can be changed via the configuration option `CYGIMP_HAL_NIOS2_DIAGNOSTICS_PORT`. The alternative destination is `discard` which just discards all diagnostics output. For RAM startup the application will inherit its diagnostics channel from the RedBoot ROM monitor.

The remaining configuration options in this package are primarily for internal use within the configuration system.

External Flash

The NEEK board comes with a single Strata-compatible external flash chip. Assuming the h/w design incorporates support for this, the Strata V2 flash driver will automatically be loaded when creating a new eCos configuration. However the driver will be inactive by default. To activate the driver the generic flash support `CYGPKG_IO_FLASH` must be added to the configuration. The platform HAL will then instantiate a flash device object.

I2C Buses and Devices

The NEEK board comes with a number of I^{2}C devices on two sets of GPIO lines. Given the right support in the h/w design the platform HAL will instantiate bit-banged I^{2}C bus objects and define I^{2}C device objects. The latter can then be manipulated using the generic eCos I^{2}C API, for example `cyg_i2c_tx`, as defined by the package `CYGPKG_IO_I2C`.

If the h/w design HAL defines symbols `HAL_NIOS2_AVALON_PIO_id_eeprom_dat_BASE` and `HAL_NIOS2_AVALON_PIO_id_eeprom_scl_BASE` then the platform HAL will instantiate an I^{2}C bus `hal_neek_cyclone3_id_eeprom_bus` and an I^{2}C device `hal_neek_cyclone3_24lc02b`, corresponding to an EEPROM chip. This chip is factory-programmed with an ethernet MAC address in bytes 2-7. If the h/w design and the eCos configuration involve an ethernet device then the platform HAL will provide this MAC address to the ethernet driver. The other bytes in the EEPROM are not used by eCos so are available to application code.

If the h/w design HAL defines symbols `HAL_NIOS2_AVALON_PIO_lcd_i2c_scl_BASE` and `HAL_NIOS2_AVALON_PIO_lcd_i2c_sdat_BASE` then the platform HAL will instantiate an I^{2}C bus `hal_neek_cyclone3_lcd_i2c_bus` and two I^{2}C device objects `hal_neek_cyclone3_wm8731` and `hal_neek_cyclone3_adv7180`.

LEDs

The NEEK board comes with four LEDs, although not all h/w designs will allow access to all four. If the h/w design incorporates a suitable GPIO port and the h/w design HAL defines the symbol `HAL_NIOS2_AVALON_PIO_led_BASE` then the platform HAL will provide two additional functions for manipulating the LEDs:

```
#include <cyg/hal/hal_io.h>
extern void hal_nios2_led_set(int which, int on);
extern void hal_nios2_led_set_all(int setting);
```

The first function can be used to switch a single LED on or off. The second can be used to change the setting of all four LEDs, using the bottom four bits of the *`setting`* argument.

Chapter 348. Nios II Embedded Evaluation Kit, Cyclone III Edition, appselector H/W Design HAL

Name

CYGPKG_HAL_NIOS2_NEEK_CYCLONE3_APPSELECTOR — eCos Support for the Appselector Hardware Design on a Nios II Embedded Evaluation Kit, Cyclone III Edition

Description

This package provides the hardware design HAL for the version 8.0 appselector hardware design running on a Nios II Embedded Evaluation Kit, Cyclone III edition, also known as the NEEK board. This is the hardware design programmed into boards as shipped from the factory, and in the examples/application_selector and factory_recovery directories of the software supplied with the board.

Note

There are a number of different and incompatible versions of the appselector hardware design. This package supports only the 8.0 version, a copy of which is supplied with eCosPro releases. If your NEEK board runs a different version of the hardware design then it will be necessary to update the board before eCos can be used. Instructions on how to do this are given below.

The hardware design includes the following functionality:

CPU

A Nios II/s processor running at 60MHz. This has 4K of instruction cache and 2K of data cache. It has level 1 jtag support only with no hardware breakpoints. The reset vector is at address 0x04100000 in external flash and the exception vector is at address 0x05000020 in external SRAM.

SDRAM

32MB of external SDRAM at 0x00000000. If RedBoot is used then the bottom 64K will be reserved for RedBoot. The remainder is used as the default location for application data, and for application code for RAM and RAMJTAG startups.

SRAM

1MB of external SRAM at 0x05000000. Some of this will be used for exception and interrupt handling. The remainder is available for use by the application. Code and data can be placed here by putting it into .sram_text, .sram_data and .sram_bss sections. The platform HAL package CYGPKG_HAL_NIOS2_NEEK_CYCLONE3_BOARD contains a memories.c testcase which can be used as an example.

IRAM

4K of on-chip RAM at 0x08000000. This can be used only for holding data, not code. Some of this is used for holding DMA descriptors for the triple-speed ethernet device. The remainder is available for use by application data, by putting it into .iram_data and .iram_bss sections. The platform HAL package CYGPKG_HAL_NIOS2_NEEK_CYCLONE3_BOARD contains a memories.c testcase which can be used as an example.

Flash

16MB of external Strata flash at 0x04000000 attached via an 16-bit data bus. This is supported via the V2 Strata flash driver CYGPKG_DEVS_FLASH_STRATA_V2. The driver will be inactive unless the generic flash support package CYGPKG_IO_FLASH has been added to the configuration. The first megabyte of the flash is reserved for holding the hardware design. Locations 0x04100000 onwards are used to hold the code for ROM startup applications, or to hold RedBoot if that is used. RedBoot's FIS and fconfig data are held at the end of the flash. The remainder is available for use by the application.

system clock

An Avalon timer labelled sys_clk used to implement the main eCos system clock. By default the system clock will operate at 100Hz, but this can be changed by editing the configuration option CYGNUM_HAL_RTC_PERIOD.

uart

An Avalon uart connected to the external transceiver on the board. This is hardwired at 115200 baud, 8 bits, no parity, 1 stop bit, and no RTS/CTS support. Usually this uart will be used by eCos and/or RedBoot for the HAL diagnostics and debug channel, so it will not be available to the application. If the uart is not used in this way then it can be accessed by the application code via the serial device driver `CYGPKG_DEVS_SERIAL_NIOS2_AVALON_UART`. The configuration will also need to include the generic serial support package `CYGPKG_IO_SERIAL`, and the option `CYGPKG_IO_SERIAL_DEVICES` will need to be enabled.

tse

A triple-speed ethernet device, and associated DMA engines. In eCos configurations which involve networking this device will be supported via the ethernet driver package `CYGPKG_DEVS_ETH_NIOS2_TSE`. The ethernet's MAC address is held in an external EEPROM attached to a bit-banged I^{2}C bus.

I2C

The NEEK board has two I^{2}C buses, implemented by bit-banging GPIO ports: `hal_neek_cyclone3_id_eeprom_bus` and `hal_neek_cyclone3_lcd_i2c_bus`. There are I^{2}C device instances for the devices attached to these buses: `hal_neek_cyclone3_24lc02b` for the EEPROM, `hal_neek_cyclone3_adv7180` for the video decoder and `hal_neek_cyclone3_wm8731` for the sound chip. The generic I^{2}C package `CYGPKG_IO_I2C` provides an API for manipulating such devices. Bytes 2 to 7 of the EEPROM are used to hold the ethernet MAC address so should not be changed by application code. If any of the bus or device instances are not used directly or indirectly then they will be removed by link-time garbage collection.

sysid

A system id register. This is used by RedBoot to check that the current hardware design matches the RedBoot build.

Other

A number of other hardware units including a jtag uart, an SPI bus, and a framebuffer device driving an LCD panel. These are not currently used by eCos so can be accessed directly by application code.

Setting up a Board

The eCos port targets a VHDL hardware design named appselector. This hardware design is provided by Altera, and new NEEK boards usually come with this h/w design preprogrammed into the external flash. However, there are several different and incompatible versions of this design. The eCos port specifically targets the 8.0 version. If your board comes with a different version of the h/w design or if a different h/w design has been programmed into flash then it will first be necessary to program the right design into flash. The required image file restore_cycloneIII_3c25.flash can be found in the nios2/ subdirectory of the installation. The sources for this h/w design are also included with the release.

The most convenient way to install a h/w design is to use Altera's flash programming tools, provided with Quartus and the Nios II Embedded Development Suite (nios2eds). The NEEK board has a built-in jtag interface accessible via a USB port, which can be used for this purpose.

The Quartus tools can be downloaded from Altera. Version 13.1 is the last version released that supports the Cyclone III FPGA that the Neek board is based upon. The free “web” version can be downloaded from http://dl.altera.com/13.1/?edition=web and the subscription version from http://dl.altera.com/13.1/?edition=subscription. Version 13.1, unlike some earlier versions, incorporates the EDS tools within the Quartus download.

Assuming that the Altera software as been correctly installed and that a USB cable has been connected between the host PC and the NEEK board, the following commands will install Altera's appselector application and support data, as well as the hardware design. On a Windows PC these commands need to be issued within the Altera EDS Nios command shell, not the Windows or eCos command shells.

```
$ cd <ecosproinstalldir>/ecos-<version>/nios2
$ nios2-flash-programmer --base=0x04000000 --go restore_cycloneIII_3c25.flash
```

If application development will use just the jtag interface then the board can now be used to run eCos applications configured for RAMJTAG startup. This involves running the Nios II gdb server supplied by Altera:

```
$ nios2-gdb-server --tcpport 9000 --tcppersist
```

eCos applications and tests configured for RAMJTAG startup can now be downloaded and executed via nios2-elf-gdb at another command line prompt. For example:

```
nios2-elf-gdb <executable-file>
(gdb) target remote localhost:9000
(gdb) set $ienable=0
(gdb) load
(gdb) continue
```

When using jtag, by default diagnostic output will be directed to the serial port and may be viewed using a terminal emulator configured for 115200/8N1 with no handshaking.

If instead application development will happen via RedBoot then the next step is to install a RedBoot image, replacing the appselector application. Note you must power cycle the board between the above step and this one. Start by connecting a serial cable between the host PC and the NEEK board, and start up a terminal emulator running at 115200/8N1 with no handshaking. Next use Altera's EDS command shell to issue the following commands to program the RedBoot image into flash via jtag:

```
$ cd <ecosproinstalldir>/ecos-<version>/loaders/nios2_neek_cyclone3_appselector
$ bin2flash --location=0x00100000 \
          --input=redboot_ROM.bin \
          --output=redboot.flash
$ nios2-flash-programmer --base=0x04000000 \
                       --sidp=0x08002f40 \
                       --id=1727563914 \
                       --no-keep-nearby \
                       --go \
                       redboot.flash
```

The --sidp and --id arguments are used to check that the board is running the correct h/w design. The --go argument causes the board to restart, so RedBoot should now be running and should have output its banner and a prompt. The terminal emulator can now be used to execute the following commands at the RedBoot prompt to initialise the Flash contents:

```
RedBoot> fis init
RedBoot> fconfig -i
```

eCos applications and tests configured for RAM startup can now be downloaded and executed via nios2-elf-gdb. For example, to run the prebuilt eCos test over serial, first exit the terminal emulator so that nios2-elf-gdb can access the serial port, and then use the following commands:

```
nios2-elf-gdb <path>/thread_gdb
(gdb) set remotebaud 115200
(gdb) target remote /dev/ttyS0
(gdb) load
(gdb) continue
```

RedBoot binaries are provided under the 'loaders' directory in the release. They may be rebuilt by making RAM and ROM startup RedBoot images in the documented manner, each in a separate working directory. For RAM startup:

```
$ ecosconfig new nios2_neek_cyclone3_appselector redboot
$ ecosconfig import <path>/redboot_RAM.ecm
$ ecosconfig check
$ ecosconfig tree
$ make
```

The `.ecm` import file can be found in the `misc` subdirectory of this package. Similarly for ROM startup:

```
$ ecosconfig new nios2_neek_cyclone3_appselector redboot
$ ecosconfig import <path>/redboot_ROM.ecm
$ ecosconfig check
$ ecosconfig tree
$ make
```

Configuration Options

This hardware design HAL package will be loaded automatically when creating an eCos configuration for the `nios2_neek_cyclone3_appselector` target, together with the Nios II architectural HAL `CYGPKG_HAL_NIOS2` and the platform HAL

CYGPKG_HAL_NIOS2_NEEK_CYCLONE3_BOARD. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Selecting the nios2_neek_cyclone3_appselector target will also load a flash driver, a serial driver, an ethernet driver, and I²C support. The flash driver will be inactive unless the configuration also includes the generic flash support package CYGPKG_IO_FLASH. The serial driver will be inactive unless the configuration includes the generic serial support package CYGPKG_IO_SERIAL and the option CYGPKG_IO_SERIAL_DEVICES is enabled. The ethernet driver will be active only in eCos configurations which involve networking. The I²C package is always active, but any functionality that is not used directly or indirectly will be removed via link-time garbage collection.

The port to the appselector h/w design supports three startup types:

ROM
: This startup type should be used for code that should execute from the external flash. The executable will start running from the Nios II reset vector and will contain all the low-level initialization code needed to bring up the system. ROM startup can be used for production systems. It can also be used for building the RedBoot ROM monitor on h/w designs that support RedBoot, and the application can then be loaded into RAM and run from there.

RAMJTAG
: This startup type will be used mainly for debugging via JTAG. The nios2-elf-gdb debugger will be used, directly or indirectly, to load the application into RAM and start it running.

RAM
: This startup type assumes that a ROM-startup RedBoot has been programmed into flash. JTAG is not used for debugging, only for the initial installation. For debugging, nios2-elf-gdb connects to the RedBoot ROM monitor over serial or ethernet and can then be used to load the application into RAM and run it. For production systems a RedBoot boot script can be used to load the application from flash to RAM and start it running.

For ROM and RAMJTAG startup, by default the uart will be used for the diagnostics channel. This can be changed via the configuration option CYGIMP_HAL_NIOS2_DIAGNOSTICS_PORT. The alternative destination is discard which just discards all diagnostics output. For RAM startup the application will inherit its diagnostics channel from the RedBoot ROM monitor.

The configuration option CYGNUM_HAL_RTC_PERIOD can be used to change the system clock frequency. The default value gives a 100Hz clock.

Chapter 349. A&M Adder Board Support

Name

eCos Support for the Adder Board — Overview

Description

This document covers two Analogue & Micro boards, the Adder I and the Adder II. The Adder I board contains an MPC850 processor, 8Mb of RAM, 4MB of flash memory, and external connections for two serial channels and ethernet. The Adder II is identical except that it is built around an MPC852T processor, which is largely compatible with the MPC850. Everything in this document applies to both boards unless otherwise stated.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of 64 blocks of 64k bytes each. In a typical setup, the first three flash blocks are used for the ROMRAM RedBoot image The topmost block is used to manage the flash and hold RedBoot fconfig values. The remaining 60 blocks between 0xFE030000 and 0xFE3EFFFF can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_POWERPC_QUICC_SMC` which supports both the SMC2 (AdderII: SMC1) and SCC3 based on-chip serial devices. These devices can be used by RedBoot for communication with the host. If either of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the Adder target.

There is an ethernet driver `CYGPKG_DEVS_ETH_POWERPC_ADDER` for the on-chip ethernet device (`CYGPKG_DEVS_ETH_POWERPC_ADDERII` for the AdderII). This driver is also loaded automatically when configuring for the Adder target.

eCos manages the on-chip interrupt controller. The architecture-defined decrementer is used to implement the eCos system clock and the microsecond delay function. Other on-chip devices (Caches, PIO, UARTs, FEC) are initialized only as far as is necessary for eCos to run. Other devices (SPI,I2C, PCMCIA) are not touched.

Tools

The Adder port is intended to work with GNU tools configured for a powerpc-eabi target. The original port was undertaken using powerpc-eabi-gcc version 3.2.1, powerpc-eabi-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing the Adder board for eCos Development

Overview

In a typical development environment, the Adder board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **powerpc-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector.	adder[II]_redboot_ROMRAM.ecm	adder[II]_redboot_ROMRAM.bin

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. The baud rate can be changed using the flash configuration console baud rate option. RedBoot also supports ethernet communication and flash management.

Initial Installation

Flash Installation

The Adder boards are shipped from A&M with a version of RedBoot already installed. If the software distribution you are using provides a more recent certified version of RedBoot then you should install that in place of the existing version.

Updating RedBoot is a simple matter of downloading a new binary image and overwriting the existing ROM image. Connect a serial cable between the Adder board and a host computer and start a terminal emulator such as HyperTerminal or minicom. When RedBoot starts up you will see something similar to this:

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 00:02:b3:46:01:00
IP: 10.0.0.202/255.255.255.0, Gateway: 10.0.0.1
Default server: 10.0.0.102, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 17:00:15, Jan  5 2004

Platform: A&M Adder II (PowerPC 852T)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x00800000, [0x0003afc0-0x007ed000] available
FLASH: 0xfe000000 - 0xfe400000, 64 blocks of 0x00010000 bytes each.
RedBoot>
```

To download the new RedBoot image to the board via ethernet, ensure that the ethernet cable is connected (if not, connect it and reset RedBoot). Then copy the new RedBoot image (`adderII_redboot_ROMRAM.bin`) to the TFTP server directory (`/tftpboot` on Linux). You can now download the new RedBoot image with the following command:

```
RedBoot> load -r -b %{FREEMEMLO} -h 10.0.0.100 adderII_redboot_ROMRAM.bin
```

If the TFTP server is running on the machine with the IP address shown against "Default server" at startup, then the `-h <host>` option may be omitted.

Alternatively, if no TFTP server is available, the file may be downloaded more slowly over the serial line with the following command:

```
RedBoot> load -r -b %{FREEMEMLO} -m ymodem
```

Use the terminal emulator's Y-Modem file transfer option to send the file `adderII_redboot_ROMRAM.bin`. Once the file has been uploaded, you can check that it has been transferred correctly using the **cksum** command. On the host (Linux or Cygwin) run the **cksum** program on the binary file:

```
$ cksum adderII_redboot_ROMRAM.bin
1574308703 150312 adderII_redboot_ROMRAM.bin
```

In RedBoot, run the **cksum** command on the data that has just been loaded:

```
RedBoot> cksum -b %{FREEMEMLO} -l 150312
POSIX cksum = 1574308703 150312 (0x5dd60b5f 0x00024b28)
```

The second number in the output of the host **cksum** program is the file size, which should be used as the argument to the `-l` option in the RedBoot **cksum** command. The first numbers in each instance are the checksums, which should be equal.

If the program has downloaded successfully, then it can be programmed into the flash using the following command:

```
RedBoot> fis create -b %{FREEMEMLO} RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0xfe000000-0xfe030000: ...
... Program from 0x0003b000-0x0006b000 at 0xfe000000: ...
... Erase from 0xfe3f0000-0xfe400000: .
... Program from 0x007f0000-0x00800000 at 0xfe3f0000: .
RedBoot>
```

The Adder board may now be reset either by cycling the power, or with the **reset** command. It should then display the startup screen for the new version of RedBoot.

This description has used the Adder II as an example. The process for the Adder I is identical except that the new image file is called `adder_redboot_ROMRAM.bin`. Make sure you load the correct file if both are present.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROMRAM version of RedBoot for the Adder I are:

```
$ mkdir redboot_adder_romram
$ cd redboot_adder_romram
$ ecosconfig new adder redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/powerpc/adder/v2_0_9/misc/adder_redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

To rebuild the ROMRAM version of RedBoot for the Adder II:

```
$ mkdir redboot_adderII_romram
$ cd redboot_adderII_romram
$ ecosconfig new adderII redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/powerpc/adder/v2_0_9/misc/adderII_redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The Adder platform HAL package is loaded automatically when eCos is configured for an `adder` or `adderII` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The Adder platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0xFE000000 and boots from that location. powerpc-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFE000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROM-RAM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFE000000. However, when it starts up the application will first copy itself to RAM at 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The Adder board contains a 4Mb AMD AM29XXXXX series flash device The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX` package contains all the code necessary to support these parts and the `CYGPKG_DEVS_FLASH_POWERPC_ADDER` package contains definitions that customize the driver to the Adder board.

Ethernet Driver

The Adder I board uses SCC2 configured to be a 10Mb/s ethernet interface. The `CYGPKG_DEVS_ETH_POWERPC_QUICC` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_POWERPC_ADDER` package contains definitions that customize the driver to the Adder board.

The Adder II board uses the separate FEC (Fast Ethernet Controller) device. The `CYGPKG_DEVS_ETH_POWERPC_FEC` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_POWERPC_ADDERII` package contains definitions that customize the driver to the Adder II board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are two flags specific to this port:

`-mcpu=860`

The powerpc-eabi-gcc compiler supports many variants of the PowerPC architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu-860` is the correct option for both Adder boards.

`-msoft-float`

The PowerPC processor used in the Adder boards does not have a floating point unit. Therefore it is necessary to translate any floating point operations into software emulation. This option tells the compiler to do that.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Adder hardware, and should be read in conjunction with that specification. The Adder platform HAL package complements the PowerPC architectural HAL and the MPC8XX variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM or ROMRAM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `hal_hardware_init` function in the assembler source file `adder.S`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash
: This is located at address 0xFE000000 of the physical memory space.

SDRAM
: This is located at address 0x00000000 of the physical memory space. The first 12k bytes are used for hardware exception vectors. The next 512 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at location 0x00060000, with the bottom 384kB reserved for use by RedBoot.

on-chip peripherals
: These are accessible via the CPU IMMR register, which is normally set to 0xFA200000. However, applications should not rely on this. See the documentation for the MPC850 or MPC852T for information on the on-chip peripherals.

off-chip peripherals
: The Adder II has an MPC180 Encryption Processor on-board. However, this is not used by eCos.

Other Issues

The Adder platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MPC8XX variant HAL, and the PowerPC architectural HAL documentation should be consulted for further details.

Chapter 350. ADS512101 Board Support

Name

eCos Support for the ADS512101 Board — Overview

Description

This document covers the ADS512101 board. The board contains an MPC5121e microprocessor, 128MiB of RAM, 64MiB of Flash and 128KiB of internal SRAM. There are external connections for a single UART and the Fast Ethernet Controller.

For typical eCos development, a RedBoot image is programmed into the on-chip flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using the serial line.

Supported Hardware

The Flash memory consists of 256 blocks each of 256KiB, occupying 64MiB. The Flash is actually composed of two 32Mib devices operating in parallel. In a typical setup, RedBoot is programmed into flash at 0xFFF00000 and occupies the next 768KiB. The topmost block is used to manage the flash and holds RedBoot fconfig values. The first 255MiB may be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_POWERPC_PSC` which supports both the PSC based on-chip serial devices. Only PSC3 is actually brought out to a usable external connector. This device can be used by RedBoot for communication with the host. The serial driver package is loaded automatically when configuring for the ADS512101 target.

The FEC driver, `CYGPKG_DEVS_ETH_POWERPC_FEC` is used to control the FEC. The package `CYGPKG_DEVS_ETH_POWERPC_ADS512101` is used to configure the generic driver for the MPC5121e and this board.

eCos manages the on-chip interrupt controller. The architecture-defined decrementer is used to implement the eCos system clock and the microsecond delay function. A GPT is used to implement a profiling timer. Other on-chip devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. The remaining devices (PCI, PATA, SATA etc.) are not touched.

Tools

The ADS512101 port is intended to work with GNU tools configured for a powerpc-eabi target. The original port was undertaken using powerpc-eabi-gcc version 4.4.5, powerpc-eabi-gdb version 7.2, and binutils version 2.20.1.

Name

Setup — Preparing the ADS512101 board for eCos Development

Overview

In a typical development environment, the ADS512101 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **powerpc-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROMRAM	RedBoot loaded from ROM into RAM	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`
ROM	RedBoot running directly from flash	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running in external RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
JTAG	RedBoot running in external RAM, loaded by JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.bin`

Under normal circumstances the ROMRAM RedBoot is used. The JTAG RedBoot is used to install the ROMRAM RedBoot on the board.

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. The baud rate can be changed using the flash configuration console baud rate option. RedBoot also supports flash management.

Initial Installation

The simplest approach to installing RedBoot is to make use of a JTAG device to run a version of RedBoot on the board and use that to download and install RedBoot. The following is a simple step-by-step guide to installing RedBoot on the board using a Ronetix PEEDI JTAG emulator:

1. Set up the PEEDI as described in the Ronetix documentation. The `peedi.mpc5121ads.cfg` file should be used to setup and configure the hardware.

2. Connect a null modem serial cable between the ADS512101 board and a suitable host. Run a serial terminal emulator (Hyperterm or minicom) on the host, connecting to the serial device at 115200 baud with no flow control.

3. Connect an ethernet cable between the board and your local network.

4. From the `loaders/ads512101` sub-directory of your eCosPro installation, copy `redboot_JTAG.srec` and `redboot_ROMRAM.bin` to the data area of a TFTP server the PEEDI can access.

5. Connect a telnet session to the PEEDI and issue a reset command to the PEEDI to put the device into a known state:

   ```
   mpc5121> reset stop
   ++ info: user reset
   mpc5121>
   ++ info: HRESET, SRESET and TRST asserted
   ++ info: TRST released
   ++ info: BYPASS check passed
   ++ info: 1 TAP controller(s) detected
   ```

```
++ info: TAP : IDCODE = 0x1540A01D, Freescale MPC5121
++ info: HRESET and SRESET released
++ info: CPU PVR is 0x80862010 (e300c4)
++ info: CPU SVR is 0x80180020
++ info: setting breakpoint at 0xFFF00100
++ info: core 0: initialized
```

6. Now issue the following command, substituting your own TFTP server address:

```
mpc5121>> mem load tftp://10.0.1.1/redboot_JTAG.srec srec
** warning: default file for this core not specified
** warning: use CORE_FILE parameter to specify default file
++ info: Loading image file:  tftp://10.0.1.1/redboot_JTAG.srec
++ info: At absolute address: 0x00000000
loading at 0x0
loading at 0x3300
loading at 0xB300
loading at 0x13300
loading at 0x1B300
loading at 0x22080

Successfully loaded 154KB (158408 bytes) in 1.2s
mpc5121>>
```

7. Now issue the go command:

```
mpc5121> go 0x100
```

You should see something similar to the following output on the board serial line.

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 08:00:3e:28:7a:ba
IP: 10.0.2.5/255.0.0.0, Gateway: 10.0.0.3
Default server: 0.0.0.0
DNS server IP: 10.0.1.1, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [JTAG]
Non-certified release, version UNKNOWN - built 15:05:36, Jun 20 2011

Copyright (C) 2000-2009 Free Software Foundation, Inc.
Copyright (C) 2003-2011 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: ADS512101 (PowerPC MPC5121e)
RAM: 0x00000000-0x08000000 [0x0003e400-0x07fb1000 available]
FLASH: 0xfc000000-0xffffffff, 256 x 0x40000 blocks
RedBoot>
```

8. RedBoot's flash management and configuration should be initialized as follows:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Unlocking from 0xfffc0000-0xffffffff: .
... Erase from 0xfffc0000-0xffffffff: .
... Program from 0x07fc0000-0x08000000 to 0xfffc0000: .
... Locking from 0xfffc0000-0xffffffff: .
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 10.0.1.1
```

```
Console baud rate: 115200
DNS domain name: example.com
DNS server IP address: 10.0.1.1
Network hardware address [MAC]: 0x08:0x00:0x3E:0x28:0x7A:0xBA
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlocking from 0xfffc0000-0xffffffff: .
... Erase from 0xfffc0000-0xffffffff: .
... Program from 0x07fc0000-0x08000000 to 0xfffc0000: .
... Locking from 0xfffc0000-0xffffffff: .
RedBoot>
```

For the "Default server IP address", enter the IP address of the TFTP server on which the `redboot_ROMRAM.bin` is to be found.

9. Now we need to download and program a ROMRAM version of RedBoot. From RedBoot, issue the following command:

```
RedBoot> load -r -b %{freememlo} redboot_ROMRAM.bin
Using default protocol (TFTP)
Raw file loaded 0x0003e400-0x000682a7, assumed entry at 0x0003e400
RedBoot>
```

10. Program the RedBoot into the board:

```
RedBoot> fis cre RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Unlocking from 0xfff00000-0xfffbffff: ...
... Erase from 0xfff00000-0xfffbffff: ...
... Program from 0x0003e400-0x000682a8 to 0xfff00000: ...
... Locking from 0xfff00000-0xfffbffff: ...
RedBoot>
```

11. RedBoot is now programmed into the board. Detach the PEEDI and reset the board and you should see the following output:

```
+Ethernet eth0: MAC address 08:00:3e:28:7a:ba
IP: 10.0.2.5/255.0.0.0, Gateway: 10.0.0.3
Default server: 0.0.0.0
DNS server IP: 10.0.1.1, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [ROMRAM]

Platform: ADS512101 (PowerPC MPC5121e)
RAM: 0x00000000-0x08000000 [0x0003e400-0x07fb1000 available]
FLASH: 0xfc000000-0xffffffff, 256 x 0x40000 blocks
RedBoot>
```

To reinstall RedBoot, a new binary file can be installed and programmed into flash from the installed ROMRAM RedBoot, from step 9 above. It is not necessary to use JTAG for this unless the board is rendered unusable.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot for the ADS512101 are:

```
    $ mkdir redboot_ads512101_romram
    $ cd redboot_ads512101_romram
    $ ecosconfig new ads512101 redboot
    $ ecosconfig import $ECOS_REPOSITORY/hal/powerpc/ads512101/current/misc/ads512101_redboot_ROMRAM.ecm
    $ ecosconfig resolve
    $ ecosconfig tree
    $ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The ADS512101 platform HAL package is loaded automatically when eCos is configured for an `ads512101` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The ADS512101 platform HAL package supports four separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has ROMRAM RedBoot running from 0x00000000 and applications will be loaded from 0x00100000. powerpc-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFFF00000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROMRAM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFFF00000. The first thing the application does is to relocate itself to RAM at location 0x00000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This startup type can be used for finished applications which will be loaded into external RAM via a JTAG debugger. The application will be self-contained with no dependencies on services provided by other software. The JTAG debugger should initialize the hardware enough to load the code into RAM, eCos startup code will perform any further hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The ADS512101 board contains 64MiB of flash memory. The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2` package contains all the code necessary to support access to the flash. The ADS512101 platform HAL package contains definitions that customize the driver to the ADS512101 board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Ethernet Driver

The ADS512101 board uses the MPC5121e's internal FEC ethernet device attached to an external PHY. The `CYGPKG_DEVS_ETH_POWERPC_FEC` package contains all the code necessary to support this device. The `CYGPKG_DEVS_ETH_POWERPC_ADS512101` package contains definitions that customize the driver to the ADS512101 board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The ADS512101 board uses an ST M41T662 I²C Real Time Clock. The `CYGPKG_DEVICES_WALLCLOCK_ST_M41TXX` package contains all the code necessary to support this device. This device also needs the `CYGPKG_IO_I2C` package to be loaded. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The ADS512101 board uses the MPC5121e's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_MPC512X` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVICES_WATCHDOG_POWERPC_MPC512X_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

UART Serial Driver

The ADS512101 board uses the MPC5121e's Programmable Serial Controllers (PSC's) configured for UART mode. Two serial UART adaptors are available on the board. However, only PSC3 is attached to a (pin D-Sub connector. PSC4 is connected to header P8.

I2C Driver

The MPC512X HAL contains a driver for the I²C busses on the board. There are several devices attached to the busses, of which, only the RTC on Bus0 is actually used bt eCos.

CAN Driver

The MPC512X contains four Freescale MSCAN devices, although only one of these is brought out to an external connector. The package `CYGPKG_DEVS_CAN_MSCAN` is a general driver for the MSCAN, and the package `CYGPKG_DEVS_CAN_ADS512101` configures this for the ADS512101 platform.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There is one flag specific to this port:

`-mcpu=e300c3`

The powerpc-eabi-gcc compiler supports many variants of the PowerPC architecture. A `-m` option should be used to select the specific variant in use. The MPC5121e is a e300c4 processor, and the current tools do not have an option to select this processor directly so instead we select a processor that is identical as far as the compiler is concerned, the e300c3.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug applications loaded in RAM, or even applications resident in ROM.

The MPC512x core only supports two hardware breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.mpc5121ads.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the clocks, chip selects and SDRAM controller.

The `peedi.mpc5121ads.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_MPC8300]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **powerpc-eabi-gdb** and the GDB interface. In the case of the latter, **powerpc-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
    (gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.mpc5121ads.cfg` file, and halts the target. This behaviour is repeated whenever the board is reset.

If the board is reset (by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a RedBoot is resident in flash, it will be run.

Consult the PEEDI documentation for information on other features.

Configuration of JTAG applications

If the JTAG device has initialized the processor, such as by using the `peedi.mpc5121ads.cfg` configuration on the PEEDI, applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be disabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Selecting the JTAG startup type in the configuration tool sets these options automatically.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on PSC3.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the ADS512101 hardware, and should be read in conjunction with that specification. The ADS512101 platform HAL package complements the PowerPC architectural HAL and the MPC51XX variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize the on-chip peripherals that eCos uses. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `hal_hardware_init` function in the assembler source file `ads512101.S`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash
: This is located at address 0xFC000000 of the physical memory space. It is mapped by the BAR registers 1-1 to virtual address 0xFC000000 with caching enabled, and to 0x50000000 with caching disabled. The PowerPC reset vector is at 0xFFF00100 so RedBoot is normally programmed from 0xFFF00000.

SDRAM
: This is located at address 0x00000000 of the physical memory space. The first 0x3000 bytes are used for the exception entry trampolines. The following 512 bytes contain the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM and JTAG startup, all remaining SDRAM is available. For RAM startup, available RAM starts at location 0x00100000, with the bottom 1MiB reserved for use by RedBoot. The SDRAM is mapped 1-1 with cache enabled at virtual address 0x00000000 and uncached at 0x20000000.

SRAM
: The 128KiB of on-chip SRAM is mapped 1-1 at 0x30000000. This memory is not used by eCos and is therefore available for application use.

Peripherals
: All on-chip peripherals are accessed relative to the address in the IMMBAR register. Both the PEEDI configuration file and eCos itself set this to 0xE0000000. The CPLD is mapped to 0xE2000000 and is accessible just beyond the IMMBAR peripherals.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information.

Example 350.1. ads512101 Real-time characterization

```
            Startup, main stack : stack used  1032 size  5920
             Startup :  Interrupt stack used   571 size  4096
             Startup : Idlethread stack used   480 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
```

```
Clock interrupt took    1.49 microseconds (74 raw clock ticks)

```

Other Issues

The ADS512101 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MPC55XX variant HAL, and the PowerPC architectural HAL documentation should be consulted for further details.

Chapter 351. Freescale MPC5554DEMO Board Support

Name

eCos Support for the MPC5554DEMO Board — Overview

Description

This document covers the Freescale MPC5554DEMO and MPC5554EVB boards. These boards are essentially identical and will be referred to collectively as the MPC5554DEMO throughout this document. The board contains an MPC5554 microprocessor, 512KB of RAM and external connections for one serial channel. There is also 2MB of on-chip flash memory and 64KB of internal SRAM.

For typical eCos development, a RedBoot image is programmed into the on-chip flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using the serial line.

Supported Hardware

The on-chip flash memory consists of 20 blocks in a variety of sizes between 16KiB and 128KiB, occupying 2MB. In a typical setup, RedBoot is programmed into flash at 0x20000 and occupies the next 256KiB. The topmost block is used to manage the flash and hold RedBoot fconfig values. The first 128KiB and blocks between 0x00060000 and 0x001DFFFF may be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_POWERPC_ESCI` which supports both the eSCI based on-chip serial devices. Only eSCI device A is actually brought out to an external connector. This device can be used by RedBoot for communication with the host. The serial driver package is loaded automatically when configuring for the Mpc5554demo target.

eCos manages the on-chip interrupt controller. The architecture-defined decrementer is used to implement the eCos system clock and the microsecond delay function. Other on-chip devices (Caches, PIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (CAN, eTPU, eMIOS etc.) are not touched.

Tools

The MPC5554DEMO port is intended to work with GNU tools configured for a powerpc-eabi target. The original port was undertaken using powerpc-eabi-gcc version 3.3.3, powerpc-eabi-gdb version 6.1, and binutils version 2.14.

Name

Setup — Preparing the MPC5554DEMO board for eCos Development

Overview

In a typical development environment, the MPC5554DEMO board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **powerpc-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from on-chip ROM	`MPC5554DEMO_redboot_ROM.ecm`	`MPC5554DEMO_redboot_ROM.bin`
RAM	RedBoot running in external RAM	`MPC5554DEMO_redboot_RAM.ecm`	`MPC5554DEMO_redboot_RAM.bin`
JTAG	RedBoot running in external RAM, loaded by JTAG	`MPC5554DEMO_redboot_JTAG.ecm`	`MPC5554DEMO_redboot_JTAG.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. The baud rate can be changed using the flash configuration console baud rate option. RedBoot also supports flash management.

Initial Installation

The simplest approach to installing RedBoot is to make use of the **eSys Flasher** utility and the P&E Wiggler shipped with the board. The reader is referred to the documentation for this utility for details of its use; the following is a simple step-by-step guide to using it to install RedBoot on the board:

1. Install the **eSys Flasher** utility on a suitable PC running Windows XP.

2. Copy `MPC5554DEMO_redboot_ROM.srec` to a suitable location on the Windows PC.

3. Connect a straight-through (not null modem) serial cable between the COM-1 serial port of the board and a serial port on a convenient host (which need not be the PC running **eSys Flasher**). Run a terminal emulator (Hyperterm or minicom) at 38400 baud.

4. Connect the P&E Wiggler to the MPC5554DEMO board and via a USB cable to the Windows PC. Connect the power supply to the MPC5554DEMO board and power it on. At some point during this process XP may ask you to install a device driver. The necessary files will have been installed with the utility, so just follow the directions to install the driver.

5. Start **eSys Flasher** and select "P&E Wiggler (USB)" from the initial dialog. If the program connects to the board then the MCU and Part ID should be displayed at the top right of the next dialog.

6. Click on the "Program Flash" button. Select "S-Record" in the following dialog (and optionally "Verify after Program"), and press "Program". In the "Open" dialog navigate to where the `MPC5554DEMO_redboot_ROM.srec` file is located and select it. The utility will now erase, program and optionally verify the flash. When finished, press the "Close" button to exit the utility.

7. Pressing the reset button on the board should cause RedBoot to start up and display the following output:

   ```
   +**Warning** FLASH configuration checksum error or invalid key
   Use 'fconfig -i' to [re]initialize database
   ```

```
RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 18:06:16, Nov 26 2007

Platform: MPC5554DEMO (PowerPC MPC5554)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007 eCosCentric Limited

RAM: 0x20000000-0x20080000, [0x20006b88-0x20051000] available
FLASH: 0x00000000-0x001fffff, 1 x 0x4000 blocks, 2 x 0xc000 blocks, 1 x 0x4000 blocks, 2 x 0x10000 blocks, 14 x 0x20
RedBoot>
```

8. RedBoot's flash management and configuration should be initialized as follows:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Unlocking from 0x001e0000-0x001fffff: .
... Erase from 0x001e0000-0x001fffff: .
... Program from 0x20060000-0x20080000 to 0x001e0000: .
... Locking from 0x001e0000-0x001fffff: .
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlocking from 0x001e0000-0x001fffff: .
... Erase from 0x001e0000-0x001fffff: .
... Program from 0x20060000-0x20080000 to 0x001e0000: .
... Locking from 0x001e0000-0x001fffff: .
RedBoot>
```

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot for the MPC5554DEMO are:

```
$ mkdir redboot_mpc5554demo_rom
$ cd redboot_mpc5554demo_rom
$ ecosconfig new mpc5554demo redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/powerpc/mpc5554demo/current/misc/mpc5554demo_redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.srec`.

Name

Configuration — Platform-specific Configuration Options

Overview

The MPC5554DEMO platform HAL package is loaded automatically when eCos is configured for an `mpc5554demo` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The MPC5554DEMO platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0x00020000 and boots from that location. powerpc-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0x00020000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This startup type can be used for finished applications which will be loaded into external RAM via a JTAG debugger. The application will be self-contained with no dependencies on services provided by other software. The JTAG debugger should initialize the hardware enough to load the code into RAM, eCos startup code will perform any further hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The MPC5554 microcontroller contains 2MiB of flash memory. The `CYGPKG_DEVS_FLASH_MPC5500` package contains all the code necessary to support access to the flash. The MPC5554DEMO platform HAL package contains definitions that customize the driver to the MPC5554DEMO board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are two flags specific to this port:

`-mcpu=8540`
The powerpc-eabi-gcc compiler supports many variants of the PowerPC architecture. A `-m` option should be used to select the specific variant in use. The MPC5554 is a Book E processor, and the current tools do not have an option to select this processor directly so instead we select a processor that is also Book E based and which is supported: the MPC8540.

`-msoft-float`
The PowerPC processor used in the MPC5554DEMO boards does not have a floating point unit. Therefore it is necessary to translate any floating point operations into software emulation. This option tells the compiler to do that.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug applications loaded in RAM, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The MPC5554 core only supports four such hardware breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI3000 notes

On the Abatron BDI3000, the `bdi3000.mpc5554demo.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the TLB, PLL, external SRAM cache and flash memory controller.

The `bdi3000.mpc5554demo.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI3000 command line interface to make the changes take effect.

On the BDI3000, debugging can be performed either via the telnet interface or using **powerpc-eabi-gdb** and the bdiGDB interface. In the case of the latter, **powerpc-eabi-gdb** needs to connect to TCP port 2001 on the BDI3000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI3000 is powered up, the target will always run the initialization section of the `bdi3000.mpc5554demo.cfg` file (which configures the CPU clock among other things), and halts the target. This behaviour is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot from ROM as normal.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
MPC5554>load 0x20000500 test.bin bin
Loading test.bin , please wait ....
Loading program file passed
MPC5554>go 0x20000540
```

Consult the BDI3000 documentation for information on other formats.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.mpc5554demo.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the TLB, PLL, external SRAM cache and flash memory controller.

The `peedi.mpc5554demo.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_MPC5500]` section. Edit this file if you wish to use software break points, and remember to reset the PEEDI using the reset button or with the **reboot** command on the PEEDI command line interface to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **powerpc-eabi-gdb** and the GDB interface. In the case of the latter, **powerpc-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.mpc5554demo.cfg` file (which configures the CPU clock among other things), and halts the target. This behaviour is repeated with the **reset reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot from ROM as normal.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
mpc5554>mem load tftp://192.168.1.1/test.bin bin 0x20000500
++ info: Loading image file:  tftp://192.168.1.1/test.bin
++ info: At absolute address: 0x20000500
loading at 0x20000500
loading at 0x20008500
loading at 0x20010500

Configuration of JTAG applications

If the JTAG device has initialized the processor, such as by using the `peedi.mpc5554.cfg` configuration on the PEEDI, or the `bdi3000.mpc5554.cfg` configuration on the BDI3000, applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be disabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Selecting the JTAG startup type in the configuration tool sets these options automatically.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on eSCI device A.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the MPC5554DEMO hardware, and should be read in conjunction with that specification. The MPC5554DEMO platform HAL package complements the PowerPC architectural HAL and the MPC55XX variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `hal_hardware_init` function in the assembler source file `mpc5554demo.S`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash

This is located at address 0x00000000 of the physical memory space. It is mapped by the BAM 1-1 to virtual address 0x00000000 with caching enabled, and by eCos to 0x10000000 with caching disabled.

SRAM

This is located at address 0x20000000 of the physical memory space. The first 512 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. The next 512 bytes are used for a shared interrupt state table, recording mask and priority values for each interrupt source. For ROM and JTAG startup, all remaining SRAM is available. For RAM startup, available RAM starts at location 0x00008000, with the bottom 32kiB reserved for use by RedBoot. The SRAM is mapped 1-1 with cache enabled at virtual address 0x20000000 and uncached at 0x30000000.

on-chip peripherals

These are available via 1-1 uncached mappings at 0xFFF00000 and 0xC3F00000.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information.

Example 351.1. mpc5554demo Real-time characterization

```
            Startup, main stack : stack used   708 size  5664
             Startup :  Interrupt stack used   856 size  4096
             Startup : Idlethread stack used   220 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 13 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    6.71 microseconds (858 raw clock ticks)

Testing parameters:
   Clock samples:            32

```

Other Issues

The MPC5554DEMO platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MPC55XX variant HAL, and the PowerPC architectural HAL documentation should be consulted for further details.

Chapter 352. MPC8309KIT Board Support

Name

eCos Support for the MPC8309KIT Board — Overview

Description

This document covers the MPC8309KIT board. The board consists of a MPC8309SOM card plugged in to a MPC830X carrier board. The SOM contains an MPC8309 microprocessor, 256MiB of RAM and 8MiB of Flash. There are external connections for a single RS232 UART and the Fast Ethernet Controller.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using the serial line or Ethernet.

Supported Hardware

The Flash memory consists of 127 blocks each of 64KiB, and 8 blocks of 8KiB, occupying 8MiB. In a typical setup, RedBoot is programmed into the base of flash at 0xFE000000 and occupies the next 768KiB. The topmost 64KiB block is used to manage the flash and holds RedBoot fconfig values. The remainder may be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_GENERIC_16X5X` which supports the 16X5X compatible DUARTs. The package `CYGPKG_IO_SERIAL_POWERPC_MPC8309KIT` provides definitions to configure the generic driver to the board. Only UART0 is actually brought out to a usable DB9 external connector via an RS232 transceiver; UART1 is delivered to the second DB9 via an RS485 transceiver. This device can be used by RedBoot for communication with the host. The serial driver package is loaded automatically when configuring for the MPC8309KIT target.

The UEC Ethernet driver, `CYGPKG_DEVS_ETH_POWERPC_UEC` is used to control the QUICC Engine UCC based Ethernet device. This driver only supports a single Ethernet interface at present: the RJ-45 socket on the SOM board.

eCos manages the on-chip interrupt controller. The architecture-defined decrementer is used to implement the eCos system clock and the microsecond delay function. A GTM is used to implement a profiling timer. Other on-chip devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. The remaining devices (PCI, CAN, USB etc.) are not touched.

Interrupt Nesting

eCos normally operates with a sequential interrupt model, where each ISR is run with interrupts disabled and coincident ISRs are run in turn. However, the PowerPC HAL and kernel are designed to support nested interrupts where required. The MPC83XX variant HAL and MPC8309KIT platform HAL have been validated for nested interrupt support.

No special configuration is required to use nested interrupts, support for this is always present. Nested interrupts can be enabled simply by re-enabling interrupts in an ISR. However, there are a number of issues that need to be considered:

1. All ISRs are entered with interrupts disabled and should be exited with interrupts disabled. So the ISR must bracket any code that can be preempted with enable and disable calls.

2. An ISR must cancel the cause of its own interrupt before re-enabling interrupts otherwise it could put the CPU into an interrupt loop. This should include a call to `cyg_interrupt_acknowledge()`, maybe writing to device registers, or even a call to `cyg_interrupt_mask()` to block the interrupt source.

3. Stack usage within ISRs and the level of nesting may require the value of `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` to be increased. Note that DSRs are also run on the interrupt stack, so excessive stack usage in any DSR must also be accounted for.

4. ISRs for standard devices do not enable interrupts, and will thus run to completion with interrupts off. These ISRs will impose latency on the start of any nested ISR and will preempt it while interrupts are enabled. However, the only ISRs currently supported are for the Ethernet, serial, I²C and system timer, all of which are either minimal, or very simple.

5. There is no prioritisation of ISRs, hardware prioritisation only determines which of any simultaneously pending ISRs is delivered to the CPU next. Any ISR can interrupt any other, low priority ISRs are not blocked by high priority ones. If some sort of prioritisation is required, it must be implemented in software by selectively masking and unmasking vectors as appropriate.

The following shows the suggested layout of an ISR that supports nesting:

```
cyg_uint32 nested_isr( cyg_uint32 vector, CYG_ADDRWORD data )
{
    CYG_INTERRUPT_STATE ints;

    cyg_interrupt_acknowledge( vector );

    // Cancel or mask interrupt here

    // Enable CPU interrupts
    HAL_ENABLE_INTERRUPTS();

    // Code here is preemptable

    // Disable interrupts before return
    HAL_DISABLE_INTERRUPTS(ints);

    return 1;
}
```

See the Timers Test for an example of a program that uses nested interrupts.

Tools

The MPC8309KIT port is intended to work with GNU tools configured for a powerpc-eabi target. The original port was undertaken using powerpc-eabi-gcc version 4.4.5, powerpc-eabi-gdb version 7.2, and binutils version 2.20.1.

Name

Setup — Preparing the MPC8309KIT board for eCos Development

Overview

In a typical development environment, the MPC8309KIT board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **powerpc-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running directly from flash	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running in external RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
JTAG	RedBoot running in external RAM, loaded by JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.bin`

Under normal circumstances the ROM RedBoot is used. The JTAG RedBoot is used to install the ROM RedBoot, and the RAM RedBoot may be used to update it.

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. The baud rate can be changed using the flash configuration console baud rate option. RedBoot also supports flash management.

Initial Installation

The simplest approach to installing RedBoot is to make use of a JTAG device to run a JTAG version of RedBoot on the board and use that to download and install ROM RedBoot. The following is a simple step-by-step guide to installing RedBoot on the board using a Ronetix PEEDI JTAG emulator:

1. Set up the PEEDI as described in the Ronetix documentation. The `peedi.mpc8309kit.cfg` file should be used to setup and configure the hardware.

2. Connect a null modem serial cable between the MPC8309KIT board and a suitable host. Run a serial terminal emulator (Hyperterm, Teraterm or minicom) on the host, connecting to the serial device at 115200 baud with no flow control.

3. Connect an Ethernet cable between the board and your local network.

4. From the `loaders/mpc8309kit` sub-directory of your eCosPro installation, copy `redboot_JTAG.srec` and `redboot_ROM.bin` to the data area of a TFTP server the PEEDI can access.

5. Connect a telnet session to the PEEDI and issue a reset command to the PEEDI to put the device into a known state:

```
mpc8309> reset stop
++ info: user reset
mpc8309>
++ info: HRESET, SRESET and TRST asserted
++ info: TRST released
++ info: BYPASS check passed
++ info: 1 TAP controller(s) detected
++ info: TAP : IDCODE = 0x16AC101D, MPC8308
++ info: overriding RCW (0xA0600000 0x44050008)
```

```
      ++ info: HRESET and SRESET released
      ++ info: CPU PVR is 0x80850020 (e300c3)
      ++ info: CPU SVR is 0x81100011
      ++ info: setting breakpoint at 0x00000100
      ++ info: core 0: initialized
```

6. Now issue the following command, substituting your own TFTP server address:

```
      mpc8309> mem load tftp://192.168.7.22/redboot_JTAG.srec srec
      * warning: default file for this core not specified
      ** warning: use CORE_FILE parameter to specify default file
      ++ info: Loading image file:  tftp://192.168.7.22/redboot_JTAG.srec

      Successfully loaded 248KB (253956 bytes) in 1.7s
      mpc8309>
```

7. Now issue the go command:

```
      mpc8309> go 0x100
```

You should see something similar to the following output on the board serial line.

```
      +**Warning** FLASH configuration checksum error or invalid key
      Use 'fconfig -i' to [re]initialize database
      Ethernet eth0: MAC address 00:04:9f:ef:03:01
      IP: 192.168.7.171/255.255.255.0, Gateway: 192.168.7.1
      Default server: 0.0.0.0
      DNS server IP: 192.168.7.3, DNS domain name: <null>

      RedBoot(tm) bootstrap and debug environment [JTAG]
      Non-certified release, version UNKNOWN - built 13:34:41, Mar  2 2012

      Copyright (C) 2000-2009 Free Software Foundation, Inc.
      Copyright (C) 2003-2012 eCosCentric Limited
      RedBoot is free software, covered by the eCos license, derived from the
      GNU General Public License. You are welcome to change it and/or distribute
      copies of it under certain conditions. Under the license terms, RedBoot's
      source code and full license terms must have been made available to you.
      Redboot comes with ABSOLUTELY NO WARRANTY.

      Platform: MPC8309KIT (PowerPC MPC8309)
      RAM: 0x00000000-0x10000000 [0x00049bc0-0x0ffe1000 available]
      FLASH: 0xfe000000-0xfe7fffff, 127 x 0x10000 blocks, 8 x 0x2000 blocks
      RedBoot>
```

8. RedBoot's flash management and configuration should be initialized as follows:

```
      RedBoot> fis init
      About to initialize [format] FLASH image system - continue (y/n)? y
      *** Initialize FLASH Image System
      ... Unlocking from 0xfe7f0000-0xfe7fffff: ........
      ... Erase from 0xfe7f0000-0xfe7fffff: ........
      ... Program from 0x0fff0000-0x10000000 to 0xfe7f0000: ........
      ... Locking from 0xfe7f0000-0xfe7fffff: ........
      RedBoot> fconfig -i
      Initialize non-volatile configuration - continue (y/n)? y
```

```
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 192.168.7.22
Console baud rate: 115200
DNS domain name: example.com
DNS server IP address: 192.168.7.3
Network hardware address [MAC] for eth0: 0x00:0x04:0x9F:0xEF:0x03:0x073
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlocking from 0xfe7f0000-0xfe7fffff: ........
... Erase from 0xfe7f0000-0xfe7fffff: ........
... Program from 0x0fff0000-0x10000000 to 0xfe7f0000: ........
... Locking from 0xfe7f0000-0xfe7fffff: ........
RedBoot>
```

For the "Default server IP address", enter the IP address of the TFTP server on which the `redboot_ROM.bin` is to be found.

9. Now we need to download and program a ROM version of RedBoot. From RedBoot, issue the following command, substituting the IP address of your TFTP server:

```
RedBoot> load -r -b %{freememlo} -h 192.168.7.22 redboot_ROM.bin
Using default protocol (TFTP)
Raw file loaded 0x00049c00-0x00089cd7, assumed entry at 0x00049c00
RedBoot>
```

10. Program the RedBoot into the board:

```
RedBoot> fis create RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Unlocking from 0xfe000000-0xfe0bffff: ...........
... Erase from 0xfe000000-0xfe0bffff: ...........
... Program from 0x00049c00-0x00089cd8 to 0xfe000000: .....
... Locking from 0xfe000000-0xfe0bffff: ...........
... Unlocking from 0xfe7f0000-0xfe7fffff: ........
... Erase from 0xfe7f0000-0xfe7fffff: ........
... Program from 0x0fff0000-0x10000000 to 0xfe7f0000: ........
... Locking from 0xfe7f0000-0xfe7fffff: ........
RedBoot>
```

11. RedBoot is now programmed into the board. Detach the PEEDI and reset the board and you should see the following output:

```
+Ethernet eth0: MAC address 00:04:9f:ef:03:73
IP: 192.168.7.182/255.255.255.0, Gateway: 192.168.7.1
Default server: 192.168.7.22
DNS server IP: 192.168.7.3, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 10:42:26, Mar  2 2012

Platform: MPC8309KIT (PowerPC MPC8309)
RAM: 0x00000000-0x10000000 [0x0001a9b8-0x0ffe1000 available]
FLASH: 0xfe000000-0xfe7fffff, 127 x 0x10000 blocks, 8 x 0x2000 blocks
RedBoot>
```

To reinstall RedBoot, the above process can be repeated, or a RAM RedBoot can be loaded by the ROM RedBoot and used like the JTAG RedBoot to load and program a new ROM RedBoot.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot for the MPC8309KIT are:

```
    $ mkdir redboot_mpc8309kit_rom
    $ cd redboot_mpc8309kit_rom
    $ ecosconfig new mpc8309kit redboot
    $ ecosconfig import $ECOS_REPOSITORY/hal/powerpc/mpc8309kit/current/misc/mpc8309kit_redboot_ROM.ecm
    $ ecosconfig resolve
    $ ecosconfig tree
    $ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The MPC8309KIT platform HAL package is loaded automatically when eCos is configured for an `mpc8309kit` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The MPC8309KIT platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has ROM RedBoot using RAM from 0x00000000 and applications will be loaded from 0x00100000. powerpc-eabi-gdb is used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0xFE000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This startup type can be used for finished applications which will be loaded into external RAM via a JTAG debugger. The application will be self-contained with no dependencies on services provided by other software. The JTAG debugger should initialize the hardware enough to load the code into RAM, eCos startup code will perform any further hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The MPC8309KIT board contains 8MiB of flash memory. The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2` package contains all the code necessary to support access to the flash. The MPC8309KIT platform HAL package contains definitions that customize the driver to the MPC8309KIT board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Ethernet Driver

The MPC8309KIT board uses the QUICC Engine UCC UEC1 Ethernet device attached to an external PHY. The `CYGPKG_DEVS_ETH_POWERPC_UEC` package contains all the code necessary to support this device. This driver only supports a single Ethernet interface at present: the RJ-45 socket on the SOM board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The `CYGPKG_DEVICES_WALLCLOCK_MPC83XX` package supports the MPC8309 RTC device. The driver supports only clocking from the 32kHz RTC input clock. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The MPC8309KIT board uses the MPC8309 internal watchdog support. This device is compatible with the watchdog on the MPC512X family and so shares that device driver. The `CYGPKG_DEVICES_WATCHDOG_MPC512X` package contains the code necessary to support this device. Within that package the `CYGNUM_DEVICES_WATCHDOG_POWERPC_MPC512X_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

UART Serial Driver

The MPC8309KIT board uses the 16X5X compatible serial DUARTs. Two serial UART adaptors are available on the board. Only UART0 is actually brought out to a usable DB9 external connector via an RS232 transceiver; UART1 is delivered to the second DB9 via an RS485 transceiver. The generic 16X5X driver `CYGPKG_IO_SERIAL_GENERIC_16X5X` supports the 16X5X compatible DUARTs. The package `CYGPKG_IO_SERIAL_POWERPC_MPC8309KIT` provides definitions to configure the generic driver to the board.

I2C Driver

The MPC512X HAL contains a driver for the I^{2}C busses on the board. There are several devices attached to the busses, see the board documentation for a description. The file `mpc512x_i2c.c` and the header `plf_io.h` contain definitions for some of these devices. The test programs `pca9534_1.c` and `pca9534_2.c` contain tests that exercise the I^{2}C bus by flashing the LEDs on the carrier board.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There is one flag specific to this port:

`-mcpu=e300c3`

The powerpc-eabi-gcc compiler supports many variants of the PowerPC architecture. A `-m` option should be used to select the specific variant in use. The MPC8309 contains an e300c3 processor, and this option allows the compiler to optimize code for this processor variant.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug applications loaded in RAM, or even applications resident in ROM.

The MPC8309 core only supports a limited number of hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Ronetix PEEDI Notes

On the Ronetix PEEDI, the `peedi.mpc8309kit.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the clocks, chip selects and SDRAM controller.

The `peedi.mpc8309kit.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_MPC8300]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **powerpc-eabi-gdb** and the GDB interface. In the case of the latter, **powerpc-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
    (gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.mpc8309kit.cfg` file, and halts the target. This behaviour is repeated whenever the board is reset.

If the '**reset run**' command is given, then the board will boot as normal. If a RedBoot is resident in flash, it will be run.

Consult the PEEDI documentation for information on other features.

Configuration of JTAG applications

If the JTAG device has initialized the processor, such as by using the `peedi.mpc8309kit.cfg` configuration on the PEEDI, applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be disabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Selecting the JTAG startup type in the configuration tool sets these options automatically.

Running JTAG applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial line.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the MPC8309KIT hardware, and should be read in conjunction with that specification. The MPC8309KIT platform HAL package complements the PowerPC architectural HAL and the MPC83XX variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize the on-chip peripherals that eCos uses. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `hal_hardware_init` function in the assembler source file `mpc8309kit.S`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash
: This is located at address 0xFE000000 of the physical memory space. It is mapped by the BAR registers 1-1 to virtual address 0xFE000000 with caching enabled, and to 0x5E000000 with caching disabled. While the PowerPC reset vector is at 0xFFF00100 the chip bootstrap mechanism means that ROM applications actually boot from 0x00000100, where the flash is remapped during startup. Initialization code remaps the flash to 0xFE000000 and moves execution there.

SDRAM
: This is located at address 0x00000000 of the physical memory space. The first 0x3000 bytes are used for the exception entry trampolines. The following 512 bytes contain the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM and JTAG startup, all remaining SDRAM is available. For RAM startup, available RAM starts at location 0x00100000, with the bottom 1MiB reserved for use by RedBoot. The SDRAM is mapped 1-1 with cache enabled at virtual address 0x00000000 and uncached at 0x20000000.

Peripherals
: All on-chip peripherals are accessed relative to the address in the IMMBAR register. Both the PEEDI configuration file and eCos itself set this to 0xE0000000.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information.

Example 352.1. mpc8309kit Real-time characterization

```
            Startup, main stack : stack used  1080 size  6048
             Startup :  Interrupt stack used  4064 size  4096
             Startup : Idlethread stack used   508 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    2.38 microseconds (79 raw clock ticks)
```

```

Other Issues

The MPC8309KIT platform HAL does not affect the implementation of other parts of the eCos HAL specification. The MPC55XX variant HAL, and the PowerPC architectural HAL documentation should be consulted for further details.

Name

GPIO Support — Details

Synopsis

#include <cyg/hal/hal_io.h>

`cyg_uint32 pin = **CYGHWR_HAL_MPC83XX_GPIO**(*ctlr*, *bit*, *mode*);`

CYGHWR_HAL_MPC83XX_GPIO_SET (*pin*);

CYGHWR_HAL_MPC83XX_GPIO_OUT (*pin*, *val*);

CYGHWR_HAL_MPC83XX_GPIO_IN (*pin*, *val*);

Description

This section describes how to use macros provided by eCos to manage GPIO functionality on the MPC83XX processors.

The MPC83XX HAL provides a number of macros to support the encoding of GPIO pin identity and configuration into a single 32 bit descriptor. This is useful to drivers and other packages that need to configure and use different lines for different devices.

A descriptor is created with `CYGHWR_HAL_MPC83XX_GPIO(ctlr, bit, mode)` which takes the following arguments:

ctlr
This identifies the GPIO controller to which the pin is attached. It may take the value 1 or 2.

bit
This gives the bit or pin number within the port. These are numbered from 0 to 32. Note that the bit numbers conform to the Freescale big-endian numbering scheme.

mode
This defines the mode in which the pin is to be used. There are 4 main options: `INPUT` sets the pin as an input, `OUTPUT` sets it as an output. `INPUT_OPENDRAIN` and `OUTPUT_OPENDRAIN` set it as input or output with an open drain.

The following examples show how this macro may be used:

```
// Define controller 1 pin 10 as an input
#define CYGHWR_HAL_MPC8309_PIN1              CYGHWR_HAL_MPC83XX_GPIO( 1, 10, INPUT )

// Define controller 2 pin 23 as an open drain output
#define CYGHWR_HAL_MPC8309_PIN23             CYGHWR_HAL_MPC83XX_GPIO( 2, 23, OUTPUT_OPENDRAIN )
```

Additionally, the macro `CYGHWR_HAL_MPC83XX_GPIO_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used.

The remaining macros all take a GPIO pin descriptor as an argument. `CYGHWR_HAL_MPC83XX_GPIO_SET` configures the pin according to the descriptor and must be called before any other macros. `CYGHWR_HAL_MPC83XX_GPIO_OUT` sets the output to the value of the least significant bit of the *val* argument. The *val* argument of `CYGHWR_HAL_MPC83XX_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

Name

Test Programs — Details

Test Programs

The MPC8309KIT HAL contains some test programs which allow various aspects of the microcontroller or the architecture to be tested.

Timers Test

The `timers` test checks the functionality of the microcontroller timers and in particular the interrupt nesting mechanism. This test also acts as and example of how to handle nested interrupts. The test programs the four available GTM timers to interrupt at a variety of different rates and records various parameters. The timers are programmed to interrupt at higher rates for higher interrupt priority timers. This information is summarized at the start of the run:

```
Options:
    LOOPS        24
    LOITER       1
    DSRS         1
    MHZ          10
    SYSTICK      1
    DELAY        0
    LATENCY      1
    LATENCY_HIST 20
    LATENCY_BASE 0

    CSB clock    133333332Hz

T  Interval Frequency    Tick Prescaler Vector
4:    127us  10256410    97ns        13     73
2:    355us  10256410    97ns        13     79
3:    731us  10256410    97ns        13     85
1:    999us  10256410    97ns        13     91
```

The options indicate what compile-time options have been applied. See the source of the test for a brief description of each. The table gives for each timer the requested interval between interrupts, the programmed frequency, the resulting length of a tick, the prescaler used to achieve this and the interrupt vector. Each timer is programmed to run at approximately 10MHz and the tick value is the resulting tick duration at that frequency. Each timer will actually interrupt every `Interval*Tick*MHZ` nanoseconds. The vector numbers also define the static priority of the interrupts, so timer 4 is highest priority, and timer 1 lowest. After initialization the test outputs a sequence of tables of the following format every 5 seconds:

```
ISRs max_nesting 5 max_nesting_seen 6
Spurious interrupts: 0

ISR Preempt:
T  Ticks    0    1    2    3    4
4:  944k 688k  81k  89k  84k   66
2:  338k 245k  28k    0  29k  34k
3:  164k 118k  13k  15k    0  16k
1:  120k  86k    0  10k  10k  12k

 3: 1649  485    0    0   16   15   20 120k  38k  620  397  396  368  352  343  329  319  243  182  721    8   60
 1: 2716  485    0    0    0    0    0  87k  28k  515  293  293  263  252  275  253  252  200  145  576   14   59
```

The first line shows the depth of ISR nesting seen since the last report, plus the maximum seen throughout the run. The second line counts the number of spurious interrupts seen, and should always be zero. The above example is taken from the end of a run, although there are only 4 timers, this run has seen a nesting level of 5 and a whole run total of 6.

The ISR Preempt table contains a row for each timer. The *Ticks* column shows the total number of ISRs called for this timer. The *0* column shows how many ISR calls interrupted thread state. The remaining columns show how many ISR calls preempted the ISR for the given timer. For example, the ISR for timer 3 preempted the ISR for timer 2 about 15000 times. Mostly the ISRs do not interrupt themselves, but timer 4's ISR has interrupted itself 66 times. This is because the ISRs delay for a while to improve the possibility of preemption, and the accumulation of latencies occasionally results in an ISR still running when the next interrupt occurs. Note that this only records the ISR immediately below the current one on the stack, not every nested ISR.

The ISR Nesting table indicates for each ISR how deeply nested the ISRs are when each is run. In each line, the 1 column indicates how many times the ISR was first on the stack, the 2 column how many times there was one preempted ISR, the 3 column how many times there were two preempted ISRs and so on. For example, the ISR for timer 1 has been at the base of the stack about 86000 times, preempted one other ISR about 26000 times and preempted a stack of five ISRs just once.

The DSRs table contains two rows for each timer. The *preempt:* row shows how many times the ISR preempted the DSR for the given timer. The zero column correspond to thread state as before. For example the ISR for timer 2 preempted the DSR for timer 4 1969 times. The *count:* row shows the range of `count` values passed to the DSR and indicates the number of DSR calls not matched exactly to ISR calls. The ISR calls the DSR every 10 ticks, so the total counts should be one tenth of the ISR Ticks value. In this run only timer 4 has accumulated any instances where a new ISR occurred before a previously posted DSR could run.

The ISR latency table shows, for each ISR the range of ISR latencies. This is done by reading the timer counter on entry to the ISR and calculating the delay from the point at which the timer triggered the interrupt. For each timer the maximum latency seen is recorded, together with the average for the last 5 seconds. In the histogram, each column represents an additional tick of the 10MHz frequency of each timer, multiplied up to its duration in nanoseconds. Entries count the number of ISRs that were seen with that latency and the 1843+ column accumulates all larger latencies.

I2C Tests

Two programs are supplied to test the functioning of I²C. The MPC8309KIT board has a number of I²C devices, but no external access to the busses. These tests access the only device that provides visible confirmation of its functions: by manipulating the LEDs attached to a PCA9534 GPIO expander on the carrier board on I²C bus 2.

There are two programs; `pca9534_1` operates the I²C device in polled mode and `pca9534_2` operates in in interrupt driven mode. Otherwise they are identical.

Chapter 353. MPC512X Variant Support

Name

`CYGPKG_HAL_POWERPC_MPC512X` — eCos Support for the MPC512X Microprocessor Family

Description

The Freescale MPC512X series of PowerPC microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for PSC serial and SPI, I²C, FEC Ethernet, watchdog devices and the PATA interface. In addition it provides common functionality and definitions that MPC512X based platform ports may require, as well as definitions useful to application developers.

This documentation covers the MPC512X functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the STM32 variant HAL provides. The areas that are specific to platform HALs and not the STM32 variant HAL include:

- memory map and related configuration and setup
- Clock parameters
- GPIO and pin configuration
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

This section describes the devices controlled by this HAL.

Cache Handling

The MPC512X contains both data and instruction caches. The `cyg/hal/hal_cache.h` header defines the cache sizes for the processor variants and defines the eCos standard macros for operating on the caches.

PSC support

The MPC512X contains a number of general purpose Programmable Serial Controllers (PSCs) which can be used as UARTs or SPI master or slave controllers (along with other modes that eCos does not support).

For each PSC, *N*, there are a number of configuration options:

CYGHWR_HAL_POWERPC_MPC512X_PSC*N*

> This defines the mode in which this PSC is to be used. If set to `UNUSED` then the PSC is not used and its external pins are available for alternate device functions. If it is set to `UART` it is used as a UART. If set to `SPI` then it is an SPI master, and if set to `SPISLAVE` an SPI slave device.

CYGHWR_HAL_POWERPC_MPC512X_PSC*N*_TXFIFO_SIZE

> This defines the size of the transmit FIFO for this PSC, and must be a multiple of 4. The default value is chosen depending on the mode.

CYGHWR_HAL_POWERPC_MPC512X_PSC*N*_RXFIFO_SIZE

> This defines the size of the receive FIFO for this PSC, and must be a multiple of 4. The default value is chosen depending on the mode.

CYGHWR_HAL_POWERPC_MPC512X_PSC*N*_TXFIFO_ADDRESS

> This defines the address in the shared FIFO RAM of the transmit FIFO for this PSC. This value is usually calculated from the defined sizes of the PSCs and should not be changed without good reason.

CYGHWR_HAL_POWERPC_MPC512X_PSC*N*_RXFIFO_ADDRESS

> This defines the address in the shared FIFO RAM of the transmit FIFO for this PSC. This value is usually calculated from the defined sizes of the PSCs and should not be changed without good reason.

It is normally the responsibility of the platform HAL to define the mode in which each PSC is to be used.

The MPC512X variant HAL supports basic polled HAL diagnostic I/O over any of the PSC UART devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_POWERPC_PSC` which provides all support for the MPC512X PSC serial devices. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor or RedBoot for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

Any PSC which is put into UART mode will be included in both the HAL's list of available polled serial devices and be available for use by the serial driver. The MPC512X UARTs provide TX and RX data lines plus hardware flow control using RTS/CTS for those UARTs that have them connected.

A separate SPI master driver is available as the package `CYGPKG_DEVS_SPI_POWERPC_PSC`, and SPI slave support is present in this variant HAL and is described later.

Interrupts

The MPC512X HAL provides standard support for interrupt decoding and delivery. The available interrupt vectors are defined in the `cyg/hal/hal_intr.h` header. Interrupts from the FIFO controller are additionally decoded into their own separate set of vectors.

The MPC512X has a somewhat unusual interrupt priority mechanism. Vectors are collected together into groups and the priority of an interrupt can only be varied within that group. The unusual part is that instead of assigning a priority to a vector, a vector is assigned to a priority. It is not permitted to assign a vector to more than one priority. eCos does not enforce unique priority assignments, this is left to the user. Priorities range from 0 to 7; any value outside that range will leave the priority unchanged at the hardware default. Hence in many placed, a priority value of 8 is used to effectively not change the setting.

GPIO and Pin Configuration

The variant HAL provides support for packaging the configuration of a GPIO line into a single 16-bit descriptor that can then be used with macros to configure the pin and set and read its value. Similar descriptor based support is also available for controlling the configuration of external IO pins.

I²C Support

This variant HAL contains an I²C driver that may be used with the standard I²C infrastructure. For each I²C bus there are a number of configuration options:

CYGINT_HAL_POWERPC_MPC512X_I2C_BUS*N*

> This interface must be `implement`ed by the platform HAL to indicate that the given I²C bus is connected to devices.

CYGHWR_HAL_POWERPC_MPC512X_I2C_BUS*N*_CLOCK

> This is the I²C bus clock speed in Hz. Usually frequencies of either 100kHz or 400kHz are chosen, the latter sometimes known as fast mode.

CYGHWR_HAL_POWERPC_MPC512X_I2C_BUS*N*_INTR_PRI

> This is the I²C bus interrupt priority. It may range from 0 to 7; the default of 8 selects the default hardware setting.

Profiling Support

The MPC512X HAL contains support for **gprof**-base profiling using a sampling timer. The default timer used is GPT7. The timer used is selected by a set of `#define`s in `src/var_misc.c` which can be changed to refer to a different timer if required. This timer is only enabled when the gprof profiling package (`CYGPKG_PROFILE_GPROF`) is included and enabled in the eCos configuration, otherwise it remains available for application use.

Clock Control

The platform HAL must provide the input clock frequency (`CYGHWR_HAL_POWERPC_MPC512X_CLOCK_REF_CLK`) in its CDL file. This is then combined with the following options defined in this package to calculate the system clocks:

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_SPMF

This defines the system PLL multiplier and should match the value supplied by the reset configuration word.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_SYS_DIV

This option defines the system clock divider multiplied by 10. It must match the value supplied by the reset configuration word. CDL does not currently handle real values, so this value must be represented by a scaled integer. Not all values that can be represented by this option are valid.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_CPMF

This option defines the Core PLL multiplier multiplied by 10. It must match the value supplied by the reset configuration word. CDL does not currently handle real values, so this value must be represented by a scaled integer.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_SDHC_DIV

This option defines the SDHC divider multiplied by 100. It must match the value programmed into the SCFR2 register by the platform HAL initialization code. The default value equates to the hardware default setting for the register. CDL does not currently handle real values, so this value must be represented by a scaled integer. Not all values that can be represented by this option are valid.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_DIU_DIV

This option defines the DIU divider multiplied by 100. It must match the value programmed into the SCFR1 register by the platform HAL initialization code. The default value equates to the hardware default setting for the register. CDL does not currently handle real values, so this value must be represented by a scaled integer. Not all values that can be represented by this option are valid.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_IPS_DIV

This option defines the IPS divider. It must match the value programmed into the SCFR1 register by the platform HAL initialization code. The default value equates to the hardware default setting for the register.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_PCI_DIV

This option defines the PCI divider. It must match the value programmed into the SCFR1 register by the platform HAL initialization code. The default value equates to the hardware default setting for the register.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_LPC_DIV

This option defines the LPC divider. It must match the value programmed into the SCFR1 register by the platform HAL initialization code. The default value equates to the hardware default setting for the register.

CYGHWR_HAL_POWERPC_MPC512X_CLOCK_NFC_DIV

This option defines the NFC divider. It must match the value programmed into the SCFR1 register by the platform HAL initialization code. The default value equates to the hardware default setting for the register.

These setting are used to calculate a variety of clock values which are then used in the HALs and drivers to set baud rates, timers and other clock-related features.

Note that when changing or configuring any of these clock settings, you should consult the relevant processor datasheet as there may be both upper and lower constraints on the frequencies of some clock signals, including intermediate clocks. There are also some clocks where, while there is no strict constraint, clock stability is improved if values are chosen wisely. Finally, be aware that increasing clock speeds using this package may have an effect on platform specific properties, such as memory timings which may have to be adjusted accordingly.

Name

SPI Slave — Hardware Support for SPI Slave Device

Synopsis

#include <cyg/hal/mpc512x_spislave.h>

typedef void **hal_mpc512x_spi_slave_rx**(*hal_mpc512x_spi_slave *slave*, *cyg_uint8 *buf*);

hal_mpc512x_spi_slave ***hal_mpc512x_spi_slave_init**(*int psc*, *cyg_uint32 tfr_size*, *cyg_uint32 flags*, *hal_mpc512x_spi_slave_rx *rx_callback*, *void *user_data*);

int **hal_mpc512x_spi_slave_tx**(*hal_mpc512x_spi_slave *slave*, *cyg_uint8 *buf*);

Introduction

SPI slave support is provided by a module in the MPC512X variant HAL. It comprises a data structure, two functions and the prototype of a function that must be supplied by the user. All of these may be defined by including the `cyg/hal/mpc512x_spislave.h` header file.

Configuration

Any PSC that is to be used as an SPI slave must be configured into `SPISLAVE` mode. If this is done then the following configuration options become available:

CYGHWR_HAL_POWERPC_MPC512X_PSCX_SPI_SLAVE_MAX

> This option defines the maximum transfer size that any SPI slave device can handle. This is used to define the size of the buffers allocated to any SPI slave device. Individual SPI slaves may define FIFO sizes less than or equal to this value.

CYGHWR_HAL_POWERPC_MPC512X_PSC*N*_SPI_SLAVE_MAX

> This option defines the maximum transfer size that the SPI slave device on PSC*N* can handle. This is used to control the size of the FIFOs allocated to this device. At initialization an application can choose an actual transfer size equal to or less than this value.

CYGHWR_HAL_POWERPC_MPC512X_PSC*N*_SPI_SLAVE_INTR_PRI

> This option defines interrupt priority for the SPI slave on PSC*N*. The priority may range from 0 to 7. The default value of 8 selects the hardware default level.

Usage

The SPI protocol is highly asymmetric. The timing of when a transfer starts, the frequency at which it is clocked and any gap between individual bytes is under the control of the master. The slave device has no mechanism for influencing any of this. For example, with an 8MHz clock the slave would have to supply one byte every microsecond, and the gap between bytes is only 125ns. In a processor that has many other demands on its time, this kind of latency is hard to guarantee. Therefore, the SPI slave support provided makes use of the hardware characteristics to avoid any software being involved in the main part of an SPI transfer.

The SPI slave support makes use of the hardware FIFOs associated with each PSC. By pre-loading the transmit FIFO with data and keeping the transfer size to less than the FIFO size, the entire transfer can occur without software involvement. Software only needs to get involved at the end of the transfer, to empty the data sent by the master from the receive FIFO, and to load data for the next transfer into the transmit FIFO. To make this work, all transfers must be less than the size configured for the FIFOs, and all transfers must be of the same pre-defined size.

An SPI slave PSC is initialized by calling `hal_mpc512x_spi_slave_init()`. The *psc* parameter identifies the PSC to be initialized, which must have been configured in `SPISLAVE` mode. The *tfr_size* parameter defines the transfer size to be used, and must be less than or equal to this PSC's maximum transfer size. *rx_callback* is a pointer to a function that will be called when data is available and *user_data* is a user-supplied value. The *flags* parameter contains configuration flags, at present these can be used to set the SPI CPHA and CPOL parameters used to control data sampling and clocking.

On return the init function will return a pointer to a hal_mpc512x_spi_slave structure which is used in the other API calls. If the initialization fails for some reason, NULL is returned. After a successful initialization, the SPI slave is ready for the master to initiate a transfer.

When the master performs a transfer, bytes will be clocked in to the receive FIFO and bytes will be clocked out of the transmit FIFO. Initialization will have pre-primed the transmit FIFO with *tfr_size* zeroes, so on the first transfer the master can only send data to the slave. Once the transfer is complete the PSC will raise an interrupt and call the *rx_callback()* function. This will be provided with a pointer to a buffer containing the received data. The *user_data* may be accessed via the *slave* pointer. This function is called from DSR mode, so should not call any functions that potentially cause a context switch; generally it should use a semaphore or other synchronization object to wake up a thread to perform any further processing. The receive buffer will be overwritten by the next transfer, so should be copied out to private memory if it needs to be preserved.

To supply data to be sent during the next transfer, the user should call `hal_mpc512x_spi_slave_tx()`. The *buf* argument points to *tfr_size* bytes to be sent. There is sufficient buffering for a single pending transfer, in addition to the contents of the FIFO, so this function may be called before the previous transfer completes. On completion of the transfer, the transmit FIFO will be filled from the pending buffer. If the pending buffer is already full when this function is called the thread will be made to wait until the buffer is empty.

The following code (with some irrelevant details omitted) gives the basic outline of how a dedicated SPI slave might be structured:

```
// Omitted: standard headers

#include <cyg/hal/mpc512x_spislave.h>

#define PSC             3
#define TFR_SIZE        32

cyg_sem_t sem;

cyg_uint8 tx_buf[CYGHWR_HAL_POWERPC_MPC512X_PSCX_SPI_SLAVE_MAX];
cyg_uint8 rx_buf[CYGHWR_HAL_POWERPC_MPC512X_PSCX_SPI_SLAVE_MAX];

// SPI slave callback
void rx_callback( hal_mpc512x_spi_slave *slave, cyg_uint8 *buf )
{
    // Copy received data to private buffer
    memcpy( rx_buf, buf, TFR_SIZE );

    // Wake up thread
    cyg_semaphore_post( &sem );
}

// Entry function for SPI slave handling thread
// Omitted: thread creation
void spi_slave(cyg_addrword_t arg)
{
    hal_mpc512x_spi_slave *slave;

    // Initialize semaphore
    cyg_semaphore_init( &sem, 0 );

    // Initialize SPI slave on the PSC
    slave = hal_mpc512x_spi_slave_init( PSC,
                                        TFR_SIZE,
                                        HAL_SPI_SLAVE_CPHA0|HAL_SPI_SLAVE_CPOL0,
                                        &rx_callback,
                                        NULL );

    // Omitted: raise error on slave == NULL

    // Loop forever handling transfers
    while( 1 )
    {
        // Wait for a transfer to complete
        cyg_semaphore_wait( &sem );

        // Omitted: deal with received data.

        // Omitted: create transmit data for next transfer.

        // Queue up for next transfer
        hal_mpc512x_spi_slave_tx( slave, tx_buf );
    }
}
```

A test program in the ADS512101 board HAL (the only board on which this device could be tested) demonstrates the use of the SPI slave support in a real program.

Chapter 354. Renesas SDK7780 Development Board Support

Name

eCos Support for the Renesas SDK7780 Development Board — Overview

Description

The Renesas SDK7780 Development Board (henceforth just "SDK7780") has an SH7780 processor, 128MB of external SDRAM, 128MB of external flash memory, an SMSC LAN91C111 ethernet controller with integrated PHY, two 9-pin SCIF serial interfaces plus required support chips for all the on-chip peripherals.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The SDK7780 contains two banks of two Spansion S29GL256M flash parts. The banks may be swapped between CS0 and CS1 by SW4-1. Bank A contains ETS and the TFTP bootloader and is left alone. Bank B contains RedBoot which is usually installed by the bootloader. Flipping SW4-1 causes the system to boot from Bank B. Only Bank B, accessed via CS0, is managed by eCos. Bank A is left untouched to preserve ETS and allow RedBoot to be reprogrammed. In a typical setup, the first two flash blocks (256K bytes) are reserved for use for the ROM RedBoot image. The topmost block is used to manage the flash and hold RedBoot fconfig values. The remaining blocks between 0x80040000 and 0x83FDFFFF can be used by application code.

The board is fitted with a JTAG socket allowing use of the E10A JTAG interface to perform hardware debugging. At present there is no GDB support for this device, howver it may be used from HEW to debug application in ROM or loaded via serial or ethernet.

There is a serial driver `CYGPKG_DEVS_SERIAL_SH_SCIF` which supports the two on-chip serial devices. Either of these devices can be used by RedBoot for communication with the host. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Either the alternative serial port, or another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the sdk7780 target.

There is an ethernet driver `CYGPKG_DEVS_ETH_SH_SDK7780` which provided configuration parameters for the onboard ethernet device. The device itself is supported by the `CYGPKG_DEVS_ETH_SMSC_LAN91CXX` package. These drivers are also loaded automatically when configuring for the sdk7780 target, although not activated until generic ethernet package support is also added.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_SH_SH4A`. This driver is also loaded automatically when configuring for the SDK7780 target.

There is a driver for the on-chip real-time clock (RTC) at `CYGPKG_DEVICES_WALLCLOCK_SH3`. This driver is also loaded automatically when configuring for the SDK7780 target.

eCos manages the on-chip interrupt controller. Timer 0 is used to implement the eCos system clock, and timer 1 is used to implement a microsecond delay function. Timer 2 is unused and left for the application. Other on-chip devices (FEMI, EMI, LMI, INTC, TMU, CAC, UBC, CPG) are initialized only as far as is necessary for eCos to run. Other devices (eg DMAC, MMCIF, HAC, SSI, FLCTL etc) are not touched.

Tools

The SDK7780 port is intended to work with GNU tools configured for an sh-elf target. The original port was done using sh-elf-gcc version 3.4.4, sh-elf-gdb version 6.3, and binutils version 2.16.

Name

Setup — Preparing the SDK7780 board for eCos Development

Overview

In a typical development environment, the SDK7780 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger sh-elf-gdb. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from the board's flash	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot_RAM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_SH_SH4_SCIF_BAUD_RATE` and rebuilding RedBoot. RedBoot also supports ethernet communication and flash management.

Initial Installation

Flash Installation

This process makes use of the ETS software programmed into flash bank A in order to write RedBoot into flash bank B. To do this you will need to set up a TFTP server on a machine that is accessible from the development board.

Before downloading and programming the RedBoot image, ETS and the TFTP Bootloader must be configured. Full details for doing this are available in the documentation that accompanies the board. The following steps should be read in conjunction with that.

The first step is to connect an RS232 cable between the upper of the SDK7780 serial ports and the host PC. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 115200 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Also connect an ethernet cable that is on the same network as the TFTP server.

Apply power to the SDK7780 and press the power button. The board should boot automatically into ETS and after an initial report of the board configuration should display the `ETS MAIN MENU`. Select option 2 `Boot Configuration Menu` and then option 1 `Change Configuration`. Now select option 1 `TFTP` and accept the default 5s delay. Check that SW4-4&5 are off and answer Y to the remaining questions. Once the process is finished, reset the board to restart.

On restart the board will boot into the TFTP Boot Loader after a 5s delay. It will immediately drop into a configuration dialog. Decide whether to use DHCP or static IP. Static IP is recommended for which you will need to enter this board's IP address and that of the TFTP server. For the kernel filename enter `redboot.bin`; answer Y to download to flash bank B; enter B for the file format; accept the default load address; answer N for the disk image and command line; enter F to select the flash boot option and Y for SW4-4 state. The output should look something like this:

```
Press 'SPACE Bar' key or wait for 5 seconds to enter TFTP Boot Loader.

Press any other key to start ETS.

Starting TFTP Boot Loader...
```

```

RAM: 0x88000000-0x8a000000, [0x8800b758-0x89fc1000] available
FLASH: 0x80000000-0x83ffffff, 512 x 0x20000 blocks
RedBoot>
```

At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. To perform this initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x83fe0000-0x83ffffff: .
... Program from 0x89fd0000-0x89ff0000 to 0x83fe0000: .
RedBoot>
```

At the end, the block of flash at location 0x83FE0000 holds information about the various flash blocks, allowing other flash management operations to be performed.

Flash Configuration

The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address:
Console baud rate: 115200
DNS server IP address:
Set eth0 network hardware address [MAC]: false
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
```

```
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x83fe0000-0x83ffffff: .
... Program from 0x89fd0000-0x89ff0000 to 0x83fe0000: .
RedBoot>
```

For most of these configuration variables, the default value is correct, although you may wish to provide a default server used for TFTP retrieval, and default DNS server. If there is no suitable BOOTP or DHCP service running on the local network then BOOTP should be disabled and, instead, RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server.

Once you have set appropriate RedBoot flash configuration values you may reset the board. When RedBoot issues its prompt, it is ready to accept connections from sh-elf-gdb, allowing applications to be downloaded and debugged. Connections can be made via either serial port, or by TCP to port 9000 (or an alternative port if manually set by the **fconfig** command).

Occasionally it may prove necessary to update the installed RedBoot image. This can be done simply by repeating the above process by toggling SW4-1 back to boot ETS and the TFTP bootloader. Alternatively, the existing RedBoot install can be used to load the RAM-resident version in which case the standard RAM RedBoot build can be used. See the RedBoot documentation for instruction on how to do this.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. Assuming your `PATH` and `ECOS_REPOSITORY` environment variables have been set correctly, the steps needed to rebuild the RAM version of RedBoot are:

```
$ mkdir redboot_ram
$ cd redboot_ram
$ ecosconfig new sdk7780 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/sh/sdk7780/VERSION/misc/redboot_RAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding the ROM version involve basically the same process. The ROM version uses the file `redboot_ROM.ecm` and generates a file named `redboot.bin`. Make sure you don't mix up the different redboot.bin files; rename them to something more memorable such as `redboot_RAM.bin` and `redboot_ROM.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The SDK7780 platform HAL package is loaded automatically when eCos is configured for an `sdk7780` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The SDK7780 platform HAL package supports two separate startup types:

RAM This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0x80000000/0xA0000000 and boots from that location. sh-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into flash at location 0x80000000/0x-A0000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port COM 0 will be claimed for HAL diagnostics.

Flash Driver

The SDK7780 board contains 128M bytes of Flash, in two banks of two Spansion S29GL256M parts in parallel. Each part consists of 512 blocks of 64KB each, but since two parts are used in parallel they are viewed as 512 blocks of 128KB each. Flash bank A is not touched by eCos, so effectively the board is viewed as having a single 64MB bank of flash.

These are AMD 29xxxxx compatible parts, and as such the `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2` package contains all the code necessary to support these parts. The SDK7780 platform HAL contains definitions that customize the driver to the SDK7780 board.

Ethernet Driver

The SDK7780 board contains an SMSC LAN91C111 ethernet device. The `CYGPKG_DEVS_ETH_SMSC_LAN91CXX` package contains all the code necessary to support this part and the `CYGPKG_DEVS_ETH_SH_SDK7780` package contains definitions that customize the driver to the SDK7780 board.

The ethernet will automatically auto-negotiate 10Mbps or 100Mbps operation with its link peer, as well as full duplex or half duplex mode.

The driver usually reads the MAC address (ESA) from the EEPROM connected to the MAC. Alternatively an address can be set in the CDL configuration in the component CYGSEM_DEVS_ETH_SH_SDK7780_ETH0_SET_ESA within the SDK7780 ethernet driver; or an address can be set in the Flash configuration of RedBoot using the **fconfig** command. If both are set, the Flash configuration is used in preference.

PCI Driver

The SDK7780 board is fitted with four 3V PCI slots, which are accessed via the PCIC funtional unit on the SH7780. eCos supports PCI devices inserted in these slots and if the PCI library is selected in the eCos configuration, a driver will usually call `cyg_pci_init()` which will automatically configure memory and I/O base address registers, as well as any interrupts the device requires.

The CPU is able to access the PCI memory space through the memory window at 0xb0000000, and the PCI I/O space through the memory window at 0xFE200000. PCI bus master devices may access system memory (usually for DMA), at windows starting at address 0x0 in both memory and I/O PCI spaces.

Note that the PCI INTD line is on a pin shared with the CTS line for SCIF0. If this interrupt is to be used, SW4-8 must be set to OFF.

SCIF Serial Driver

The SDK7780 board uses the SH7780 internal SCIF serial support Two serial ports are available: SCIF0 which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/ser0`" in the interrupt-driven driver; and SCIF1 which is mapped to virtual vector channel 1 and "`/dev/ser1`". Only SCIF0 supports modem control signals such as those used for hardware flow control, and SW4-8 must be set to ON for CTS to be routed to the DB9 connector.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

RTC Driver

The SDK7780 board uses the SH7780 internal RTC support. The `CYGPKG_DEVICES_WALLCLOCK_SH3` package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The SDK7780 board uses the SH7780 internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_SH_SH4A` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91RM9200_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are two flags specific to this port:

`-m4`
: The sh-elf-gcc compiler supports many variants of the SH architecture, from the SH2 onwards. A `-m` option should be used to select the specific variant in use, and with current tools `-m4` is the correct option for the SH7780.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the SDK7780 hardware, and should be read in conjunction with that specification. The SDK7780 platform HAL package complements the SH architectural HAL and the SH4 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the external SDRAM and programming the various internal registers including clocks, EMI and LMI. The values used for most of these registers are assigned fixed values from a table in the header `cyg/hal/platform.inc`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

off-chip Flash

This is located at address 0x00000000 of the physical memory space and is therefore accessible in the P1 region at location 0x80000000. An uncached shadow of this memory is available in the P2 region at 0xA0000000. The contents of the flash are organized as described earlier.

external SDRAM

This is located at address 0x08000000 of the physical memory space and is therefore accessable in the P1 region at location 0x88000000. An uncached shadow of this memory is available in the P2 region at 0xA8000000. The first 512 bytes are used for hardware exception vectors. The next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup, all remaining SDRAM is available. For RAM startup, available SDRAM starts at location 0x88020000, with the bottom 128Kbytes reserved for use by RedBoot.

on-chip peripherals

These are accessible via the P4 region at location 0xE0000000 onwards. The on-chip PCI controller has apertures into the PCI memory bus at 0xB0000000 and 0xFD000000 in the P2 region, and access to to the PCI IO space at 0xFE200000. Other base addresses of on-chip peripherals can be found in the SH7780 Hardware Manual.

off-chip peripherals

All off-chip peripherals used by eCos are accessed via on-chip bus controllers such as LMI or PCI. All others are left untouched.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer 0, which should not be used directly by application code. Timer 1 is used to implement a microsecond resolution busy delay service. Timers 2 to 5 are not used by eCos so application code is free to manipulate these as required. The actual HAL macros for managing the clock are provided by the SH architecture processor HAL.

There is a software model of the structure of the SH family clock supply subsystem which performs the correct calculations to yield not only the inputs for the CPU clock but also the peripheral clocks fed to the serial device, memory controllers and other devices. The values for the master crystal, the PLL multipliers and various dividers are supplied by the platform HAL. Some care must be taken in defining these since wrong values will cause the timers and the SCIF baud rate to be miscalculated (resulting visibly in garbage on the serial output).

The SH7780 extends the SH family clock model by providing a CLOCKGEN subsystem allowing the hardware clock frequency to be controlled. The CLOCKGENA.PLL1CR register is the primary means to do this, and is initialised by switches 1, 2, 3 and 7 on DIP switch block MD_SW. The delivery default settings for these switches is to select clock mode 0 giving a 400MHz CPU clock, 100MHz local bus and 50MHz peripheral clock.

If the DIP switches are changed from the default then the values of `CYGHWR_HAL_SH_OOC_DIVIDER_IFC`, `CYGHWR_HAL_SH_OOC_DIVIDER_BFC` and `CYGHWR_HAL_SH_OOC_DIVIDER_PFC` must be changed to match.

Other Issues

The SDK7780 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SH4 variant HAL, and the SH architectural HAL documentation should be consulted for further details.

It should be noted that the floating point support in the SH HAL has a caveat that, if the FPSCR register is changed, it may get reverted at a later stage by certain operations performed by the GCC compiler. This behaviour is intentional as the alternative would be to update the GCC compiler's internal state about the FPSCR at every context switch which would be expensive for a feature that is unlikely to be used frequently. If the FPSCR is to be changed by the application, the developer should call the function `__set_fpscr(int)`, passing it the new FPSCR value.

Chapter 355. SuperH SH4-202 MicroDev Board Support

Name

eCos Support for the SuperH SH4-202 MicroDev Board — Overview

Description

The SuperH SH4-202 MicroDev board (henceforth just "MicroDev") has an SH4-202 processor, 64MB of external SDRAM, 32MB of external flash memory, an SMSC LAN91C111 ethernet controller and connectors plus required support chips for all the on-chip peripherals.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of 128 blocks of 256k bytes each. In a typical setup, the first flash block is used for the ROM RedBoot image and the second is used to store a version of RedBoot that can run out of RAM. The topmost two blocks are used to manage the flash and hold RedBoot fconfig values. The remaining 124 blocks between 0xA0080000 and 0xA1F7FFFF can be used by application code.

The board is fitted with a PLCC socket suitable for an EEPROM (or PROM) such as the 1Mbit ST M29WO10B. This is enabled by toggling two DIP switches, after which the EEPROM is mapped into the same address as the flash memory. Therefore, the flash is not accessible if booting from the EEPROM.

There is a serial driver `CYGPKG_DEVS_SERIAL_SH_SCIF` which supports the on-chip serial device. This device can be used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the MicroDev target.

There is an ethernet driver `CYGPKG_DEVS_ETH_SH_MICRODEV` for the on-chip ethernet device. This driver is also loaded automatically when configuring for the MicroDev target.

eCos manages the on-chip interrupt controller. Timer 0 is used to implement the eCos system clock, and timer 1 is used to implement a microsecond delay function. Timer 2 is unused and left for the application. Other on-chip devices (FEMI, EMI, INTC, TMU, CAC, UBC) are initialized only as far as is necessary for eCos to run. Other devices (eg RTC, DMAC, etc) are not touched.

Tools

The MicroDev port is intended to work with GNU tools configured for an sh-elf target. The original port was done using sh-elf-gcc version 3.2.1, sh-elf-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing the MicroDev board for eCos Development

Overview

In a typical development environment, the MicroDev board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger sh-elf-gdb. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory. Alternatively RedBoot may be programmed into a PLCC EEPROM and inserted into socket U21, although in that case, the flash memory is not accessible.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from the board's flash	`redboot_ROM.ecm`	`redboot_ROM.bin`
EEPROM	RedBoot running from the board's socketed EEPROM	`redboot_EEPROM.ecm`	`redboot_EEPROM.bin`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot_RAM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_SH_SH4_SCIF_BAUD_RATE` and rebuilding RedBoot. RedBoot also supports ethernet communication and flash management.

Initial Installation

Flash Installation

This process assumes that the board is connected to a SuperH Micro Probe. The Micro Probe should be set up as described in Appendix A of the "SH4 Development Tools User Guide". You should also have access to the SuperH development tools since it is necessary to use the version of GDB that comes with those tools to access the Micro Probe, **sh-elf-gdb** will not work.

Programming the RedBoot ROM monitor into flash memory requires an application that can manage flash blocks. RedBoot itself has this capability. Rather than have a separate application that is used only for flash management during the initial installation, a special RAM-resident version of RedBoot is loaded into memory and run. This version can then be used to load the normal flash-resident version of RedBoot and program it into the flash.

The first step is to connect an RS232 null modem cable between the MicroDev serial port and the host PC. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking).

Now run the **sh4gdb** command, giving it the name of the RAM redboot ELF file, connect to the Micro Probe, load the executable and run it. The entire session should look like this:

```
$ sh4gdb redboot_RAM.elf
GNU gdb 5.2.1
Copyright 2002 Free Software Foundation, Inc.
GDB is free software, covered by the GNU General Public License, and you are
welcome to change it and/or distribute copies of it under certain conditions.
Type "show copying" to see the conditions.
There is absolutely no warranty for GDB.  Type "show warranty" for details.
This GDB was configured as "--host=i686-pc-linux-gnu --target=sh-superh-elf"...
(gdb) sh4si superh
```

```
The target is assumed to be little endian
The target architecture is assumed to be sh4
0xa0000000 in ?? ()
(gdb) load
Loading section .vectors, size 0x9e0 lma 0x88010000
Loading section .text, size 0x1ab20 lma 0x880109e0
Loading section .rodata, size 0x3e6c lma 0x8802b500
Loading section .data, size 0xf30 lma 0x8802f370
Start address 0x88010000, load size 131740
Transfer rate: 351306 bits/sec, 433 bytes/write.
(gdb) cont
Continuing.
```

The required `redboot_RAM.elf` file is normally supplied with the eCos release in the `loaders` directory. If it needs to be rebuilt then instructions for this are supplied below.

If this sequence fails in any way then check the setup and connections of the Micro Probe. It if is successful then you should see the following printed out on the serial line:

```
+FLASH configuration checksum error or invalid key
... waiting for BOOTP information
Ethernet eth0: MAC address 00:08:ee:00:0b:37
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [RAM]
Non-certified release, version UNKNOWN - built 14:28:55, Sep  8 2003

Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x88000000-0x8c000000, 0x8812cca0-0x8bfb1000 available
FLASH: 0xa0000000 - 0xa2000000, 128 blocks of 0x00040000 bytes each.
RedBoot>
```

If the ethernet cable is not plugged in there may be a fairly long wait after the "... waiting for BOOTP information" message. At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. To perform this initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Unlock from 0xa1fc0000-0xa2000000: .
... Erase from 0xa1fc0000-0xa2000000: .
... Program from 0x8bfbf000-0x8bfff000 at 0xa1fc0000: .
... Lock from 0xa1fc0000-0xa2000000: .
RedBoot>
```

At the end, the block of flash at location 0xA1FC0000 holds information about the various flash blocks, allowing other flash management operations to be performed. The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Console baud rate: 38400
DNS server IP address:
Set eth0 network hardware address [MAC]: false
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlock from 0xa1f80000-0xa1f81000: .
... Erase from 0xa1f80000-0xa1f81000: .
... Program from 0x8bfb2000-0x8bfb3000 at 0xa1f80000: .
... Lock from 0xa1f80000-0xa1f81000: .
RedBoot>
```

For most of these configuration variables, the default value is correct. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled and, instead, RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work, it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m xmodem -b %{freememlo}
```

The file `redboot_ROM.bin` should now be uploaded using the terminal emulator. The file is a raw binary and should be transferred using the X-modem protocol.

```
Raw file loaded 0x8812d000-0x8814e32f, assumed entry at 0x8812d000
xyzModem - CRC mode, 1064(SOH)/0(STX)/0(CAN) packets, 2 retries
RedBoot>
```

Once RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0xa0000000-0xa0040000: .
... Program from 0x8812d000-0x8816d000 at 0xa0000000: .
... Unlock from 0xa1fc0000-0xa2000000: .
... Erase from 0xa1fc0000-0xa2000000: .
... Program from 0x8bfbf000-0x8bfff000 at 0xa1fc0000: .
... Lock from 0xa1fc0000-0xa2000000: .
RedBoot>
```

The flash-resident version of RedBoot has now been programmed at location 0xA0000000, and the flash info block at 0xA1FC0000 has been updated. The initial setup is now complete. Power off the Micro Probe and reset the MicroDev board using S6. You should see the following:

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 00:08:ee:00:0b:37
Can't get BOOTP info for device!

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 14:22:57, Sep  8 2003

Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x88000000-0x8c000000, 0x8800db98-0x8bfb1000 available
FLASH: 0xa0000000 - 0xa2000000, 128 blocks of 0x00040000 bytes each.
RedBoot>
```

When RedBoot issues its prompt, it is also ready to accept connections from sh-elf-gdb, allowing applications to be downloaded and debugged.

Occasionally it may prove necessary to update the installed RedBoot image. This can be done simply by repeating the above process, using the Micro Probe. Alternatively, the existing RedBoot install can be used to load the RAM-resident version. You can even install the RAM resident RedBoot in the "RedBoot[backup]" flash region. See the RedBoot documentation for instruction on how to do this.

EEPROM Installation

The board has a 32-pin PLCC socket suitable for an EEPROM, silk screened U21. To use RedBoot running from EEPROM, you must first program the file `redboot_EEPROM.bin` (normally supplied with the eCos release in the `loaders` directory) into the EEPROM using an appropriate programmer. No byte swapping is required. If RedBoot needs to be rebuilt, then instructions for this are supplied below, and the import file `redboot_EEPROM.ecm` should be used.

To configure the board to boot from the EEPROM instead of flash, you must power off the board and change the following DIP switch settings, which may both be found on DIP switch 2 (silk screened S2): switch 2 (silk screened FEMI SIZ1) should be set to

ON, which will change the access width for FEMI area 0 from 32-bit to 8-bit; switch 6 (silk screened FPGA SW3) should be set to OFF to configure the FPGA to map memory accesses for FEMI area 0 to point at the EEPROM instead of flash. In this mode, it is no longer possible to access flash memory as the EEPROM is mapped into the same area in the address space.

Note that it is usually preferable to boot from flash instead of EEPROM as flash is accessed 32-bits at a time, whereas the EEPROM is accessed 8-bits at a time, which therefore affects performance as this requires 4 times as many read cycles.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the RAM version of RedBoot are:

```
$ mkdir redboot_ram
$ cd redboot_ram
$ ecosconfig new sh4_202_md redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/sh/sh4_202_md/v2_0_2/misc/redboot_RAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding the ROM versions involves basically the same process. The ROM version uses the file `redboot_ROM.ecm` and generates a file `redboot.bin`. Make sure you don't mix up the different redboot.bin files; rename them to something more memorable such as `redboot_RAM.bin` and `redboot_ROM.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The MicroDev platform HAL package is loaded automatically when eCos is configured for an sh4_202_md target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The MicroDev platform HAL package supports two separate startup types:

RAM This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0xA0000000 and boots from that location. sh-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into flash at location 0xA0000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option CYGSEM_HAL_ROM_MONITOR should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option CYGSEM_HAL_USE_ROM_MONITOR should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The MicroDev board contains 32Mb of Intel StrataFlash, specifically, two E28F128 parts in parallel. The CYGPKG_DEVS_FLASH_STRATA package contains all the code necessary to support these parts and the CYGPKG_DEVS_FLASH_SH_MICRODEV package contains definitions that customize the driver to the MicroDev board.

Note that if booting from EEPROM instead of flash, the flash driver will not be able to detect or use the flash parts.

Ethernet Driver

The MicroDev board contains an SMSC LAN91C111 ethernet device. The CYGPKG_DEVS_ETH_SMSC_LAN91CXX package contains all the code necessary to support this part and the CYGPKG_DEVS_ETH_SH_MICRODEV package contains definitions that customize the driver to the MicroDev board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option CYGNUM_HAL_RTC_DENOMINATOR which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are two flags specific to this port:

`-m4`
: The sh-elf-gcc compiler supports many variants of the SH architecture, from the SH2 onwards. A `-m` option should be used to select the specific variant in use, and with current tools `-m4` is the correct option for the SH4-202.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the MicroDev hardware, and should be read in conjunction with that specification. The MicroDev platform HAL package complements the SH architectural HAL and the SH4 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the external DRAM and programming the various internal registers. The values used for most of these registers are assigned fixed values from a table in the header `cyg/hal/platform.inc`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

off-chip Flash

This is located at address 0x00000000 of the physical memory space and is therefore accessible in the P1 region at location 0x80000000. An uncached shadow of this memory is available in the P2 region at 0xA0000000. The contents of the flash are organized as described earlier.

off-chip EEPROM

If selected by the DIP switches, this occupies the same addresses as the off-chip flash, and the flash is no longer visible.

external SDRAM

This is located at address 0x08000000 of the physical memory space and is therefore accessable in the P1 region at location 0x88000000. An uncached shadow of this memory is available in the P2 region at 0xA8000000. The first 256 bytes are used for hardware exception vectors. The next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup, all remaining SDRAM is available. For RAM startup, available SDRAM starts at location 0x80100000, with the bottom 1MB reserved for use by RedBoot.

on-chip peripherals

These are accessible via the P4 region at location 0xE0000000 onwards.

off-chip peripherals

The ethernet device is located at 0xA7500000. The FPGA interrupt controller is located at 0x06110000. These are the only off-chip peripherals accessed by eCos. All others are left untouched.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer 0, which should not be used directly by application code. Timer 1 is used to implement a microsecond resolution busy delay service. Timer 2 is not used by eCos so application code is free to manipulate this as required. The actual HAL macros for managing the clock are provided by the SH architecture processor HAL.

There is a software model of the structure of the SH family clock supply subsystem which performs the correct calculations to yield not only the inputs for the CPU clock but also the peripheral clocks fed to the serial device, memory controllers and other devices.

The values for the master crystal, the PLL multipliers and various dividers are supplied by the platform HAL. Some care must be taken in defining these since wrong values will cause the timers and the SCIF baud rate to be miscalculated. If the OSCAR chip switches are changed from the default then the value of `CYGHWR_HAL_SH_OOC_XTAL` must be changed to match.

Other Issues

The MicroDev platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SH4 variant HAL, and the SH architectural HAL documentation should be consulted for further details.

It should be noted that the floating point support in the SH HAL has a caveat that, if the FPSCR register is changed, it may get reverted at a later stage by certain operations performed by the GCC compiler. This behaviour is intentional as the alternative would be to update the GCC compiler's internal state about the FPSCR at every context switch which would be expensive for a feature that is unlikely to be used frequently. If the FPSCR is to be changed by the application, the developer should call the function `__set_fpscr(int)`, passing it the new FPSCR value.

Chapter 356. STMicroelectronics ST40 Evaluation Board Support

Name

eCos Support for the STMicroelectronics ST40 Evaluation Board — Overview

Description

The STMicroelectronics ST40 Evaluation Board (henceforth just "ST40EB") has an ST40RA166XH processor, 32MB of external SDRAM, 4MB of external flash memory, an STE10/100A ethernet controller with integrated PHY (Intel i21143/DEC Tulip compatible), two 9-pin SCIF serial interfaces, LCD display panel and connectors plus required support chips for all the on-chip peripherals.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of two ST M29W160DB parts in parallel, giving a total of 4M bytes of external Flash. In a typical setup, the first four flash blocks (256K bytes) are reserved for use for the ROM RedBoot image and the subsequent two are used to store a version of RedBoot that can run out of RAM. The topmost block is used to manage the flash and hold RedBoot fconfig values. The remaining blocks between 0xA0080000 and 0xA03DFFFF can be used by application code.

The board is fitted with a HUDI socket allowing use of the ST40-Connect/SH JTAG interface to perform hardware debugging. To use this, a set of GDB macro files are provided with a GNU GDB toolset provided by ST, and to connect to the board in this case the command to be used from the GDB prompt is:

```
(gdb) mb360 XX.XX.XX.XX
```

XX.XX.XX.XX is the IP address (or DNS name) allocated to the ST40-Connect.

Images loaded in this way must be for RAM startup, and should ensure that the eCos CDL configuration option "Work with a ROM monitor" (`CYGSEM_HAL_USE_ROM_MONITOR`) is disabled. This happens automatically for RedBoot.

There is a serial driver `CYGPKG_DEVS_SERIAL_SH_SCIF` which supports the two on-chip serial devices. Either of these devices can be used by RedBoot for communication with the host. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Either the alternative serial port, or another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the st40raeb target.

There is an ethernet driver `CYGPKG_DEVS_ETH_SH_ST40EB` for the ST40EB's onboard ethernet device. The device is accessed via the PCI bus. This driver is also loaded automatically when configuring for the st40raeb target, although not activated until generic ethernet package support is also added.

eCos manages the on-chip interrupt controller. Timer 0 is used to implement the eCos system clock, and timer 1 is used to implement a microsecond delay function. Timer 2 is unused and left for the application. Other on-chip devices (FEMI, EMI, LMI, INTC, TMU, CAC, UBC, CPG) are initialized only as far as is necessary for eCos to run. Other devices (eg RTC, DMAC, ST expansion module interface (STEMI) etc) are not touched.

Tools

The ST40EB port is intended to work with GNU tools configured for an sh-elf target. The original port was done using sh-elf-gcc version 3.2.1, sh-elf-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing the ST40EB board for eCos Development

Overview

In a typical development environment, the ST40EB board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger sh-elf-gdb. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from the board's flash	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	Used for upgrading ROM version	`redboot_RAM.ecm`	`redboot_RAM.bin`
RAM_NOETH	Used for programming RedBoot the first time	`redboot_RAM_NOETH.ecm`	`redboot_RAM_NOETH.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_SH_SH4_SCIF_BAUD_RATE` and rebuilding RedBoot. RedBoot also supports ethernet communication and flash management.

Initial Installation

Flash Installation

This process assumes that the board is connected to an ST40-Connect/SH. The ST40-Connect should be set up as described in the ST Micro Connect Manual. You should also have access to the SuperH development tools since it is necessary to use the version of GDB that comes with those tools to access the ST40-Connect, **sh-elf-gdb** will not work.

Programming the RedBoot ROM monitor into flash memory requires an application that can manage flash blocks. RedBoot itself has this capability. Rather than have a separate application that is used only for flash management during the initial installation, a special RAM-resident version of RedBoot is loaded into memory and run. This version can then be used to load the normal flash-resident version of RedBoot and program it into the flash.

The first step is to connect an RS232 null modem cable between either of the ST40EB serial ports and the host PC. Next start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 115200 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking).

Now run the **sh4gdb** command, giving it the name of the RAM_NOETH redboot ELF file, connect to the ST40-Connect, load the executable and run it. The entire session should look like this:

```
$ sh4gdb -nw redboot_RAM_NOETH.elf
GNU gdb 5.2.1
Copyright 2002 Free Software Foundation, Inc.
GDB is free software, covered by the GNU General Public License, and you are
welcome to change it and/or distribute copies of it under certain conditions.
Type "show copying" to see the conditions.
There is absolutely no warranty for GDB.  Type "show warranty" for details.
This GDB was configured as "--host=i686-pc-linux-gnu --target=sh-superh-elf"...
(gdb) mb360 172.31.1.90
The target is assumed to be little endian
The target architecture is assumed to be sh4
0xa0000000 in ?? ()
(gdb) load
Loading section .vectors, size 0x9d0 lma 0x88020000
Loading section .text, size 0x1d650 lma 0x880209d0
Loading section .rodata, size 0x4364 lma 0x8803e020
Loading section .data, size 0x12b8 lma 0x880423a0
Start address 0x88020000, load size 144956
Transfer rate: 1159648 bits/sec, 3814 bytes/write.
(gdb) cont
Continuing.
```

The required `redboot_RAM_NOETH.elf` file is normally supplied with the eCos release in the `loaders` directory. If it needs to be rebuilt then instructions for this are supplied below. The RAM_NOETH build is used this time instead of plain RAM as it does not contain any PCI or ethernet support. PCI support has been observed to cause complications with using the ST40-Connect.

If this sequence fails in any way then check the setup and connections of the ST40-Connect. It if is successful then you should see the following printed out on the serial line:

```
+FLASH configuration checksum error or invalid key

RedBoot(tm) bootstrap and debug environment [RAM]
Non-certified release, version UNKNOWN - built 09:27:11, Sep 20 2004

Platform: ST40 Eval Board (ST40)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x88000000-0x8a000000, [0x880491e0-0x89fd1000] available
FLASH: 0x80000000 - 0x80400000, 32 blocks of 0x00020000 bytes each.
RedBoot>
```

At this stage the RedBoot flash management initialization has not yet happened so the warning about the configuration checksum error is expected. To perform this initialization use the **fis init -f** command:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
*** Initialize FLASH Image System
... Erase from 0x80040000-0x803e0000: .............................
... Erase from 0x80400000-0x80400000:
... Erase from 0x803e0000-0x80400000: .
... Program from 0x89fe0000-0x8a000000 at 0x803e0000: .
RedBoot>
```

At the end, the block of flash at location 0x89FE0000 holds information about the various flash blocks, allowing other flash management operations to be performed.

It is now possible to load the flash-resident version of RedBoot. Because of the way that flash chips work, it is better to first load it into RAM and then program it into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
```

The file `redboot_ROM.bin` should now be uploaded using the terminal emulator on your host. The file is raw binary and should be transferred using the Y-modem protocol.

```
Raw file loaded 0x8804fc00-0x88075137, assumed entry at 0x8804fc00
xyzModem - CRC mode, 1197(SOH)/0(STX)/0(CAN) packets, 4 retries
RedBoot>
```

Once the ROM version of RedBoot has been loaded into RAM it can be programmed into flash:

```
RedBoot> fis create RedBoot -b %{freememlo}
An image named 'RedBoot' exists - continue (y/n)? y
```

```
... Erase from 0x80000000-0x80040000: ..
... Program from 0x8804fc00-0x8808fc00 at 0x80000000: ..
... Erase from 0x803e0000-0x80400000: .
... Program from 0x89fe0000-0x8a000000 at 0x803e0000: .
RedBoot>
```

The flash-resident version of RedBoot has now been programmed at location 0x80000000/0xA0000000, and the flash info block at 0x89FE0000/0xA9FE0000 has been updated (on the SuperH, addresses beginning 0xA are the non-cacheable shadow versions in the P2 region of addresses beginning 0x8 from the P1 region). The initial setup is now complete. Power off the ST40-CONNECT and reset the ST40EB board using the reset button SW2. You should see something similar to the following:

```
+FLASH configuration checksum error or invalid key
... waiting for BOOTP information
Ethernet eth0: MAC address 00:80:e1:12:00:3b
IP: 172.31.1.99/255.255.255.0, Gateway: 172.31.1.1
Default server: 172.31.1.2, DNS server IP: 172.31.1.1

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 01:21:36, Sep 20 2004

Platform: ST40 Eval Board (ST40)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x88000000-0x8a000000, [0x8800e380-0x89fd1000] available
FLASH: 0x80000000 - 0x80400000, 32 blocks of 0x00020000 bytes each.
RedBoot>
```

If the ethernet cable is not plugged in there may be a fairly long wait after the "... waiting for BOOTP information" message.

Flash Configuration

The next step is to set up RedBoot's non-volatile configuration values:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address:
Console baud rate: 115200
DNS server IP address:
Set eth0 network hardware address [MAC]: false
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x803e0000-0x80400000: .
... Program from 0x89fe0000-0x8a000000 at 0x803e0000: .
RedBoot>
```

For most of these configuration variables, the default value is correct, although you may wish to provide a default server used for TFTP retrieval, and default DNS server. If there is no suitable BOOTP service running on the local network then BOOTP should be disabled and, instead, RedBoot will prompt for a fixed IP address, netmask, and addresses for the local gateway and DNS server.

Once you have set appropriate RedBoot flash configuration values you may reset the board. When RedBoot issues its prompt, it is ready to accept connections from sh-elf-gdb, allowing applications to be downloaded and debugged. Connections can be made via either serial port, or by TCP to port 9000 (or an alternative port if manually set by the **fconfig** command).

Occasionally it may prove necessary to update the installed RedBoot image. This can be done simply by repeating the above process, using the ST40-Connect. Alternatively, the existing RedBoot install can be used to load the RAM-resident version in which case the standard RAM RedBoot build can be used instead of the RAM_NOETH build. You can even install the RAM resident RedBoot in the "RedBoot[backup]" flash region. See the RedBoot documentation for instruction on how to do this.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. Assuming your `PATH` and `ECOS_REPOSITORY` environment variables have been set correctly, the steps needed to rebuild the RAM version of RedBoot are:

```
$ mkdir redboot_ram
$ cd redboot_ram
$ ecosconfig new st40raeb redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/sh/st40eb/VERSION/misc/redboot_RAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding the ROM or RAM_NOETH versions involve basically the same process. The ROM version uses the file `redboot_ROM.ecm` and the RAM_NOETH version uses the file `redboot_RAM_NOETH.ecm` and both versions generate a file named `redboot.bin`. Make sure you don't mix up the different redboot.bin files; rename them to something more memorable such as `redboot_RAM.bin` and `redboot_ROM.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The ST40EB platform HAL package is loaded automatically when eCos is configured for an `st40raeb` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The ST40EB platform HAL package supports two separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0x80000000/0xA0000000 and boots from that location. sh-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

  This startup type can also be used with the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` disabled to allow eCos applications loaded into RAM to be run using the ST40-Connect and debugged using the SuperH **sh4gdb** version of GDB in the same way as the RAM version of RedBoot was loaded earlier.

ROM
: This startup type can be used for finished applications which will be programmed into flash at location 0x80000000/0xA0000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup, or for standalone RAM applications loaded and debugged with **sh4gdb**.

If the application does not rely on a ROM monitor for diagnostic services then serial port COM 0 will be claimed for HAL diagnostics.

Flash Driver

The ST40EB board contains 4M bytes of Flash, specifically, two ST M29W160DB parts in parallel. Each part starts with bootblocks of 16K bytes, 8K bytes, 8K bytes and 32K bytes respectively, followed by 31 blocks of 64K bytes each. These are AMD 29xxxxx compatible parts, and as such the `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX` package contains all the code necessary to support these parts and the `CYGPKG_DEVS_FLASH_SH_ST40EB` package contains definitions that customize the driver to the ST40EB board.

Ethernet Driver

The ST40EB board contains an STE10/100A ethernet device. This is largely compatible with Intel i21143/DEC Tulip parts. The device is accessed via the PCI bus. The `CYGPKG_DEVS_ETH_INTEL_I21143` package contains all the code necessary to support this part and the `CYGPKG_DEVS_ETH_SH_ST40EB` package contains definitions that customize the driver to the ST40EB board.

The ethernet will automatically auto-negotiate 10Mbps or 100Mbps operation with its link peer, as well as full duplex or half duplex mode.

The driver usually reads the MAC address (ESA) from the EEPROM connected to the STE. Alternatively an address can be set in the CDL configuration in the component CYGSEM_DEVS_ETH_SH_ST40EB_ETH0_SET_ESA within the ST40EB ethernet driver; or an address can be set in the Flash configuration of RedBoot using the **fconfig** command. If both are set, the Flash configuration is used in preference.

PCI Driver

The ST40EB board is fitted with three 5V PCI slots, which are accessed via a PCI-PCI bridge, as is the onboard STE10/100A ethernet device. The 3.3V PCI slot is accessed directly. eCos supports PCI devices inserted in these slots and if the PCI library is selected in the eCos configuration, a driver will usually call `cyg_pci_init()` which will automatically configure memory and I/O base address registers, as well as any interrupts the device requires.

The CPU is able to access the PCI memory space through the memory window from 0xb0000000 to 0xb5ffffff, and the PCI I/O space through the memory window from 0xb6000000 to 0xb6ffffff. PCI devices may access system memory (usually for DMA), at windows starting at address 0x0 in both memory and I/O PCI spaces.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are two flags specific to this port:

`-m4`

The sh-elf-gcc compiler supports many variants of the SH architecture, from the SH2 onwards. A `-m` option should be used to select the specific variant in use, and with current tools `-m4` is the correct option for the ST40.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the ST40EB hardware, and should be read in conjunction with that specification. The ST40EB platform HAL package complements the SH architectural HAL and the SH4 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the external SDRAM and programming the various internal registers including clocks, EMI and LMI. The values used for most of these registers are assigned fixed values from a table in the header `cyg/hal/platform.inc`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

off-chip Flash
: This is located at address 0x00000000 of the physical memory space and is therefore accessible in the P1 region at location 0x80000000. An uncached shadow of this memory is available in the P2 region at 0xA0000000. The contents of the flash are organized as described earlier.

external SDRAM
: This is located at address 0x08000000 of the physical memory space and is therefore accessable in the P1 region at location 0x88000000. An uncached shadow of this memory is available in the P2 region at 0xA8000000. The first 256 bytes are used for hardware exception vectors. The next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup, all remaining SDRAM is available. For RAM startup, available SDRAM starts at location 0x80020000, with the bottom 128Kbytes reserved for use by RedBoot.

on-chip peripherals
: These are accessible via the P4 region at location 0xE0000000 onwards. The on-chip PCI controller is located at base address in the P2 region at 0xB0000000, and a memory-mapped view of the PCI space configuration registers at 0xB7000000. Other base addresses of on-chip peripherals can be found in the ST40RA datasheet (P/N: ADCS 7260755H).

off-chip peripherals
: All off-chip peripherals used by eCos are accessed via on-chip bus controllers such as LMI, EMI or PCI. All others are left untouched.

Clock Support

The platform HAL provides configuration options for the eCos system clock. This always uses the hardware timer 0, which should not be used directly by application code. Timer 1 is used to implement a microsecond resolution busy delay service. Timer 2 is not used by eCos so application code is free to manipulate this as required. The actual HAL macros for managing the clock are provided by the SH architecture processor HAL.

There is a software model of the structure of the SH family clock supply subsystem which performs the correct calculations to yield not only the inputs for the CPU clock but also the peripheral clocks fed to the serial device, memory controllers and other devices. The values for the master crystal, the PLL multipliers and various dividers are supplied by the platform HAL. Some care must be taken in defining these since wrong values will cause the timers and the SCIF baud rate to be miscalculated (resulting visibly in garbage on the serial output).

The ST40 extends the SH family clock model by providing a CLOCKGEN subsystem allowing the hardware clock frequency to be controlled. The CLOCKGENA.PLL1CR register is the primary means to do this, and is initialised by switches 1, 2 and 3 on DIP switch block SW3. As the ST40EB is fitted with an ST40RA166 processor, it is assumed that a speed of 166MHz has been selected. This corresponds to SW3-1 set to OFF, SW3-2, set to OFF and SW3-3 set to ON.

If the DIP switches are changed from the default then the value of `CYGHWR_HAL_SH_OOC_XTAL` must be changed to match. Consult the ST40RA documentation on appropriate values for the clock and associated divider options for the subclocks if you wish these to be altered from the default.

Other Issues

The ST40EB platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SH4 variant HAL, and the SH architectural HAL documentation should be consulted for further details.

It should be noted that the floating point support in the SH HAL has a caveat that, if the FPSCR register is changed, it may get reverted at a later stage by certain operations performed by the GCC compiler. This behaviour is intentional as the alternative would be to update the GCC compiler's internal state about the FPSCR at every context switch which would be expensive for a feature that is unlikely to be used frequently. If the FPSCR is to be changed by the application, the developer should call the function `__set_fpscr(int)`, passing it the new FPSCR value.

Part LXXXVI. TILE-Gx Architecture

Table of Contents

Chapter 357. TILE-Gx Architectural Support

Name

Overview — eCos Support for the TILE-Gx Family of Processors

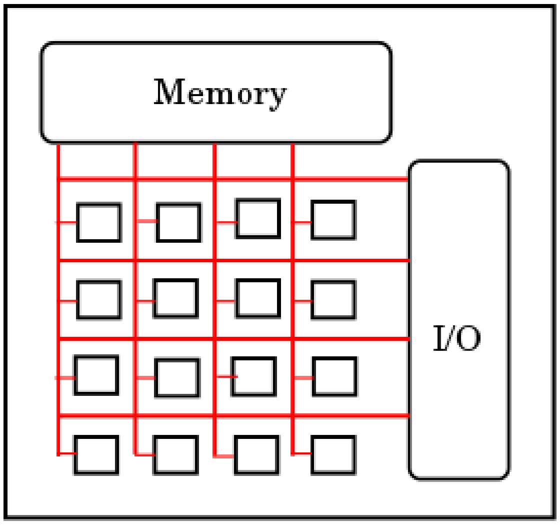
Description

This package `CYGPKG_HAL_TILEGX` provides architectural HAL support for running eCos aplications on a Tilera TILE-Gx processor. In many ways this is a very unusual architecture for running eCos, and therefore the TILE-Gx eCos port is also somewhat different from ports to other architectures.

This section of the package documentation gives a brief description of the TILE-Gx hardware, how it is typically used, and the main limitations of the eCos port. Later sections describe the process of preparing hardware for running an eCos application, the various configuration options provided by the port, and some of the implementation details.

The Hardware

A TILE-Gx chip contains of an array of CPU cores, known as tiles. It also contains a set of memory interfaces and I/O peripherals. The cores, memory and peripherals are connected via a mesh interconnect. One of the peripherals, USB, can be used to connect the TILE-Gx chip to a host PC for software development.



Each tile is a fully-fledged and fairly conventional CPU, aimed at running an advanced operating system like Linux. It has a register bank of 64 64-bit registers, some of which have a dedicated purpose such as communication over the mesh network. There are also a considerable number of special purpose registers or SPRs. Many of these are intended for system software, for example to control the memory management unit and the interrupt subsystem.

Each tile has a split instruction/data primary cache and a secondary cache. The hardware also implements a distributed tertiary cache over the mesh interconnect. Assuming the MMU is set up correctly on each tile the hardware will maintain cache coherency. Shared memory can be used for exchanging large amounts of data between tiles. The mesh interconnect also provides two buses, the I/O Dynamic Network or IDN and the User Dynamic Network or UDN. These allow the transfer of fairly small packets, up to a couple of hundred 64-bit words of data, between tiles.

On power up the hardware runs a hypervisor boot image, typically loaded from a serial ROM although alternative images can be loaded from a host PC over USB. Usually the hypervisor proceeds to run an SMP Linux kernel on all the tiles, and applications run as processes on top of Linux in a protected environment. The kernel runs on top of the hypervisor, and control over the various peripherals and memory resources is shared between the two in complicated ways. It is possible to partition the chip's tiles such that Linux only runs on some of them, while others run a bare metal executable or BME application. A BME application replaces the hypervisor and runs with full access to the hardware. The eCos port uses this functionality to run eCos applications on some of the tiles.

Limitations

The eCos port to the TILE-Gx architecture is subject to some important restrictions, and application developers should be aware of these.

1. At the time of writing eCos does not provide full SMP functionality. It is possible to run eCos applications on multiple tiles at the same time, but these tiles all run their own private instance of eCos. Each tile is allocated its own private memory. Once the eCos applications are running on the various tiles they can communicate over the UDN bus or over shared memory, and they can also communicate with Linux processes running inside the Linux partition. The TMC support package `CYGPKG_HAL_TILEGX_TMC` in `packages/hal/tilegx/tmc` provides some support code for this, and more importantly some detailed examples.

2. Also at the time of writing eCos does not support operating in 64-bit mode. In practice this is not a major problem. Although TILE-Gx is a 64-bit architecture the instruction set provides full support for running in 32-bit mode, and **tile-gcc** has a *`-m32`* flag to support this. Running in 32-bit mode should have no detrimental effect on performance. In fact it may improve performance very slightly because pointers in data structures will consume less memory, allowing more data to fit into the caches and reducing the memory bandwidth requirements. The main restriction is that the address space of an eCos application is limited to two gigabytes (it should be four gigabytes but **tile-gdb** appears to get confused at times when dealing with 32-bit pointers with the top bit set).

3. The eCos ports depends on various bits of Tilera software. The port has been performed with the TileraMDE-4.1.0.148119 release of the Multicore Development Environment. If there are incompatible changes to the MDE, for example if the hypervisor code for loading and starting a BME application is rewritten, then such changes could stop the eCos port working in strange ways. The TMC package's examples for setting up shared memory between a Linux process and an eCos application are also particularly vulnerable to breakage given the rapid rate of development of the Linux kernel.

4. The Tilera support for BME applications is limited. That means that sharing resources between the Linux partition and BME tiles running eCos is generally difficult, and at times may be impossible. For example there is no easy way for eCos to allocate additional physical memory: after bootstrap all unallocated memory belongs to the Linux partition and the hypervisor. If more memory is needed then the allocation has to be performed by a Linux process and the details of the allocation can then be passed on to the eCos application, allowing the latter to map the memory into its address space.

   Particular difficulties are likely to arise when it comes to peripherals. Sharing a peripheral between an eCos application and a Linux device driver will typically be impossible: the latter will not have been written to allow sharing, and any spinlocks or other locking mechanisms that may exist will not be accessible to an eCos application.

Name

Setup — preparing the hardware for eCos development

Overview

Just as the TILE-Gx hardware is rather different from more conventional hardware used to run eCos, the process of setting up the hardware is also rather different. Most importantly eCos only runs on some of the tiles in a chip, with Linux and the hypervisor running on the other tiles. It is the hypervisor that is responsible for booting all the tiles. Setting up the hardware involves constructing and running a suitable hypervisor image. Such an image contains the following:

1. The hypervisor executable, `hv`. This is a 64-bit ELF executable. A default build is provided with the Tilera Multicore Development Environment (MDE) in the `$TILERA_ROOT/tile/boot` subdirectory, but a custom build may be necessary to cope with specific hardware such as ethernet PHY chips.

2. A hypervisor configuration file, typically with `.hvc` suffix. An example can be found in the MDE file `$TILERA_ROOT/tile/etc/hvc/vmlinux.hvc`. Amongst other functionality this configuration file allows some of the tiles to be designated as BME or bare metal executable tiles, which will run a dedicated application directly on the hardware instead of layered on top of Linux and the hypervisor. eCos applications run in a BME tile.

3. A Linux kernel, for example `$TILERA_ROOT/tile/boot/vmlinux`. This is another 64-bit ELF executable. Again a custom build of the Linux kernel may be needed on some hardware. Note that the default `vmlinux` file has not been stripped of debug information and has not been compressed, so it will be some tens of megabytes in size.

4. An initial RAM file system, for example `$TILERA_ROOT/tile/boot/initramfs.cpio.gz`. This contains executables, shared libraries, and other files needed by the Linux system at run-time. Applications are very likely to involve a custom version of this RAM file system containing additional files, for example the application executables. Usually ELF files will be stripped off their debug information as they are incorporated into the initramfs file, and of course the latter is compressed.

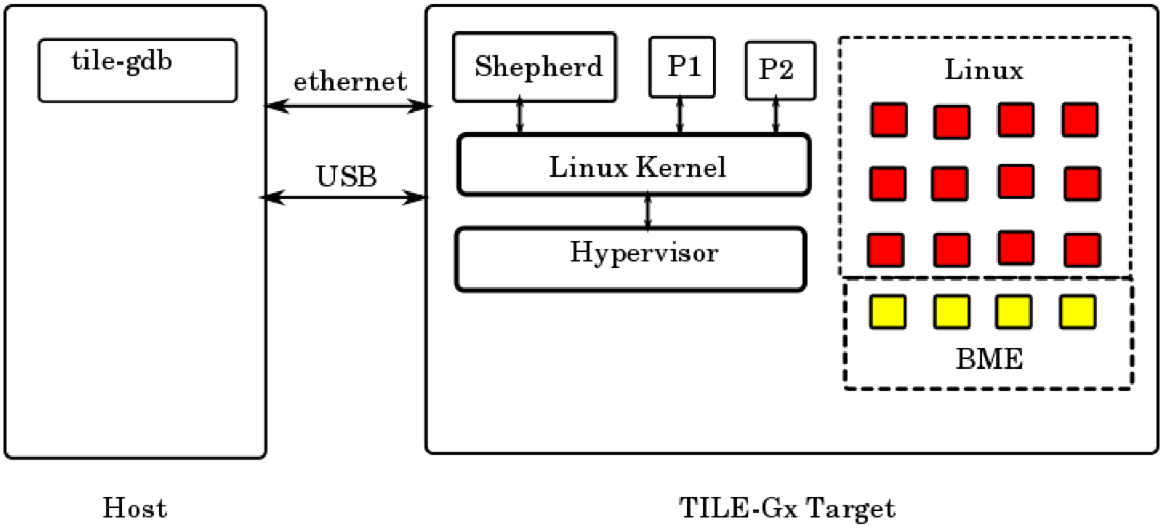
5. If the hypervisor configuration file specifies that one or more tiles should form a BME partition, the executable that should run on those tiles must also be incorporated into the hypervisor image since it is the hypervisor that will launch that executable.

A hypervisor image is created directly by the **tile-mkboot** command, or indirectly by **tile-monitor**. An initramfs file is created by **tile-gen-initramfs**. Full information on these commands is provided in the Tilera documentation, especially UG509 The Multicore Development Environment System Programmer's Guide. That information is not repeated here, instead this document focusses only on eCos-specific aspects. It is assumed throughout that the application developer has a working MDE installation and that the hardware is already set up for developing Linux applications.

The setup process is different for debug and production systems. A debug system allows eCos applications to be loaded and debugged via **tile-gdb**, and will be used for most of the development process. In a production system the eCos application is loaded and starts running automatically during bootstrap, but cannot be debugged via **tile-gdb** (except under certain circumstances when running on the simulator instead of real hardware). There are also three different scenarios: running on real hardware with the hypervisor image loaded over USB; running on real hardware with the hypervisor image booting automatically from a serial ROM; and running on the simulator.

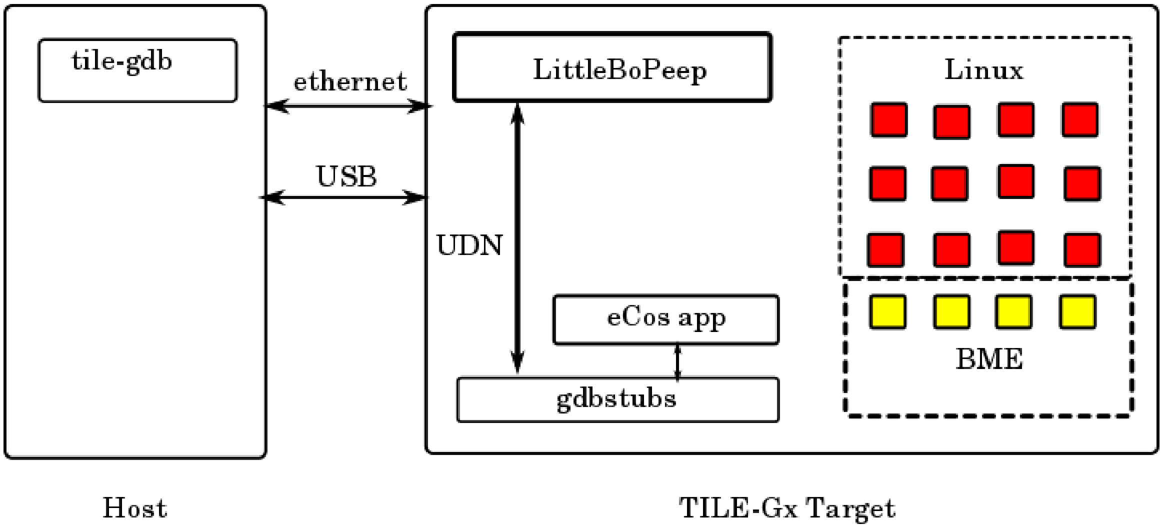
Debugging Overview

Debugging an application running on a TILE-Gx chip generally involves software rather than any hardware debug technology. First consider a process running in the Linux partition of a TILE-Gx chip:



This shows a 4x4 TILE-Gx chip with 12 of the tiles configured as a Linux partition and 4 tiles configured as a BME partition. There are two application processes running in the Linux partition, P1 and P2, both sitting on top of the Linux kernel which in turn sits on top of the hypervisor. There is also an auxiliary process, the shepherd. A host PC is connected to the TILE-Gx target via USB and ethernet. Debugging an application on the TILE-Gx target involves running **tile-gdb** on the host PC. This debugger instance connects to the shepherd process on the target, and communication between the two uses the gdb remote protocol over TCP/IP. When for example **tile-gdb** needs to read a memory location inside process P1 it constructs a memory read remote protocol request and sends this to the shepherd on the target. The shepherd decodes the request and then makes a `ptrace` system call into the Linux kernel. The kernel performs the desired operation and passes the result back to the shepherd. This constructs a remote protocol reply message which gets sent back to **tile-gdb** on the host, and the debugger now has the required information.

Debugging an eCos application running inside a BME tile involves a similar but not identical process. The key difference is that a Linux kernel running in the TILE-Gx chip has no control over any of the BME tiles, so the `ptrace` system call is useless. Instead the main debug functionality is provided by a special eCos application, gdbstubs, held in the file `gdb_module.64`. The hypervisor boots this eCos application into each BME tile. The user's eCos application is loaded and run on top of gdbstubs. Now, unfortunately gdbstubs does not have the same ready access to the outside world as the Linux shepherd: the target's network and USB interfaces are managed by the Linux side so gdbstubs cannot easily provide TCP/IP communication. Instead there is another process, LittleBoPeep running inside the Linux partitition alongside the shepherd. LittleBoPeep accepts TCP/IP connections from **tile-gdb** instances on the host. Remote protocol requests are passed on to gdbstubs running on the appropriate BME tiles over the TILE-Gx internal UDN communication network. gdbstubs decodes the request, performs the appropriate operation such as reading a memory location, and sends the reply back to LittleBoPeep over UDN. LittleBoPeep then forwards the reply to **tile-gdb** on the host, and the debugger now has the required information.



UDN messages are addressed to a specific tile, so for LittleBoPeep to receive messages from gdbstubs it must bind itself to a specific tile within the Linux partition. It will always select the last tile in that partition. This may cause problems if other Linux applications attempt to use UDN communications. By default a user-level process like LittleBoPeep does not have permission to access the UDN network, so it has to make a call into the Linux kernel to obtain access. The Linux kernel will only allow one process per tile to perform UDN communication, which is a somewhat strange restriction since the UDN hardware supports four separate communication channels and LittleBoPeep only needs one of them. Therefore if some other process runs on the same tile as LittleBoPeep and claims UDN access first, LittleBoPeep's UDN initialization will fail. Alternatively if LittleBoPeep initializes first then the other process' attempt at claiming UDN access will fail. This problem cannot be worked around without changing the Linux kernel.

Hardware, USB Bootstrap, Debug system

The first scenario involves a debug system running on real hardware with the hypervisor image booted via USB and **tile-monitor**. This is likely to be the most common scenario during software development. The first step is to take an existing `.hvc` hypervisor configuration file, for example `$TILERA_ROOT/tile/etc/hvc/vmlinux.hvc`, and append lines like the following:

```
# Define the BME tiles
bme bmeapp private 3,0 3,1 3,2 3,3
  memory 0 default
  pertile va=0x6c000000
```

These lines define a BME partition consisting of four tiles: 3,0 3,1 3,2 and 3,3. The BME partition can be given more, fewer, or different tiles by changing this list of tile addresses. The application that will be run on each tile is given an alias of `bmeapp`, and that alias will be mapped on to a real filename via a **tile-monitor** command line argument. The keyword `private` is essential: it informs the hypervisor that each BME tile is independent from the other and needs its own memory. The alternative would be a BME partition running a single SMP application with the memory shared between the BME tiles, and SMP is not supported with the current TILE-Gx eCos port.

The line `memory 0 default` determines which memory controller is used for the BME tiles' memory. This particular line is cloned from the MDE's `tilegx/examples/bme/client_server/sim.hvc`. Application developers may wish to use different settings for this as per the Tilera manual UG509, section 8.4.3.

The bulk of the memory allocated to a BME application is determined automatically by the hypervisor from information in the ELF executable. However the hypervisor will allocate an additional block of pertile memory to hold the initial stack, some hypervisor data structures, and so on. The line `pertile va=0x6c000000` places that additional block within the 32-bit address space supported by an eCos application. This line must not be changed since eCos expects to find the memory at that address.

Note that the Tilera tools support only a single BME partition definition in the hypervisor configuration file. Therefore it is not possible to run different applications on different BME tiles, or to have different memory settings for different tiles. Usually this will not be an issue for a debug system because the executable is always a gdbstubs binary.

Once the hypervisor configuration file is ready it is possible to boot up the system with **tile-monitor**:

```
tile-monitor --verbose --dev /usb0 --hvc ecos.hvc \
             --mkboot-args -+- --no-strip -+- \
             --bme bmeapp=<path0>/gdb_module.64 \
             --upload <path1>/LittleBoPeep /LittleBoPeep \
             --launch - /LittleBoPeep 3,0 3,1 3,2 3,3 -
```

The various options are as follows:

- `--verbose` is optional. It enables additional diagnostics within **tile-monitor** which may help to track down problems.
- `--dev /usb0` tells **tile-monitor** how to interact with the target hardware, in this case through the `tileusb0` device provided by the Tilera USB device driver. If the hardware is accessed via some other means then argument will need to be adjusted accordingly.
- `--hvc ecos.hvc` identifies the hypervisor configuration file that should be used.
- `--mkboot-args -+- --no-strip -+-` causes **tile-monitor** to pass the argument `--no-strip` when it invokes a sub-process **tile-mkboot** to create the hypervisor image. By default **tile-mkboot** will strip all debug information out of ELF executables that go into the hypervisor image, including the BME executable. Unfortunately **tile-strip** is not compatible with eCos executables and will corrupt them, preventing the hypervisor from correctly loading these executables into the BME tiles. Suppressing the automatic stripping bypasses this problem.
- `--bme bmeapp=<eCos executable>`. The BME lines in the hypervisor configuration file specified bmeapp as an alias for the executable that should be run on all BME tiles. Here we specify exactly which file corresponds to that alias. For a debug system the executable should always be a gdbstubs binary `gdb_module.64`. A prebuilt version of that executable should be included in the release, or alternatively a binary can be rebuilt as described below.
- `--upload <path1>/LittleBoPeep /LittleBoPeep`. This uploads the LittleBoPeep executable to the target, storing in in the root of the RAM file system.
- `--launch - /LittleBoPeep 3,0 3,1 3,2 3,3 -` Once LittleBoPeep has been uploaded to the Linux system it is started with the appropriate arguments. These arguments specify the BME tiles running gdbstubs and should match the list in the hypervisor configuration file.

The above invocation of **tile-monitor** uses the default hypervisor executable, the default Linux kernel executable and the default initramfs file from `$TILERA_ROOT/tile/boot`. Alternative versions of these can be specified if desired using `--hv-bin-dir`, `--vmlinux` or `--initramfs` options. See the **tile-monitor** documentation for more information.

Once the hypervisor image has been created, downloaded over USB, and started the hypervisor will set up the BME tiles and start the bmeapp application on each one. When gdbstubs is that application it will pause early on during initialization, waiting to be contacted by LittleBoPeep over the UDN network. Some time later, when uploading and launching LittleBoPeep **tile-monitor** should report the following:

```
[monitor] Uploading...
[monitor] Uploading complete.
[monitor] Process 551 created using '/LittleBoPeep'.
```

The exact process number may vary depending on what else is running. LittleBoPeep will now start running, connect to gdbstubs running on the specified tiles, and report the status of each one on the system console:

```
LittleBoPeep: starting.
LittleBoPeep: tile 3,0, gdbstubs active, listening on port 10300
LittleBoPeep: tile 3,1, gdbstubs active, listening on port 10301
```

```
LittleBoPeep: tile 3,2, gdbstubs active, listening on port 10302
LittleBoPeep: tile 3,3, gdbstubs active, listening on port 10303
```

At this point LittleBoPeep, running in the Linux partition, is ready to accept TCP connections from **tile-gdb** on any network interface to any of the specified ports. Assume that the target-side Linux system has been set up with TCP/IP networking enabled and that the gbe0 network interface has been assigned the network address 10.1.1.42. Also assume that the user has configured and built a RAM-startup eCos application, for example the Hello World example, as per the eCos User Guide. It is now possible to load and run the eCos executable on one of the BME tiles:

```
% tile-gdb --quiet hello
Reading symbols from .../hello...done.
(gdb) target remote 10.1.1.42:10300
Remote debugging using 10.1.1.42:10300
0x00016550 in ?? ()
(gdb) load
Loading section .text, size 0x15d80 lma 0x10010000
Loading section .data, size 0x180 lma 0x10025d80
Start address 0x10010000, load size 89856
Transfer rate: 37 KB/sec, 987 bytes/write.
(gdb) break exit
Breakpoint 1 at 0x10021d40: file .../src/exit.cxx, line 75.
(gdb) continue
Continuing.
Hello, eCos world!
[Switching to Thread 2]

Breakpoint 1, exit (status=0x0) at .../src/exit.cxx:75
75  {
(gdb) maintenance packet r
sending: "r"
received: ""
(gdb) quit
A debugging session is active.

    Inferior 1 [Remote target] will be killed.

Quit anyway? (y or n) y
```

Obviously the sizes, transfer rate, and so on will vary somewhat. The command **target remote 10.1.1.42:10300** tells tile-gdb to establish a TCP/IP connection to IP address 10.1.1.42, port 10300, and communicate using the gdb remote protocol. The IP address corresponds to the target's gbe0 network interface - note that any of the target's network interfaces may be used, gbe0 is used here simply as an example. The port number is one of the ones reported by LittleBoPeep and corresponds to tile 3,0. The eCos application is loaded and runs to completion, hitting a breakpoint at the `exit()` function. Note that the application's console output goes over the debug channel and is reported by **tile-gdb**. LittleBoPeep supports concurrent debug sessions to every BME tile running gdbstubs, but only one **tile-gdb** instance can interact with a given tile at a time.

Normally when gdb exits the target-side application is left running. Most of the time this is not what is wanted when developing an eCos application. Instead the desired behaviour is that the tile gets restarted, ready for loading and running another build of the application being debugged. That is achieved by the **maintenance packet r** command. Quitting **tile-gdb** after that command has been issued will cause the tile to restart, and LittleBoPeep will report:

```
LittleBoPeep: tile 3,0 is resetting.
LittleBoPeep: tile 3,0, gdbstubs active, listening on port 10300
```

The port assignment used by LittleBoPeep is straightforward: given a gdbstubs instance running on tile x,y, LittleBoPeep will accept TCP connections on port (10000 + 100x + y). This numbering scheme should support chips with up to 10000 tiles, although of course trying to debug applications on even a small fraction of that number of tiles will prove problematical.

eCos applications run with limited memory protection, and have unrestricted access to system resources such as the special purpose registers used for controlling the MMU and interrupts. Therefore an eCos application can crash the tile it is running on, for example by accidentally overwriting some critical area of memory. At that point **tile-gdb** and LittleBoPeep will no longer be able to communicate with the gdbstubs executable running on the target tile, and LittleBoPeep will report this:

```
LittleBoPeep has lost one of her sheep.
  Tile 3,0 has stopped responding to UDN packets.
  This tile is now marked as crashed and cannot be used again until the hardware is reset.
```

Most commonly this condition will be detected when the application stops producing output and the user attempts to interrupt it with a ctrl-C. Unfortunately the gdb remote protocol provides no easy way for LittleBoPeep to reliably send a suitable diagnostic message to **tile-gdb**, so the debugger will simply report that the connection to the target has been closed.

It should be noted that eCos does run with the MMU enabled and that the eCos application only has access to the memory allocated to its tile by the hypervisor during bootstrap, plus any additional memory explicitly mapped into the address space typically by calling `hal_tilegx_mmap()`. That additional memory may correspond to memory-mapped I/O devices. It may also be memory allocated by a Linux application using the TMC library whose details are then passed on to the eCos application. eCos does not have access to other memory in the system so for example it cannot overwrite kernel data structures on some other tile running Linux.

The above **tile-gdb** example assumes that the system is set up with Linux TCP/IP networking enabled, so that **tile-gdb** can connect to LittleboPeep. If this is not the case, for example because all network interfaces are needed for non-TCP/IP communications, then a slightly different approach is needed. **tile-monitor** and the target-side shepherd process provide tunnelling support: **tile-monitor** will accept connections on the host PC and forward any data to the shepherd over the USB connection; the shepherd process will establish a matching TCP/IP connection within the Linux partition and forward any data to its destination within the target. Tunnelling requires some additional arguments when invoking **tile-monitor**:

```
tile-monitor --verbose --dev /usb0 --hvc ecos.hvc \
             --mkboot-args -+- --no-strip -+- \
             --bme bmeapp=<path0>gdb_module.64 \
             --tunnel 10300 10300 --tunnel 10301 10301 \
             --tunnel 10302 10302 --tunnel 10303 10303 \
             --upload <path1>/LittleBoPeep /LittleBoPeep \
             --launch - /LittleBoPeep 3,0 3,1 3,2 3,3 -
```

tile-monitor on the host PC will accept connections on port 10300, and the shepherd will establish a matching target-side connection to port 10300. Each tunnel argument establishes one such pairing. Inside the **tile-gdb** session it is necessary to use a remote address of `localhost:10300` instead of `10.1.1.42:10300`, connecting via **tile-monitor** instead of directly to the remote port.

Hardware, ROM Bootstrap, Debug System

This scenario also allows eCos applications to be debugged via **tile-gdb** and LittleBoPeep. However the hypervisor image is not booted into the target hardware via **tile-monitor** and USB. Instead the hardware boots automatically from a serial ROM. Setting up a system like this requires two steps: constructing a suitable hypervisor boot image; and programming that image into the serial ROM.

Creating the boot image involves either the **tile-mkboot** command or **tile-monitor --create-bootrom** which implicitly invokes the former. The latter approach is taken here. As before a boot image incorporates a hypervisor executable, a hypervisor configuration file, a Linux kernel, an initramfs file, the executable to run on any BME tiles, and a small number of support files. The hypervisor executable and configuration file can be the same as before, and `gdb_module.64` should again be used as the BME executable. However the Linux kernel and the initramfs file need special attention.

A typical serial ROM is comparatively small, usually 16MB. Worse, that ROM normally holds a primary boot loader and two separate boot images, the current image plus a backup image to allow recovery if and when things go wrong. That means a new boot image file has to be a bit less than 8MB. Given that an uncompressed unstripped Linux kernel is some tens of megabytes, clearly it is necessary to strip and compress it when generating the boot image. **tile-mkboot** will do this by default to all executables, but this behaviour can be suppressed with the *`--no-strip`* option.

Unfortunately **tile-mkboot** will also attempt to strip and compress any BME executables, and does not provide any finer-grained control over this behaviour. Applying **tile-strip** to an eCos executable will corrupt it, and the hypervisor's BME loader code does not support loading compressed executables. Therefore if **tile-mkboot** stripping and compression is enabled then the eCos application cannot be loaded into a BME tile, but if it is disabled then the resulting boot image file will be far too large for the serial ROM.

The solution is to pre-strip and pre-compress the Linux kernel file before constructing the boot image.

```
$ tile-strip -o vmlinux_stripped $TILERA_ROOT/tile/boot/vmlinux
$ bzip2 -9 vmlinux_stripped
```

That takes care of the Linux kernel. It is also necessary to customize the initramfs file so that LittleBoPeep is started automatically during the Linux bootstrap process. The process of constructing a custom initramfs with **tile-gen-initramfs** is documented in the Tilera manual UG509, section 3.4.2. It involves editing a `contents.txt` file, adding the following lines:

```
file /usr/bin/LittleBoPeep DIR/LittleBoPeep 755 0 0
file /etc/rc.local DIR/rc.local 644 0 0
```

This assumes that the LittleBoPeep executable has been placed in the same directory as the edited `contents.txt` and that a file `rc.local` has been created alongside it. That file should contain:

```
/usr/bin/LittleBoPeep 3,0 3,1 3,2 3,3 &
```

(This assumes that the application being developed does not already involve an `rc.local` file to start various processes within the Linux partition. If that file already exists then the LittleBoPeep line can just be appended.)

The Linux bootstrap will automatically run `/etc/rc.local` if that exists, so LittleBoPeep will be started in the background and will connect to gdbstubs on the four tiles specified. Obviously if the hypervisor configuration file lists a different set of tiles then `rc.local` should be updated to match.

Once a suitable Linux kernel and initramfs file are ready the boot image can be created:

```
tile-monitor --no-dev --create-bootrom image.bootrom \
             --hvc ecos.hvc --mkboot-args -+- --no-strip -+- \
             --vmlinux vmlinux_stripped.bz2 \
             --initramfs ecos_initramfs.cpio.gz \
             --bme bmeapp=<path>/gdb_module.64
```

This should produce a suitable file `image.bootrom`. That file can now be transferred to a running TILE-Gx system and programmed into the serial ROM using **sbim -i image.bootrom**. When the hardware is rebooted the hypervisor will automatically set up the BME tiles as per the `ecos.hvc` configuration file, load and start `gdb_module.64` on each BME tile, and start the Linux kernel on the remaining tiles. The Linux kernel will go through its boot process and end up running `/etc/rc.local`, which in turn will start LittleBoPeep running. LittleBoPeep will connect to gdbstubs on the specified tiles, then it will accept debug connections from **tile-gdb** over TCP/IP as before.

Hardware, USB Bootstrap, Production System

Once the eCos application has been debugged to the developer's satisfaction it is time to switch from a debug system to a production system. This no longer involves gdbstubs or LittleBoPeep. Instead the eCos application is incorporated directly into the hypervisor boot image and started automatically. Note that this will happen fairly early on in the bootstrap process, before the Linux kernel is started let alone any Linux processes running on top of the kernel. Console output from the eCos application will go the target's system console.

The first step is to change the eCos configuration option **CYG_HAL_STARTUP** from RAM to ROM. For the TILE-Gx architecture RAM startup is for applications which will run on top of gdbstubs, while ROM startup is for applications which are incorporated into the hypervisor boot image. The eCos configuration should then be rebuilt and the application relinked. Assume this application is called `ecosapp`.

Now, an eCos application is a 32-bit executable. The hypervisor BME loading code only supports 64-bit executables. To work around this the TILE-Gx architectural HAL comes with a utility script **tile-ecos-32to64** which reads in a full 32-bit executable, discards anything which will not be needed on the target-side such as debug information, and outputs a 64-bit pseudo-executable.

```
tile-ecos-32to64 ecosapp ecosapp.64
```

The output file `ecosapp.64` will not be a fully-fledged ELF executable and other tools such as **tile-objdump** may be confused by it. It is intended only for use by the hypervisor's BME loader. If say a disassembly is required then **tile-objdump** should be applied to the original 32-bit file, not the generated 64-bit pseudo-executable. The system can now be started via **tile-monitor**:

```
tile-monitor --verbose --dev /usb0 --hvc ecos.hvc \
             --mkboot-args -+- --no-strip -+- \
             --bme bmeapp=ecosapp.64
```

Most of these arguments are the same as when booting a debug system over USB. The same hypervisor executable, hypervisor configuration file, Linux kernel and initramfs file can be used. A different file is associated with the `bmeapp` alias, and there is no need to upload and launch LittleBoPeep since there are no gdbstubs instances running in any of the BME tiles for it to talk to.

The Tilera hypervisor only supports a single application which will be run on all BME tiles. If the system needs different functionality on different tiles then the eCos application must be a union of all functionality, and a run-time decision must be made as to which tile runs what code.

Hardware, ROM Bootstrap, Production System

Setting up a production system which can boot from ROM is very similar to setting up a debug system. It will again be necessary to strip and compress the Linux kernel before generating the boot image. As far as eCos is concerned there is no need for anything extra in the initramfs file. In particular the LittleBoPeep executable would serve no purpose so does not need to be included or started from `rc.local`.

As far as the eCos executable is concerned, this must be processed in the same way as when booting a production system over USB. The eCos configuration must be changed to ROM startup and rebuilt, the application must be relinked, and the resulting 32-bit executable must be processed with **tile-ecos-32to64**. Once this is done the boot image can be created using **tile-monitor**:

```
tile-monitor --no-dev --create-bootrom image.bootrom \
             --hvc ecos.hvc --mkboot-args -+- --no-strip -+- \
             --vmlinux vmlinux_stripped.bz2 \
             --bme bmeapp=ecosapp.64
```

The resulting `image.bootrom` file can now be transferred to a running TILE-Gx system and programmed into the serial ROM using **sbim -i image.bootrom**.

Simulator, Debug System

Running an application in the simulator is mostly similar to running on the hardware, albeit very much slower. Also the simulator does not implement all the hardware functionality, for example ethernet emulation is very limited. Typically a slightly different hypervisor configuration file is used, see `$TILERA_ROOT/tile/etc/hvc/vmlinux-sim.hvc` as opposed to `$TILERA_ROOT/tile/etc/hvc/vmlinux.hvc`. The file will need to be edited to incorporate a BME partition.

The simulator is usually started by another **tile-monitor** invocation:

```
tile-monitor --verbose --simulator --config gx8016 \
             --console --functional --gdb-port 9000 \
             --bm-debug-on-panic --debug-on-crash \
             --hvc ecos-sim.hvc \
             --mkboot-args -+- --no-strip -+- \
             --bme bmeapp=<path0>/gdb_module.64 \
             --tunnel 10300 10300 --tunnel 10301 10301 \
             --tunnel 10302 10302 --tunnel 10303 10303 \
             --upload <path1>/LittleBoPeep /LittleBoPeep \
             --launch - /LittleBoPeep --spin 3,0 3,1 3,2 3,3 -
```

Here **tile-monitor** is instructed to start a functional simulation of a gx8016 chip and provide the system console. A hypervisor image is created containing `gdb_module.64` and that executable will be started automatically on all BME tiles defined in the hypervisor configuration file. Once Linux is up and running in the simulator LittleBoPeep is loaded and started. Given the simulator's very limited ethernet support TCP/IP networking will not be available, so **tile-gdb** will have to connect to LittleBoPeep over a tunnel set up by **tile-monitor** on the host PC and the shepherd process on the target.

LittleBoPeep is started with an additional argument, *`--spin`*. This works around another limitation within the TILE-Gx Linux world. When gdbstubs sends a gdb remote protocol message or reply to LittleBoPeep over the UDN network, there is no easy way for that UDN traffic to wake up a sleeping Linux process. Normally LittleBoPeep polls the UDN network for incoming data at 10 millisecond intervals, waking up every clock tick. That gives acceptable latencies and bandwidth when debugging on real hardware. However simulating a 10 millisecond interval takes many real seconds, impacting gdb communication performance sufficiently badly that **tile-gdb** becomes almost unusable. Running LittleBoPeep with *--spin* forces it to poll continuously for incoming UDN traffic instead of at intervals. This will greatly improve debug performance, but of course debugging will still be slow compared with real hardware. It should be noted that *--spin* disables the code in LittleBoPeep which detects crashed tiles, so these will no longer be reported.

Simulator, Production System

Although rarely useful, it is possible to run a production system on the simulator. As with production systems running on real hardware, the eCos configuration needs to be switched to ROM startup and rebuilt, the eCos application needs to be relinked, and **tile-ecos-32to64** has to be used to convert the 32-bit executable to a 64-bit pseudo-executable which can be read by the hypervisor's BME loader.

```
tile-monitor --verbose --simulator --config gx8016 \
             --console --functional --gdb-port 9000 \
             --bm-debug-on-panic --debug-on-crash \
             --hvc ecos-sim.hvc \
             --mkboot-args -+- --no-strip -+- \
             --bme bmeapp=ecosapp.64
```

The **tile-monitor** options are largely the same as when running a debug system. `ecosapp.64` is used instead of the gdbstubs `gdb_module.64` file. There is no need to upload or launch LittleBoPeep since there are no gdbstubs instances for it to interact with, and if LittleBoPeep is not used then there is no need to set up TCP/IP tunnels between the host and target.

The TILE-Gx architectural HAL does provide a configuration option which may prove useful in this environment: `CYGHWR_HAL_TILEGX_SIMULATOR`. Enabling this option causes the eCos application to trigger a backdoor provided by the simulator. The simulation will be halted until **tile-gdb** is attached to the simulator, and information will be output on exactly how that should be done. However note that the executable file used should be the original 32-bit one, not the 64-bit pseudo-executable since that no longer contains any debug information. The resulting debug session will have limited debug functionality compared with the gdbstubs/LittleBoPeep solution, for example it will not support thread-aware debugging, and of course the simulator does not provide a full simulation of all the hardware. Never the less this does provide a limited way of debugging eCos code in a production system, which is not possible on real hardware.

Rebuilding gdbstubs and LittleBoPeep

A full release of eCos for the TILE-Gx architecture should include prebuilt binaries of gdbstubs and LittleBoPeep. If for any reason it is necessary to rebuild these, the process is straightforward. First, LittleBoPeep. The source code for this is found in the `host` subdirectory of the TILE-Gx architectural HAL package, `packages/hal/tilegx/arch`, together with a makefile. Simply running **make** inside that directory produce a new LittleBoPeep executable. To rebuild a gdbstubs executable, create a new directory and inside that directory run the following commands:

```
$ ecosconfig new tilegx stubs
U CYGDBG_HAL_COMMON_INTERRUPTS_SAVE_MINIMUM_CONTEXT, new inferred value 0
U CYGDBG_HAL_COMMON_CONTEXT_SAVE_MINIMUM, new inferred value 0
$ ecosconfig tree
$ make
...
```

At the end of the build the `install/bin` subdirectory will contain a 32-bit `gdb_module.img` executable and a 64-bit pseudo-executable `gdb_module.64`. The latter file is suitable for including in a hypervisor image in a debug system.

Options — Configuring the TILE-Gx Architectural HAL Package

Loading and Unloading the Package

The TILE-Gx architectural HAL package CYGPKG_HAL_TILEGX will be loaded automatically when eCos is configured for a tilegx target, as will other hardware-specific packages such as the TMC support library. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The configuration option CYG_HAL_STARTUP can take one of two values: RAM and ROM. RAM startup is the default except when rebuilding a gdbstubs image. RAM startup should be used in a debug system when the application runs on top of gdbstubs, allowing the use of **tile-gdb**. Applications linked against a RAM-startup build of eCos cannot be incorporated into a hypervisor boot image. ROM startup should be used in a production system, and when rebuilding a gdbstubs image. Applications linked against a ROM-startup build of eCos should be incorporated into a hypervisor boot image and run on the target, not on top of gdbstubs.

There are two related options: CYGSEM_HAL_ROM_MONITOR and CYGSEM_HAL_USE_ROM_MONITOR. These options need to exist only to satisfy expectations elsewhere in the eCos source base. There should be no need to change the default values.

RAM Sizing

On a typical eCos target all available memory will be used by eCos. Often the amount of memory will be fixed at compile-time, but some targets support run-time memory sizing. This approach will not work on a TILE-Gx system: typically most of the memory will be needed by the Linux partition, and each BME tile running eCos will need its own allocation.

Instead the memory size of each BME tile is determined at the point that the hypervisor loads the ROM-startup executable held in the boot image. That executable will be gdbstubs in a debug system, or the eCos application in a production system. The memory consists of a ROM region holding the code and a RAM region for data. In a debug system gdbstubs will use only a small amount of the RAM region and the rest will be used for the code and data of the RAM-startup application that will be loaded and run via **tile-gdb**. The hypervisor will also allocate a small amount of additional memory at location 0x6c000000 for the startup stack and some data structures, and some memory at the top of the address space for interrupt vectors.

It is possible but non-trivial to increase the amount of memory available at run-time, using the shared memory techniques described in the TMC support package. Essentially a process running in the Linux partition would allocate a large block of memory and pass the details on to the eCos application, which can then map the block into its own address space. However this additional memory has to be managed entirely by the application. There is no easy way to add it to the eCos system heap.

For a ROM startup application or for gdbstubs the RAM size is controlled by the configuration option CYGNUM_HAL_TILEGX_RAM_SIZE, and has a default value of 4096K or 4 megabytes. The size can be increased or decreased to match the application's actual needs. However the hypervisor will perform rounding of the requested size. For RAM sizes up to 16MB the hypervisor will round the requested size up to 64K, 256K, 1MB, 4MB or 16MB. For RAM sizes larger than 16MB the hypervisor will allocate multiple blocks of 16MB each. eCos will use the amount of memory actually allocated by the hypervisor so there is no point in specifying an intermediate value size of say 8MB: the hypervisor will round this up to 16MB and eCos will use all 16MB.

For a RAM startup application changing CYGNUM_HAL_TILEGX_RAM_SIZE usually has little or no effect. eCos will use the actual amount of memory allocated by the hypervisor to gdbstubs, irrespective of the value of this option. However the option is used in the linker script to specify the size of the RAM region. If the total application code and static data requirements exceed the option's 4MB default value then the application will fail to link because the linker believes that only 4MB are available. In these circumstances it is possible to increase the option's value and thus allow the link to succeed. Obviously it will still be necessary to run a suitably-sized gdbstubs executable so that the hypervisor really will allocate the desired amount of memory.

For a production system, changing this configuration option in the ROM startup eCos application is straightforward. For a debug system things are a little more complicated: the option would have to affect the gdbstubs executable, not the application being debugged, since it is the former that is loaded by the hypervisor. Rebuilding a custom gdbstubs executable with a different RAM size is not hard, but it is annoying. As an alternative the RAM size can also be set when using **tile-ecos-32to64** to convert a 32-bit executable to a 64-bit pseudo-executable:

```
$ tile-ecos-32to64 -m 16384 gdb_module.img gdb_module_16MB.64
```

This creates a variant of the usual `gdb_module.64` with an 16384K or 16MB RAM size instead of the default 4MB, using the prebuilt `gdb_module.img` file shipped with the release.

Diagnostics

The option `CYGHWR_HAL_TILEGX_DIAGNOSTICS_DESTINATION` controls what happens to eCos console output. For a ROM startup application eCos output will be sent to the hypervisor over the IDN bus and will be displayed on the system console. For a RAM startup application eCos output will by default be sent to LittleBoPeep and then on to **tile-gdb**. However it is possible to redirect the console output to the hypervisor and hence the system console if desired.

System Clock

The configuration options **CYGNUM_HAL_RTC_NUMERATOR** and `CYGNUM_HAL_RTC_DENOMINATOR` control the frequency of the eCos system clock, or more precisely they are used to calculate the value programmed into the TILE_TIMER_CONTROL special purpose register. The number of nanoseconds between clock ticks is given by NUMERATOR/DENOMINATOR. The default value of the NUMERATOR is 1000000000, the number of nanoseconds in a second. Therefore simple clock frequencies can be achieved simply setting the DENOMINATOR to that frequency. For example the default 100Hz system clock is achieved by a DENOMINATOR value of 100. For more complicated clock frequencies the calculation could involve unacceptable rounding errors, and it may be necessary to change both the NUMERATOR and DENOMINATOR to avoid these.

When running on the simulator the default 100Hz clock requires a simulation of 10 milliseconds between clock ticks, and that may take a few tens of second of real time. If the application spends much of its time waiting for the next clock tick then performance may be greatly improved by running with a faster clock.

Simulator Support

Any ROM startup application including gdbstubs can be run on the Tilera simulator if desired, without changing any configuration options. However it is possible to build the system specifically for running on the simulator by enabling the configuration option `CYGHWR_HAL_TILEGX_SIMULATOR`. This enables some extra code in the eCos startup code which causes the system to pause until **tile-gdb** is connected and resumes execution. The simulator will output details of exactly how **tile-gdb** should connect, but note that the file being debugged should be the original 32-bit executable and not the 64-bit pseudo-executable generated by **tile-ecos-32to64**. Enabling the option also causes the system to halt if and when a non-recoverable double fault exception occurs, which may make debugging such faults slightly less difficult. Finally it changes the behaviour of some eCos testcases, causing them to run far fewer iterations than a testcase running on real hardware.

Compiler Flags

The package has two sets of configuration options related to compiler and linker flags. The first set consists of `CYGBLD_GLOBAL_CFLAGS` and `CYGBLD_GLOBAL_LDFLAGS`, plus supporting options `CYGBLD_GLOBAL_COMMAND_PREFIX`, `CYGBLD_LINKER_SCRIPT`, and `CYGHWR_MEMORY_LAYOUT` needed by other parts of the eCos source base. `CFLAGS` defines the default compiler flags that will be used for all packages, `LDFLAGS` the default linker flags. The most important flag is `-m32` to force a 32-bit build.

The second consists of `CYGPKG_HAL_TILEGX_CFLAGS_ADD` and `CYGPKG_HAL_TILEGX_CFLAGS_REMOVE`, plus supporting options `CYGPKG_HAL_TILEGX_TESTS` and `CYGBLD_HAL_TILEGX_BUILD_STUBS64`. `CFLAGS_ADD` is used to specify additional compiler flags that should be used when compiling the TILE-Gx architectural HAL package, and `CFLAGS_REMOVE` can be used to remove some of the global flags.

Name

HAL Port — Implementation Details

Description

This section of the documentation gives an outline description of the most important parts of the architectural HAL package, and especially how the eCos HAL specification has been mapped on to the TILE-Gx hardware.

The TILE-Gx HAL is organized somewhat differently from HALs for other targets. Typically an eCos port involves three or four separate HAL packages: the architectural HAL handles features that are common to every chip within an architecture; a variant HAL copes with different families within an architecture, for example one family may support only on-chip memory and no MMU while another family is designed for use with external memory; within a family there may be different processors supporting different sets of peripherals; finally a platform HAL handles anything specific to the circuit board rather than to the chip, for example the amount of external memory. The TILE-Gx port does not require these complications. Most of the hardware variations will be handled by the hypervisor or within the Linux partition and do not affect the eCos side of things.

Data Types

The eCos port to the TILE-Gx architecture only supports 32-bit mode. `int`, `long` and pointers are all 32 bits, and a `long long` is 64 bit. The chip always runs in little-endian mode.

Header Files

The architectural HAL package provides the standard HAL header files `cyg/hal/hal_arch.h`, `cyg/hal/hal_intr.h`, `cyg/hal/hal_io.h`, and so on. However there is one important difference between the TILE-Gx versions of these headers and their equivalents for other architectures. Typically `hal_intr.h` provides definitions of all the interrupt and exception vectors, directly or indirectly. Similarly `hal_io.h` provides definitions for some or all of the on-chip peripherals. These definitions are required by some parts of eCos, for example the kernel needs to know which interrupt corresponds to the system clock, but they are specific to individual processors or variants. The gcc toolchain supports the architecture as a whole so cannot supply these definitions.

For TILE-Gx the situation is different. The multicore development environment comes with a full set of definitions in various headers below the `arch` subdirectory, for example `arch/interrupts.h` defines all the interrupt vectors, and `arch/spr_def.h` defines the special purpose registers. **tile-gcc** will find these header files automatically. The headers are intended for use by the Linux kernel but are mostly usable by eCos and eCos applications. There may be some instances where these header files reference Linux-specific functionality, or where they assume a 64-bit build. Duplicating all this information in the eCos header files would serve no purpose.

Memory Layout and the Linker Script

The memory layout for a ROM startup application or for gdbstubs is as follows:

Location	Purpose
0x00010000	Code (.text section, read-only data)
0x10000000	Data (.data and .bss sections, eCos heap)
0x6C000000	Startup stack and Hypervisor Data
0xFFFFFFFFFE000000	Interrupt vectors

The amount of memory allocated for the ROM region is just large enough to hold the application's code and read-only data, plus enough for a shadow copy of the .data initialized static data section. That shadow copy is needed to allow for platform restarts. The hypervisor will round up this amount to a suitable page boundary.

eCos memory accesses go through the MMU so the above memory locations are translated to physical addresses. Therefore one eCos tile's location 0x10000000 will correspond to a different physical memory address from another tile's location 0x10000000, and these memory regions are not shared between tiles.

The amount of memory allocated for the RAM region is determined by the **CYGNUM_HAL_TILEGX_RAM_SIZE** configuration option, but can be overridden by passing a suitable *-m <size>* option to **tile-ecos-32to64** when the executable is converted into a format suitable for including into a hypervisor boot image. The first 4K are reserved for a system data structure `hal_tilegx_global_state` which contains information such as the virtual vector table, interrupt-related data, and MMU settings. In a debug system this data structure must be shared between the ROM-startup gdbstubs and the RAM-startup application, which is most conveniently done by placing it at a well-known location.

In a debug system the next 60K of the RAM region, up to location 0x10010000, is reserved for use by gdbstubs. The remaining memory holds the application code, data, and heap.

The hypervisor allocates some additional memory at location 0x6c000000 (strictly, at the pertile va location specified in the hypervisor configuration file, but that location should be 0x6c000000). The hypervisor assumes that the application is an ordinary BME application which will need memory for its stack and heap, and which will also need information from the hypervisor such as the tile's CPU speed. The eCos requirements are different but there is no easy way to return this memory to the hypervisor. Instead eCos can still make good use of it for the startup and interrupt stack, and it does need some of the same information from the hypervisor. If an application wishes to access this hypervisor information it can do so via `hal_tilegx_global_state.hv_global_info`, as defined in `cyg/hal/hal_tilegx.h`.

When an interrupt occurs the cpu branches to a location determined by the current cpu protection level and the interrupt vector number. eCos always runs at protection level 2, which means that the relevant locations occupy approximately 16K starting at location 0xFFFF_FFFF_FE00_0000. eCos needs to provide these interrupt vectors so an executable contains a section for this. Strictly the location can be changed by manipulating the INTERRUPT_VECTOR_BASE_2 special purpose register but there is no good reason for doing so.

The linker script `src/tilegx.ld` defines all the above, in conjunction with `pkgconf/hal_tilegx.h` and `pkgconf/mlt_tilegx.h`.

For a RAM startup application running on top of gdbstubs, the application's code will be placed at location 0x10010000 onwards, immediately after the memory reserved for `hal_tilegx_global_state` and gdbstubs. The application's static data will follow immediately after the code. The rest of the memory will be allocated to the system heap for dynamic memory allocation. A RAM startup application will run in the memory map set up by the hypervisor, so the RAM size is determined by the `CYGNUM_HAL_TILEGX_RAM_SIZE` option used when gdbstubs was configured, or alternatively by the memory size passed to **tile-ecos-32to64**. The RAM startup initialization code will determine the actual amount of RAM and size the system heap accordingly.

Startup

During bootstrap the hypervisor will initialize all BME tiles as per the configuration file, allocating memory as per the executable's memory map, then jumping to the executable's entry point. The hypervisor runs at protection level 2, and starts the executable with the same protection level. There is never any need for eCos to change this protection level, and doing so would introduce various complications especially in the interrupt handling code.

For ROM startup the application entry point is `hal_tilegx_start` in `src/vectors.S`. If the application has been started by the hypervisor then that will have already taken care of much of the low-level initialization, for example zeroing the .bss uninitialized static data region. However it is also possible for an application to perform a restart. This happens most commonly when a **maintenance packet r** command is issued from inside `tile-gdb` and the debug session is then terminated, but a restart can also be caused by a double fault exception or by using the `HAL_PLATFORM_RESET()` macro defined in `cyg/hal/hal_intr.h`. After a restart the assembler initialization code needs to do rather more work, including restoring all initialized static data to their original values, zeroing all uninitialized static data, and switching to an appropriate stack.

If eCos has been built with configuration option `CYGHWR_HAL_TILEGX_SIMULATOR` enabled and if it is actually running inside the simulator then the application will halt at this point, allowing the user to attach **tile-gdb**.

Once the assembler initialization code has finished it jumps to the C function hal_tilegx_c_startup(), defined in src/tilegx.c. This performs initialization or reinitialization of various other subsystems including the memory management unit's translation lookaside buffers (TLBs), interrupt handling, virtual vectors, and gdbstubs as appropriate. Finally it runs through any C++ static constructors, including those for other eCos packages like the eCos kernel, and calls the generic cyg_start() routine.

For RAM startup the application entry point is again hal_tilegx_start in src/vectors.S, but the code executed is somewhat different from that for ROM startup. Again there is a jump to hal_tilegx_c_startup() in src/tilegx.c, and from there to cyg_start().

Thread Contexts

The HAL_SavedRegisters structure defined in cyg/hal/hal_arch.h defines the storage needed for saving and restoring a thread context during context switches and interrupt handling. Mostly it consists of the registers r0-r53, but there is some additional state which overlaps the stack frames defined by the TILE-Gx ABI. The details are generally of no interest to application developers.

There is one piece of system state which is not held in the saved context structure and which arguably should be: the special purpose register SPR_CMPEXCH_VALUE. This register is not used in ordinary code. It serves only to help implement shared memory spinlocks:

```
      int result;
      __insn_mtspr(SPR_CMPEXCH_VALUE, oldval);
      result = __insn_cmpexch4(&spinlock, newval);
```

It is possible for an interrupt to occur between setting SPR_CMPEXCH_VALUE and applying the cmpexch4 or cmpexch instructions, and the register may get overwritten before the code resumes. The Linux kernel saves and restores this special purpose register during interrupt handling, adding several cycles to the interrupt latency. The eCos HAL does not save this register on the assumption, and instead the spinlock code has to disable interrupts around the above pair of instructions:

```
      CYG_INTERRUPT_STATE ints_state;
      int result;
      HAL_DISABLE_INTERRUPTS(ints_state);
      __insn_mtspr(SPR_CMPEXCH_VALUE, oldval);
      result = __insn_cmpexch4(&spinlock, newval);
      HAL_RESTORE_INTERRUPTS(ints_state);
```

This makes interrupt handling more efficient but spinlocks more expensive. Since eCos does not support SMP operations spinlocks are unlikely to be used often, and it is expected that this approach will be a net performance gain.

Interrupts

Interrupt management requires several pieces of functionality. First it must be possible to disable and reenable interrupts, so that critical code sections can run atomically. Second it must be possible to mask and unmask individual interrupt sources. Third, if support for nested interrupts is enabled via the configuration option CYGSEM_HAL_COMMON_INTERRUPTS_ALLOW_NESTING then it should be possible to assign priorities to the various interrupts, such that inside an interrupt handler lower priority interrupts are masked and higher priority interrupts are unmasked. Finally other eCos code including the kernel and any device drivers must be able to register their own interrupt handling functions. There are two versions of such handlers: a low-level VSR must be written in assembler, but is called very early after an interrupt triggers; a higher-level ISR can be written in C, but the system needs to do more work before the ISR can be called.

Each TILE-Gx tile has two special purpose registers or SPRs which control how interrupts are handled. INTERRUPT_MASK_2 can be used to mask or unmask the various interrupt sources (there are other registers for protection levels 0, 1, and 3 but those are irrelevant to the eCos port). INTERRUPT_CRITICAL_SECTION can be used to block all maskable interrupts. At first glance this second register could be used to implement the disable/reenable functionality. Unfortunately that does not quite work. If a CPU exception occurs while INTERRUPT_CRITICAL_SECTION is set then that is treated as a non-recoverable double fault. Since gdbstubs depends on CPU exceptions for some of the debug functionality, the implementation takes a different approach.

During normal execution INTERRUPT_MASK_2 holds the set of all interrupts that are currently masked, as expected. A shadow copy of this set is held in the global hal_tilegx_global_state.global_interrupt_mask. Disabling interrupts involves setting INTERRUPT_MASK_2 to 0xFFFF_FFFF_FFFF_FFFF, and reenabling interrupts involves restoring INTERRUPT_MASK_2 as per the shadow copy.

The above explanation is actually oversimplified. Implementing prioritized nested interrupts requires some additional complications. Associated with each interrupt source is an interrupt mask holding the set of all interrupts with equal or lower priorities. There are also two pseudo-interrupt sources, none and disabled, with associated masks 0 and 0xFFFF_FFFF_FFFF_FFFF. At any time the value of the INTERRUPT_MASK_2 SPR is the union of the global interrupt mask and the current interrupt's mask. During normal execution the current interrupt is none so INTERRUPT_MASK_2 holds the same value as the global interrupt mask. When interrupts are disabled the current interrupt is disabled so INTERRUPT_MASK_2 holds 0xFFFF_FFFF_FFFF_FFFF. While processing an interrupt INTERRUPT_MASK_2 holds all globally masked interrupts and all interrupts masked for the current interrupt. Keeping everything up to date in the right order requires considerable care, but achieves the desired functionality.

Assuming an unmasked interrupt triggers, the hardware jumps to location 0xFFFF_FFFF_FE00_0000 + (0x100 * interrupt_number). The ROM startup executable or gdbstubs provides the code that resides at that location, as per the macro intvec in src/vectors.S. This initial code allocates space for a HAL_SavedRegisters structure on the stack , saves a small number of registers, loads a per-interrupt VSR function pointer from hal_tilegx_global_state, and jumps to that VSR. Usually that VSR will be hal_default_interrupt_vsr, again in src/vectors.S, but applications can install their own VSR functions if interrupt latency is particularly critical for an interrupt source. Any such VSR is likely to be based at least in part on the default one.

The default VSR saves additional registers, updates the current interrupt field in hal_tilegx_global_state and the INTERRUPT_MASK_2 SPR, synchronizes with the kernel, and enables nested interrupts. It then calls the ISR associated with the current interrupt. ISRs can be written in C but there are constraints on what they are allowed to do. More information on this is provided in the kernel documentation. When the ISR returns the VSR performs additional processing, possibly including a context switch to a higher-priority thread that is now runnable, before eventually returning to the interrupted code.

CPU Exceptions

On TILE-Gx exceptions like SIGILL, an illegal instruction exception, are implemented in much the same way as interrupts. However exceptions cannot be masked. The CPU jumps to a location near 0xFFFF_FFFF_FE00_0000, where the ROM startup executable or gdbstubs will have placed suitable code. That code jumps to a VSR, which this time will usually be hal_default_exception_vsr instead of hal_default_interrupt_vsr. This in turn calls hal_tilegx_exception_handler() in src/tilegx.c which will usually deliver the exception to the kernel. There are various special cases, for example a SIGILL exception may be the result of hitting a **tile-gdb** breakpoint.

One of the exceptions is special: double fault. This occurs when a CPU exception occurs while the INTERRUPT_CRITICAL_SECTION SPR is set. Double faults are not recoverable: critical information held in other SPRs will have been overwritten. If running in the simulator and CYGHWR_HAL_TILEGX_SIMULATOR is set then the simulation will be halted. Otherwise, in the absence of a better solution, an attempt will be made to restart the system. The structure field hal_tilegx_global_state.started_by will be set to hal_tilegx_started_by_double_fault, allowing application code to detect this after the restart and take any action that might be appropriate. Double faults should be rare, but application developers should be aware of the possibility.

The Idle Thread

The kernel's idle thread will execute the nap instruction, causing the tile to sleep until the next interrupt occurs.

The System Clock

The kernel clock has been implemented using the TILE_TIMER_CONTROL special purpose register, so that hardware is not available for use by application code. The auxiliary tile timer is available for use by the application, but note that the simulator does not implement that timer.

The counter value programmed into the TILE_TIMER_CONTROL register is determined from the system clock frequency, which is information provided by the hypervisor, and from the configuration options CYGNUM_HAL_RTC_NUMERATOR and

`CYGNUM_HAL_RTC_DENOMINATOR`. The hardware does not support automatic reloading of the counter when a clock interrupt occurs, so the interrupt handler has to reload it explicitly. That code attempts to compensate for the time taken from the interrupt triggering to the counter being reloaded. The accuracy cannot be completely guaranteed, especially in a debug system, so a small amount of clock drift may occur.

The Cache

The TILE-Gx architecture has a complicated caching system including per-tile primary and secondary caches and a distributed tertiary cache. The hardware maintains data cache coherency so there is very rarely any need for code to exercise fine-grained control over the cache such as flushing cachelines. Therefore the various cache-related eCos macros like `HAL_DCACHE_SYNC()` are defined as no-ops. The hardware does not maintain coherency between the instruction and data cache so eCos does define a number of instruction cache macros like `HAL_ICACHE_INVALIDATE()`. These are needed by the gdbstubs code to implement breakpoints, and are unlikely to be of any interest to application developers.

Diagnostics

The port supports two destinations for diagnostic output. Applications built for ROM startup will send their diagnostic output to the hypervisor over the IDN bus, and the hypervisor will output the text on the system console. For a RAM startup application diagnostic output will normally be sent to **tile-gdb** via LittleBoPeep, but the output can be redirected to the hypervisor if desired. This behaviour is controlled by the `CYGHWR_HAL_TILEGX_DIAGNOSTICS_DESTINATION` configuration option.

Other Functionality

The TILE-Gx architectural HAL provides two non-standard functions which can be used to manage the MMU settings:

```
#include <cyg/hal/hal_tilegx.h>

int hal_tilegx_mmap(unsigned long long virtual_address,
                    unsigned long long physical_address,
                    unsigned long long dtlb_attributes);

void hal_tilegx_munmap(unsigned long long virtual_address);
```

`hal_tilegx_mmap()` can be used to map a physical address into the tile's virtual address space with the specified attributes. The physical address can correspond to real memory. Typically this will be allocated by a process running in the Linux partition, and the details can then be forwarded to an eCos application which will map it into its address space. Alternatively the physical address can correspond to a memory-mapped device. The virtual address can be anywhere in the address space that is not already used, but preferably in the range 0x0000_0000 to 0x7FFF_FFFF to avoid problems with 32-bit pointers. Low memory is normally used for the system's ROM and RAM regions and 0x6C00_0000 is used for the hypervisor data, but anywhere between 0x4000_0000 to 0x6800_0000 or 0x7000_0000 to 0x7FFF_FFFF is normally fine. The address should be aligned to a boundary suitable for the block size. The final argument will be written to the `DTLB_CURRENT_ATTR` SPR and consists of numerous fields. The Tilera documentation should be consulted for more information. `hal_tilegx_mmap()` returns 0 if the operation fails, typically because all of the data TLBs are already in use, or 1 on success.

`hal_tilegx_munmap()` can be used to undo a previous `hal_tilegx_mmap()` call.

Chapter 358. TILE-Gx TMC Library

Name

Overview — eCos Port of a Subset of the TMC Library

Description

The Tilera Multicore Components or TMC Library provides a variety of primitives for building parallel programs. It is documented in UG527, “The Applications Libraries Reference Manual”. The eCos package `CYGPKG_HAL_TILEGX_TMC` implements a subset of this library. The subset supports communication between Linux applications running on some of the tiles on a TILE-Gx chip and eCos applications running on other tiles. The package also contains a number of example applications demonstrating the communication functionality.

The package `CYGPKG_HAL_TILEGX_TMC` is automatically included in any configuration for a TILE-Gx target. It does not have to be added to the configuration. The package does not add any overhead to eCos applications which do not use any of its functionality, so there is no reason for ever removing the package from the configuration.

The Tilera TMC library consists of the following components:

1. UDN helper routines for communication over the UDN bus. Most of these have been ported to eCos.
2. Performance tuning. The routine `tmc_perf_get_cpu_speed()` is implemented.
3. Spinning shared memory synchronization primitives. These have all been ported to eCos.
4. Scheduler shared memory synchronization primitives. These have not been ported. The primitives interact with the Linux kernel, and there is no way for an eCos application running on a BME tile to do that.
5. Specified-attribute memory page allocation. These have not been ported. Allocating memory pages involves calling into the hypervisor and the hypervisor is no longer present on BME tiles running eCos. However it is possible for a Linux application to allocate one or more pages, pass the details on to an eCos application, and have the latter map the pages into its address space.
6. Common memory, allowing pages to be mapped at the same virtual address in different processes. These have not been ported. Linux applications run in 64-bit mode with a 64-bit address space, whereas eCos applications run in 32-bit mode with 32-bit addresses. This makes it difficult to use the same virtual addresses.
7. CPU sets and affinitization. These have not been ported. The primitives are intended to allow threads to be bound to specific tiles. Since each eCos instance runs on only one tile there is no point in attempting to support such affinitization.
8. User space interrupt installation routines. These have not been ported. eCos has its own model of how interrupts should be handled and its own routines for managing interrupts. Trying to support the TMC's model of interrupt handling as well would complicate things for little or no gain.
9. Interprocessor interrupt event-handling. These have not been ported. It is not clear that they are actually useful since there is no primitive for generating an IPI interrupt. Instead UDN communications provides a way of sending data asynchronously to another tile, and if desired that UDN communication can be processed by an interrupt handler.
10. Using mspaces for standard malloc/free. These have not been ported. Under Linux they provide an alternative implementation of the C library's `malloc()` and `free()` routines, offering some control over home caching and memory page sizes. For eCos applications it makes more sense to use the standard eCos heap using memory provided by the hypervisor during startup.
11. Cache control. These functions have not been ported, and the Tilera documentation recommends against using these low-level shared memory primitives. The main functionality provided, memory fences to guarantee visibility of stores to cache coherent memory, is instead provided by the eCos `HAL_MEMORY_BARRIER()` macro.
12. Multiple heap allocation. These routines allow for the allocation of separate mspaces with control over cache homing and other functionality. They involve interaction with the hypervisor's memory page support which is not possible for an eCos application.

13. Task management and cleanup. These primitives relate to support for multiple processes and interaction with the Tilera shepherd process. Since eCos does not support multiple processes, only multiple threads, the primitives are not applicable.

The package only provides implements of the header files `<tmc/udn.h>`, `<tmc/spin.h>`, and `<tmc/perf.h>`. The other header files do exist but will generate a compile-time warning if they are included. Providing these dummy headers prevents the compiler from accidentally including the Linux TMC headers.

Restrictions

The eCos TMC support is subject to a number of important restrictions which application developers must be aware of.

When a Linux process uses `tmc_alloc_map()` or a similar routine to allocate a block of memory, that memory is owned by the Linux process. Details of the block including the physical address can be passed on to eCos applications which can then map it into their address space. If the Linux process exits or gets killed off the Linux kernel and hypervisor will reclaim the allocated block, which may then get reused for some other Linux process or for the kernel or hypervisor itself. Meanwhile the eCos application may still have a mapping to the underlying physical memory and may still write to it, corrupting memory that now belongs to some random other part of the system. Neither the hypervisor nor the Linux kernel have any way of keeping track of what memory has been mapped into an eCos application's address space, so they cannot do anything to avoid this problem.

The only solution is to make sure that the eCos application is always informed when the Linux process exits, so that it can unmap any shared memory pages. That is not always easy to achieve, especially in a debug environment, but it is the application developer's responsibility.

Separately, UDN communication is subject to a major restriction. By default a Linux application does not have access to the UDN bus, and must explicitly obtain such access from the Linux kernel by a call to `tmc_udn_init()`. The kernel only grants UDN access to one task per tile. In a debug environment LittleBoPeep runs on one of the tiles providing gdb debug functionality for eCos tiles, and LittleBoPeep needs to use the UDN bus for this. Therefore Linux applications requiring UDN access cannot run on the same tile as LittleBoPeep, usually the highest-numbered tile not used for BME.

UDN Support

The following UDN routines are supported:

`tmc_udn_header_from_cpu()`
`tmc_udn_send_buffer()`
`tmc_udn0_receive_buffer()`, `tmc_udn1_receive_buffer()` and `tmc_udn2_receive_buffer()`
`tmc_udn_send()`
`tmc_udn_send_1()` to `tmc_udn_send_20()`
`tmc_udn0_receive()` to `tmc_udn2_receive()`
`tmc_udn0_available_count()` to `tmc_udn2_available_count()`
`tmc_udn_available_mask()`

The functions related to UDN channel 3, `tmc_udn3_receive_buffer()`, `tmc_udn3_receive()` and `tmc_udn3_available_count()` are not supported. UDN channel 3 is used for communication between LittleBoPeep and gdbstubs, and if application code tried to use this channel as well then things would get very confusing with UDN traffic going to the wrong program.

There are four other UDN functions in the Tilera TMC library which are not supported under eCos: `tmc_udn_init()`, `tmc_udn_close()`, `tmc_udn_activate()`, and `tmc_udn_persist_after_exec()`. Under Linux `tmc_udn_init()` is needed to request access to the UDN bus from the Linux kernel. That is not necessary under eCos since eCos applications run at protection level 2, which is sufficient for UDN access. The three other functions are also related to access rights and are equally unnecessary.

Spinning Shared Memory Synchronization

The following are supported:

tmc_spin_mutex_t

```
TMC_SPIN_MUTEX_INIT                       tmc_spin_mutex_init()
tmc_spin_mutex_lock()                     tmc_spin_mutex_trylock()
tmc_spin_mutex_unlock()
```

tmc_spin_queued_mutex_t

```
TMC_SPIN_QUEUED_MUTEX_INIT                tmc_spin_queued_mutex_init()
tmc_spin_queued_mutex_lock()              tmc_spin_queued_mutex_trylock()
tmc_spin_queued_mutex_unlock()
```

tmc_spin_rwlock_t

```
TMC_SPIN_RWLOCK_INIT                      tmc_spin_rwlock_init()
tmc_spin_rwlock_rdlock()                  tmc_spin_rwlock_wrlock()
tmc_spin_rwlock_tryrdlock()               tmc_spin_rwlock_trywrlock()
tmc_spin_rwlock_rdunlock()                tmc_spin_rwlock_wrunlock()
tmc_spin_rwlock_unlock()
```

tmc_spin_barrier_t

```
TMC_SPIN_BARRIER_INIT()                   tmc_spin_barrier_init()
tmc_spin_barrier_wait()
```

These data types and functions have the same semantics as the Tilera TMC versions, so the Tilera documentation can be consulted for more details.

An important point about these routines is that the various unlock functions and the barrier wait function involve a memory barrier, guaranteeing that all memory writes are visible to other tiles. Therefore code that only manipulates shared data while owning a lock automatically avoids many memory consistency problems.

Example Applications

The package comes with a number of example applications in the `examples` subdirectory:

`udn0`

This example illustrates UDN communication between a TILE-Gx Linux application and one or more instances of an eCos application.

`udn1`

This example is derived from `udn0`. It adds direct communication between the instances of the eCos application.

`shm0`

This example sets up a block of shared memory between a Linux application and one or more instances of an eCos application. The shared memory is used to hold large amounts of data. The Linux application sends UDN messages to control what each eCos instance does with that shared data.

`shm1`

This example also sets up a block of shared memory. However UDN communication is used only during initialization, to set up the shared memory. All subsequent communication between Linux and eCos goes via the shared memory.

`spintest`

This is a testcase for the various spinning shared memory synchronization primitives.

`not61850`

This is an example involving a Linux host application, a TILE-GX Linux application, and one or more instances of an eCos worker application. It combines ethernet traffic using the gxio/mpipe library routines running in the TILE-Gx Linux application, and communication between that and the eCos workers over shared memory and the UDN bus. It was written to a specific customer's requirements and may be of limited interest to other users.

Real-time characterization of selected targets
