This is the string used for the `Device` identificaion property recorded for a SystemView trace. It can identify the hardware device used for a capture. If this option is disabled then the `HAL_PLATFORM_BOARD` manifest is used.

CYGOPT_SYSTEMVIEW_RECORDER_HAL

The following options are specific to configurations where the simple, platform supplied, I/O channel support is used for direct communication with the SystemView application `UART` Recorder support. The eCos `HAL` Recorder implementation allows for Kernel instrumentation (and Infra tracing) to be generated without the Recorder itself increasing the instrumentation load.

`CYGNUM_SYSTEMVIEW_RECORDER_HAL_UART_BAUD`

This option defines the communication rate for the platform supplied low-level communication channel. The value configured here should match the value set for the host SystemView application `Target->Recorder Configuration->UART` selection.

`CYGNUM_SYSTEMVIEW_RECORDER_HAL_TXBUF`

This option defines the size of the temporary holding buffer used when transmitting data from the RTT buffer to the remote host SystemView application. This option is a compromise between the data footprint and the amount of data written by SystemView Record events.

This holding buffer can be smaller than the SystemView RTT buffer, and never needs to be larger. The buffer minimises the number of `SEGGER_RTT_ReadUpBufferNoLock()` calls and provides for a tighter TX loop transmitting bytes to the host SystemView application, which may be important since for the HAL Recorder world the performance/latency of the event transmission **will** affect the application performance and the timing of the system.

Also, due to the ordering of the initialisation code it is possible for a number of Kernel instrumentation events to be generated (and recorded in the SystemView RTT buffer) prior to the HAL communication channel being initialised and pending RTT data forwarded to the host SystemView application.

`CYGOPT_SYSTEMVIEW_RECORDER_HAL_WAIT`

When enabled this option will block the system in the HAL Recorder callback until an active SystemView connection is started. This can be used to ensure no event overflow occurs, allowing for a complete application startup to be instrumented. This option should only be enabled when explicitly required by the developer, since the target will be unresponsive until a SystemView connection is established.

CYGOPT_SYSTEMVIEW_RECORDER

As an alternative to the H/W debugger J-Link RTT direct-memory-access method of obtaining continuous events, the remote SystemView application can utilise a network connection or a UART connection to communicate with a target application supplied continuous recorder instance. This option, when enabled, provides the run-time support for such recorders. This uses a helper thread to periodically poll the SystemView buffer and forward data using the appropriate eCos I/O world.

Note

Unlike the alternative `CYGOPT_SYSTEMVIEW_RECORDER_HAL` approach, this Recorder does not rely on target platform specific support, but purely on normal eCos support. However, since the standard eCos thread and device driver interfaces are used, it means that **if** Kernel instrumentation is enabled then the Recorder helper threads and drivers **will** record events as well as the application threads/drivers being analysed.

This means that this helper thread Recorder approach is **not** recommended for Kernel instrumented configuration.

The following options are common to the Recorder support, irrespective of the configured transport options.

`CYGNUM_SYSTEMVIEW_RECORDER_PRI`

The Recorder thread priority is normally low to minimise the instrusiveness of the SystemView support (defaults to 1 higher than “idle”). The priority can be raised if overflows are detected due to the thread not being scheduled often enough, though the first approach (if possible) may just be to increase the SystemView buffer size (`CYGNUM_SYSTEMVIEW_RTT_BUFFER_SIZE`).

Note

It should be noted that since the recorder is a normal eCos thread, the operation of the recorder thread will cause SystemView thread events to be generated, and other events depending on the configuration options selected.

`CYGNUM_SYSTEMVIEW_RECORDER_TX_IDLE`

This option specifies the delay in milliseconds between checks for pending data from the remote SystemView application when the TX side is idle. When TX data is available the channel is also checked for pending RX.

`CYGNUM_SYSTEMVIEW_RECORDER_TX_POLL`

This option specifies the number of milliseconds the Recorder thread will sleep between polled checks for pending data for the remote SystemView application. The actual delay depends on the period of the scheduler tick, which is defined by the target configuration, but is normally ~10ms. So the delay implemented by this option will be rounded to the next higher scheduler tick boundary.

This setting in conjunction with the Recorder thread priority, the idle delay, the size of the RTT buffer and the corresponding TX threshold, can be tuned to avoid loss of instrumentation (RTT overflow) and the timeliness of TX to the SystemView application when matching the bandwidth of the Recorder channel with the frequency of SystemView events being recorded.

`CYGNUM_SYSTEMVIEW_RECORDER_TX_WATERMARK`

This option sets the threshold for the SystemView RTT buffer fill used to trigger a transmission to the application over the communication channel. This option can be tuned to affect the frequency of the Recorder write operations used to flush the RTT event buffer.

As well as the common Recorder options above, the configured transport channels may provide further options for the helper thread based Recorder configuration.

CYGBLD_SYSTEMVIEW_RECORDER_UART

This option enables the UART based continuous recording support to be available to the `CYGOPT_SYSTEMVIEW_RECORDER` world.

Note

This serial support is distinct from, and mutually exclusive to, the separate direct-UART access support provided when using the `CYGOPT_SYSTEMVIEW_RECORDER_HAL` feature.

This presents a serial I/O connection that can be accessed by the remote SystemView application to obtain event records. If the relevant packages are configured this can be a U(S)ART connection or a CDC-ACM (USB) connection. The SystemView event delivery is via the threaded `CYGOPT_SYSTEMVIEW_RECORDER` support.

`CYGDAT_SYSTEMVIEW_RECORDER_UART_DEVICE`

This option specifies the name of the serial peripheral device to use for the SystemView UART Recorder channel. This needs to be configured appropriately for the target, to an available device that will **not** be used by the normal application code. The serial channel is dedicated to SystemView event transport.

`CYGNUM_SYSTEMVIEW_RECORDER_UART_BAUD`

This option specifies the communication rate to be used for the Recorder serial channel. It should match the setting configured for the host SystemView application `UART` Recorder.

Part LXXII. RedBoot User's Guide

Table of Contents

Chapter 224. Getting Started with RedBoot

RedBoot™ is an acronym for "Red Hat Embedded Debug and Bootstrap", and is the standard embedded system debug/bootstrap environment from eCosCentric, replacing the previous generation of debug firmware: CygMon and GDB stubs. It provides a complete bootstrap environment for a range of embedded operating systems, such as embedded Linux® and eCos®, and includes facilities such as network downloading and debugging. It also provides a simple flash file system for boot images.

Note

Red Hat no longer maintain nor support RedBoot and have contributed both RedBoot and eCos to the stewardship of the Free Software Foundation (FSF). eCosCentric are now the sole commercial maintainers of both eCos and RedBoot.

RedBoot provides a wide set of tools for downloading and executing programs on embedded target systems, as well as tools for manipulating the target system's environment. It can be used for both product development (debug support) and for end product deployment (flash and network booting).

Here are some highlights of RedBoot,s capabilities:

- Boot scripting support
- Simple command line interface for RedBoot configuration and management, accessible via serial (terminal) or Ethernet (telnet)
- Integrated GDB stubs for connection to a host-based debugger via serial or ethernet. (Ethernet connectivity is limited to local network only)
- Attribute Configuration - user control of aspects such as system time and date (if applicable), default Flash image to boot from, default failsafe image, static IP address, etc.
- Configurable and extensible, specifically adapted to the target environment
- Network bootstrap support including setup and download, via BOOTP, DHCP and TFTP
- X/Y/Z Modem support for image download via serial
- Power On Self Test

Although RedBoot is derived from eCos, it may be used as a generalized system debug and bootstrap control software for any embedded system and any operating system. For example, with appropriate additions, RedBoot could replace the commonly used BIOS of PC (and certain other) architectures. Red Hat is currently installing RedBoot on all embedded platforms as a standard practice, and RedBoot is now generally included as part of all eCosCentric eCos ports. Users who specifically wish to use RedBoot with the eCos operating system should refer to the *Getting Started with eCos* document, which provides information about the portability and extendability of RedBoot in an eCos environment.

More information about RedBoot on the web

The eCosCentric RedBoot Documentation contains updated documentation for all public and commercial versions of RedBoot, including new features and capabilities.

The RedBoot Net Distribution web site contains downloadable sources and documentation for all publically released targets.

Installing RedBoot

To install the RedBoot package on target hardware, follow the procedures detailed in the documentation accompanying the release. This is normally found in the [eCos and eCosPro Reference Manual] or may also be found in the respective target hardware documentation in eCosCentric's eCos and eCosPro Reference Manual for publically available target hardware.

Although there are other possible configurations, RedBoot is usually run from the target platform‚s flash boot sector or boot ROM, and is designed to run when your system is initially powered on. The method used to install the RedBoot image into non-volatile storage varies from platform to platform. In general, it requires that the image be programmed into flash in situ or programmed into the flash or ROM using a device programmer. In some cases this will be done at manufacturing time; the platform being delivered with RedBoot already in place. In other cases, you will have to program RedBoot into the appropriate device(s) yourself. Installing to flash in situ may require special cabling or interface devices and software provided by the board manufacturer. The details of this installation process for a given platform will be found in Installation and Testing. Once installed, user- specific configuration options may be applied, using the **fconfig** command, providing that persistent data storage in flash is present in the relevant RedBoot version. See the section called “Configuring the RedBoot Environment” for details.

User Interface

RedBoot provides a command line user interface (CLI). At the minimum, this interface is normally available on a serial port on the platform. If more than one serial interface is available, RedBoot is normally configured to try to use any one of the ports for the CLI. Once command input has been received on one port, that port is used exclusively until the board is reset or the channel is manually changed by the user. If the platform has networking capabilities, the RedBoot CLI is also accessible using the `telnet` access protocol. By default, RedBoot runs `telnet` on port TCP/9000, but this is configurable and/or settable by the user.

RedBoot also contains a set of GDB “stubs”, consisting of code which supports the GDB remote protocol. GDB stub mode is automatically invoked when the '$' character appears anywhere on a command line unless escaped using the '\' character. The platform will remain in GDB stub mode until explicitly disconnected (via the GDB protocol). The GDB stub mode is available regardless of the connection method; either serial or network. Note that if a GDB connection is made via the network, then special care must be taken to preserve that connection when running user code. eCos contains special network sharing code to allow for this situation, and can be used as a model if this methodology is required in other OS environments.

RedBoot Editing Commands

RedBoot uses the following line editing commands.

- Delete (0x7F) or Backspace (0x08) erases the character to the left of the cursor.
- ^A or HOME moves the cursor (insertion point) to the beginning of the line.
- ^K erases all characters on the line from the cursor to the end.
- ^E or END positions the cursor to the end of the line.
- ^D or DELETE erases the character under the cursor.
- ^F or RIGHT-ARROW moves the cursor one character to the right.
- ^B or LEFT-ARROW moves the cursor one character to the left.
- ^P or UP-ARROW replaces the current line by a previous line from the history buffer. A small number of lines can be kept as history. Using ^P (and ^N), the current line can be replaced by any one of the previously typed lines.
- ^N or DOWN-ARROW replaces the current line by the next line from the history buffer.

Note

In this description, ^A means the character formed by typing the letter “A” while holding down the control key.

In the case of the **fconfig** command, additional editing commands are possible. As data are entered for this command, the current/previous value will be displayed and the cursor placed at the end of that data. The user may use the editing keys (above) to move around in the data to modify it as appropriate. Additionally, when certain characters are entered at the end of the current value, i.e. entered separately, certain behavior is elicited.

- ^ (caret) switch to editing the previous item in the **fconfig** list. If fconfig edits item A, followed by item B, pressing ^ when changing item B, allows you to change item A. This is similar to the up arrow. Note: ^P and ^N do not have the same meaning while editing **fconfig** data and should not be used.

- . (period) stop editing any further items. This does not change the current item.

- Return leaves the value for this item unchanged. Currently it is not possible to step through the value for the start-up script; it must always be retyped.

RedBoot Command History

RedBoot provides support for listing and repeating previously entered commands. A list of previously entered commands may be obtained by typing **history** at the command line:

```
RedBoot> history
  0 fis list
  1 fconfig -l
  2 load -m ymodem
  3 history
```

The following history expansions may be used to execute commands in the history list:

- !! repeats last command.

- !**n** repeats command **n**.

- !**string** repeats most recent command starting with **string**.

RedBoot Startup Mode

RedBoot can normally be configured to run in a number of startup modes (or just "modes" for short), determining its location of residence and execution:

ROM mode
ROMINT mode
EEPROM mode

In this mode, RedBoot both resides and executes from ROM memory (ROMINT:internal flash, ROM:external flash, EPROM: EEPROM memory). This mode is used when there are limited RAM resources. The flash commands cannot update the region of flash where the RedBoot image resides. In order to update the RedBoot image in flash, it is necessary to run a RAM mode instance of RedBoot. The exact location is defined by the port and provided in the target hardware documentation section of the eCos and eCosPro Reference Manual.

ROMRAM mode

In this mode, RedBoot resides in ROM memory (flash or EPROM), but is copied to RAM memory before it starts executing. The RAM footprint is larger than for ROM mode, but there are two advantages to make up for this: it normally runs faster (relevant only on slower boards) and it is able to update the flash region where the image resides.The exact location is defined by the port and provided in the target hardware documentation section of the eCos and eCosPro Reference Manual.

RAM mode
SRAM mode
JTAG mode

In this mode, RedBoot both resides and executes from RAM or SRAM memory. The memory may be on-chip RAM or SRAM or external RAM or SRAM. The exact location is defined by the port and provided in the target hardware documentation section of the eCos and eCosPro Reference Manual. This is used for updating a primary ROM mode image in situ and sometimes as part of the RedBoot installation on the board when there's already an existing (non-RedBoot) boot monitor available.

You can only use ROM, ROMRAM and EEPROM mode images for booting a board - a RAM mode image cannot run unless loaded by another ROM monitor. There is no need for this startup mode if a RedBoot ROMRAM mode image is the primary boot monitor. When this startup mode is programmed into flash (as a convenience as it's fast to load from flash) it will generally be named as "RedBoot[RAM]" in the FIS directory.

The chosen mode has influence on flash and RAM resource usage (see the section called “RedBoot Resource Usage”) and the procedure of an in situ update of RedBoot in flash (see Chapter 227, *Updating RedBoot*).

The startup mode is controlled by the option CYG_HAL_STARTUP which resides in the platform HAL. Some platforms provide only some of the RAM, ROM, ROMRAM, etc. modes, others provide additional modes.

To see mode of a currently executing RedBoot, issue the **version** command, which prints the RedBoot banner, including the startup mode (here ROM):

```
RedBoot>version

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 13:31:57, May 17 2002
```

RedBoot Resource Usage

RedBoot takes up both flash and RAM resources depending on its startup mode and number of enabled features. There are also other resources used by RedBoot, such as timers. Platform-specific resources used by RedBoot are listed in the platform specific parts of this manual.

Both flash and RAM resources used by RedBoot depend to some degree on the features enabled in the RedBoot configuration. It is possible to reduce in particular the RAM resources used by RedBoot by removing features that are not needed. Flash resources can also be reduced, but due to the granularity of the flash (the block sizes), reductions in feature size do not always result in flash resource savings.

Flash Resources

On many platforms, a ROM mode RedBoot image resides in the first flash sectors, working as the board's primary boot monitor. On these platforms, it is also normal to reserve a similar amount of flash for a secondary RAM mode image, which is used when updating the primary ROM mode image.

On other platforms, a ROMRAM mode RedBoot image is used as the primary boot monitor. On these platforms there is not normally reserved space for a RAM mode RedBoot image, since the ROMRAM mode RedBoot is capable of updating the primary boot monitor image.

Most platforms also contain a FIS directory (keeping track of available flash space) and a RedBoot config block (containing RedBoot board configuration data).

To see the amount of reserved flash memory, run the **fis list** command:

```
RedBoot> fis list
Name              FLASH addr  Mem addr    Length      Entry point
RedBoot           0x00000000  0x00000000  0x00020000  0x00000000
```

```
RedBoot[RAM]       0x00020000  0x06020000  0x00020000  0x060213C0
RedBoot config     0x0007F000  0x0007F000  0x00001000  0x00000000
FIS directory      0x00070000  0x00070000  0x0000F000  0x00000000
```

To save flash resources, use a ROMRAM mode RedBoot, or if using a ROM mode RedBoot, avoid reserving space for the RedBoot[RAM] image (this is done by changing the RedBoot configuration) and download the RAM mode RedBoot whenever it is needed. If the RedBoot image takes up a fraction of an extra flash block, it may be possible to reduce the image size enough to free this block by removing some features.

RAM Resources

RedBoot reserves RAM space for its run-time data, and such things as CPU exception/interrupt tables. It normally does so at the bottom of the memory map. It may also reserve space at the top of the memory map for configurable RedBoot features such as the net stack and zlib decompression support.

To see the actual amount of reserved space, issue the **version** command, which prints the RedBoot banner, including the RAM usage:

```
RedBoot> version

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 13:31:57, May 17 2002

Platform: FooBar (SH 7615)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x06000000-0x06080000, 0x06012498-0x06061000 available
FLASH: 0x00000000 - 0x00080000, 8 blocks of 0x00010000 bytes each.
```

To simplify operations that temporarily need data in free memory, the limits of free RAM are also available as aliases (aligned to the nearest kilo-byte limit). These are named FREEMEMLO and FREEMEMHI, and can be used in commands like any user defined alias:

```
RedBoot> load -r -b %{FREEMEMLO} file
Raw file loaded 0x06012800-0x06013e53, assumed entry at 0x06012800
```

```
RedBoot> x -b %{FREEMEMHI}
06061000: 86 F5 EB D8 3D 11 51 F2  96 F4 B2 DC 76 76 8F 77  |….=.Q…..vv.w|
06061010: E6 55 DD DB F3 75 5D 15  E0 F3 FC D9 C8 73 1D DA  |.U…u]…...s..|
```

To reduce RedBoot's RAM resource usage, use a ROM mode RedBoot. The RedBoot features that use most RAM are the net stack, the flash support and the gunzip support. These, and other features, can be disabled to reduce the RAM footprint, but obviously at the cost of lost functionality.

Configuring the RedBoot Environment

Once installed, RedBoot will operate fairly generically. However, there are some features that can be configured for a particular installation. These depend primarily on whether flash and/or networking support are available. The remainder of this discussion assumes that support for both of these options is included in RedBoot.

Target Network Configuration

Each node in a networked system needs to have a unique address. Since the network support in RedBoot is based on TCP/IP, this address is an IP (Internet Protocol) address. There are two ways for a system to “know” its IP address. First, it can be stored locally on the platform. This is known as having a static IP address. Second, the system can use the network itself to discover its IP address. This is known as a dynamic IP address. RedBoot supports this dynamic IP address mode by use of either the BOOTP protocol, or a subset of the DHCP protocol. In this case, RedBoot will ask the network (actually some generic server on the network) for the IP address to use.

Note

Currently, RedBoot only supports BOOTP and a very simple form of DHCP which is limited to additional data items, not lease-based address allocation. If you wish to use this subset of DHCP, then ensure you the configuration option `CYGSEM_REDBOOT_NETWORKING_DHCP` is enabled in RedBoot's configuration.

If you are intending to use RedBoot for network debugging, and are also intending to use BOOTP or DHCP in the loaded application, then you should not also use BOOTP/DHCP with RedBoot. Otherwise the DHCP server is likely to give both RedBoot's and the application's network stacks the same IP address which will result in problems.

The choice of IP address type is made via the **fconfig** command. Once a selection is made, it will be stored in flash memory. RedBoot only queries the flash configuration information at reset, so any changes will require restarting the platform.

Here is an example of the RedBoot **fconfig** command, showing network addressing:

```
RedBoot> fconfig -l
Run script at boot: false
Use BOOTP for network configuration: false
Local IP address: 192.168.1.29
Default server IP address: 192.168.1.101
DNS server IP address: 192.168.1.1
GDB connection port: 9000
Network debug at boot time: false
```

In this case, the board has been configured with a static IP address listed as the Local IP address. The default server IP address specifies which network node to communicate with for TFTP service. This address can be overridden directly in the TFTP commands.

The `DNS server IP address` option controls where RedBoot should make DNS lookups. A setting of 0.0.0.0 will disable DNS lookups. The DNS server IP address can also be set at runtime.

If the selection for `Use BOOTP for network configuration` had been `true`, these IP addresses would be determined at boot time, via the BOOTP protocol. The final number which needs to be configured, regardless of IP address selection mode, is the `GDB connection port`. RedBoot allows for incoming commands on either the available serial ports or via the network. This port number is the TCP port that RedBoot will use to accept incoming connections.

These connections can be used for GDB sessions, but they can also be used for generic RedBoot commands. In particular, it is possible to communicate with RedBoot via the telnet protocol. For example, on Linux®:

```
% telnet redboot_board 9000
Connected to redboot_board
Escape character is ’^],.
RedBoot>
```

Host Network Configuration

RedBoot may require three different classes of service from a network host:

- dynamic IP address allocation, using BOOTP
- TFTP service for file downloading
- DNS server for hostname lookups

Depending on the host system, these services may or may not be available or enabled by default.

In particular, on most Linux distributions, none of these services will be configured out of the box. As the method for configuring and enabling these services varies widely between Linux distributions and even between versions of the same distribution, the reader is advised to refer to the system documentation of your chosen Linux distribution and version for more details.

The Windows Desktop operating system does not provide these services. Instead these services are included with Windows Server. Please refer to your system administrator, or Microsoft TechNet, for details on how to configure these services on your Windows Server. Alternatively, if you do not have access to a Windows Server or Linux or do not wish to use either, you can use freely available MaraDNS, currently available from http://www.maradns.org/, to provide a DNS server and the Open TFTP Server, currently available from https://sourceforge.net/projects/tftp-server/, to provide a TFTP service on your Windows Desktop.

BOOTP/DHCP server settings for most Linux distributions

First, ensure that you have the proper package, `dhcp` (not `dhcpd`) installed. The DHCP server provides Dynamic Host Configuration, that is, IP address and other data to hosts on a network. It does this in different ways. Next, there can be a fixed relationship between a certain node and the data, based on that node,s unique Ethernet Station Address (ESA, sometimes called a MAC address). The other possibility is simply to assign addresses that are free. The sample DHCP configuration file shown does both. Refer to the DHCP documentation for more details.

Example 224.1. Sample DHCP configuration file

```
--------------- /etc/dhcpd.conf -----------------------------
default-lease-time 600;
max-lease-time 7200;
option subnet-mask 255.255.255.0;
option broadcast-address 192.168.1.255;
option domain-name-servers 198.41.0.4, 128.9.0.107;
option domain-name “bogus.com”;
allow bootp;
shared-network BOGUS {
  subnet 192.168.1.0 netmask 255.255.255.0
    {
       option routers 192.168.1.101;
       range 192.168.1.1 192.168.1.254;
    }
}
host mbx {
   hardware ethernet 08:00:3E:28:79:B8;
   fixed-address 192.168.1.20;
   filename “/tftpboot/192.168.1.21/zImage”;
   default-lease-time -1;
   server-name “srvr.bugus.com”;
   server-identifier 192.168.1.101;
   option host-name “mbx”;
}
```

Once the DHCP package has been installed and the configuration file set up, type:

```
# service dhcpd start
```

DNS server for most Linux distributions

First, ensure that you have the proper package installed. Then change the configuration (in `/etc/named.conf`) so that the `forwarders` point to the primary nameservers for your machine, normally using the nameservers listed in `/etc/resolv.conf`.

Example 224.2. Sample `/etc/named.conf` for most Linux distributions

```
--------------- /etc/named.conf -----------------------------
// generated by named-bootconf.pl

options {
  directory "/var/named";
  /*
   * If there is a firewall between you and nameservers you want
   * to talk to, you might need to uncomment the query-source
   * directive below.  Previous versions of BIND always asked
   * questions using port 53, but BIND 8.1 uses an unprivileged
   * port by default.
   */
  // query-source address * port 53;

  forward first;
  forwarders {
    212.242.40.3;
    212.242.40.51;
  };
};

//
// a caching only nameserver config
//
// Uncomment the following for Red Hat Linux 7.2 or above:
// controls {
//         inet 127.0.0.1 allow { localhost; } keys { rndckey; };
// };
// include "/etc/rndc.key";
zone "." IN {
  type hint;
  file "named.ca";
};

zone "localhost" IN {
  type master;
  file "localhost.zone";
  allow-update { none; };
};

zone "0.0.127.in-addr.arpa" IN {
  type master;
  file "named.local";
  allow-update { none; };
};
```

Make sure the server is started. Older distributions may use the command:

```
# service named start
```

and is started on the next reboot with the command

```
# chkconfig named on
```

Newer Linux distributions may use the command:

```
# systemctl start named
```

and is started on the next reboot with the command

```
# systemctl enable named
```

Finally, if you are developing on Linux and using your host to provide the DNS server, you may wish to change `/etc/resolv.conf` to use `127.0.0.1` as the nameserver for your local machine. Depending on the Linux distribution and its age, you may have to manually set the nameserver in your Network Configuration.

RedBoot network gateway

RedBoot only provides simple routing. If a remote host is not on the same directly connected IP subnet as that associated with the network interface (even if on the same ’wire,), then you will need to configure a gateway which can be used to route packets to the remote host. First you should ensure RedBoot has been built with support for using a gateway using the configuration option `CYGSEM_REDBOOT_NETWORKING_USE_GATEWAY`. Then you can either:-

- Hard-code a gateway into the configuration with the option `CYGDAT_REDBOOT_DEFAULT_GATEWAY_IP_ADDR`;
- Use RedBoot's persistent flash configuration to set the “Gateway IP address” gateway persistently in flash using the **fconfig** command; or
- Configure RedBoot to use obtain an address from a DHCP server (not just BOOTP), and then configure the DHCP server to provide the gateway IP address.

Verification

Once your network setup has been configured, perform simple verification tests as follows:

- Reboot your system, to enable the setup, and then try to ’ping, the target board from a host.
- Once communication has been established, try to ping a host using the RedBoot ping command - both by IP address and hostname.
- Try using the RedBoot load command to download a file from a host.

Chapter 225. RedBoot Commands and Examples

Introduction

RedBoot provides three basic classes of commands:

- Program loading and execution
- Flash image and configuration management
- Miscellaneous commands

Given the extensible and configurable nature of eCos and RedBoot, there may be extended or enhanced sets of commands available.

The basic format for commands is:

```
RedBoot> COMMAND [-S]... [-s val]... operand
```

Commands may require additional information beyond the basic command name. In most cases this additional information is optional, with suitable default values provided if they are not present.

Format	Description	Example
-S	A boolean switch; the behavior of the command will differ, depending on the presence of the switch. In this example, the **`-f`** switch indicates that a complete initialization of the FIS data should be performed. There may be many such switches available for any given command and any or all of them may be present, in any order.	`RedBoot>` **`fis init -f`**
-s *`val`*	A qualified value; the letter "s" introduces the value, qualifying it's meaning. In the example, **`-b 0x100000`** specifies where the memory dump should begin. There may be many such switches available for any given command and any or all of them may be present, in any order.	`RedBoot>` **`dump -b 0x100000 -l 0x20`**
`operand`	A simple value; some commands require a single parameter for which an additional **`-X`** switch would be redundant. In the example, **`JFFS2`** is the name of a flash image. The image name is always required, thus is no need to qualify it with a switch. Note that any un-qualified operand must always appear at the end of the command.	`RedBoot>` **`fis delete JFFS2`**

The list of available commands, and their syntax, can be obtained by typing **help** at the command line:

```
RedBoot> help
Manage aliases kept in FLASH memory
      alias name [value]
Set/Query the system console baud rate
      baudrate [-b <rate>]
Manage machine caches
```

```
      cache [ON | OFF]
Display/switch console channel
      channel [-1|<channel number>]
Display disk partitions
      disks
Display (hex dump) a range of memory
      dump -b <location> [-l <length>] [-s]
Manage flash images
      fis {cmds}
Manage configuration kept in FLASH memory
      fconfig [-i] [-l] [-n] [-f] [-d] | [-d] nickname [value]
Execute code at a location
      go [-w <timeout>] [-c] [-n] [entry]
Help about help?
      help [<topic>]
Set/change IP addresses
      ip_address [-l <local_ip_address>[/<mask_length>]] [-h <server_address>]
Load a file
      load [-r] [-v] [-d] [-c <channel>] [-h <host>] [-m {TFTP | HTTP | {x|y|z}MODEM | disk}]
      [-b <base_address>] <file_name>
Network connectivity test
      ping [-v] [-n <count>] [-t <timeout>] [-i <IP_addr]
      -h <host>
Reset the system
      reset
Display RedBoot version information
      version
Display (hex dump) a range of memory
      x -b <location> [-l <length>] [-s]
```

Commands can be abbreviated to their shortest unique string. Thus in the list above, **d,du,dum** and dump are all valid for the **dump** command. The **fconfig** command can be abbreviated **fc**, but **f** would be ambiguous with **fis**.

There is one additional, special command. When RedBoot detects '$' or '+' (unless escaped via '\') in a command, it switches to GDB protocol mode. At this point, the eCos GDB stubs take over, allowing connections from a GDB host. The only way to get back to RedBoot from GDB mode is to restart the platform.

Note

Multiple commands may be entered on a single line, separated by the semi-colon “;” character.

The standard RedBoot command set is structured around the bootstrap environment. These commands are designed to be simple to use and remember, while still providing sufficient power and flexibility to be useful. No attempt has been made to render RedBoot as the end-all product. As such, things such as the debug environment are left to other modules, such as GDB stubs, which are typically included in RedBoot.

The command set may be also be extended on a platform basis.

Common Commands

Name

alias — Manipulate command line aliases

Synopsis

`alias { name } [ value ]`

Arguments

Name	Type	Description	Default
name	Name	The name for this alias.	*none*
value	String	Replacement value for the alias.	*none*

Description

The **alias** command is used to maintain simple command line aliases. These aliases are shorthand for longer expressions. When the pattern %{name} appears in a command line, including in a script, the corresponding value will be substituted. Aliases may be nested.

If no value is provided, then the current value of the alias is displayed.

If the system supports non-volatile configuration data via the **fconfig** command (see the section called “Persistent State Flash-based Configuration and Control ”), then the value will be saved and used when the system is reset.

Examples

Set an alias.

```
RedBoot> alias joe "This is Joe"
Update RedBoot non-volatile configuration - continue (y/n)? n
```

Display an alias.

```
RedBoot> alias joe
'joe' = 'This is Joe'
```

Use an alias. Note: the "=" command simply echoes the command to to console.

```
RedBoot> = %{joe}
This is Joe
```

Aliases can be nested.

```
RedBoot> alias frank "Who are you? %{joe}"
Update RedBoot non-volatile configuration - continue (y/n)? n
RedBoot> = %{frank}
Who are you? This is Joe
```

Notice how the value of %{frank} changes when %{joe} is changed since the value of %{joe} is not evaluated until %{frank} is evaluated.

```
RedBoot> alias joe "This is now Josephine"
Update RedBoot non-volatile configuration - continue (y/n)? n
RedBoot> = %{frank}
Who are you? This is now Josephine
```

Name

baudrate — Set the baud rate for the system serial console

Synopsis

`baudrate` [-b *`rate`*]

Arguments

Name	**Type**	**Description**	**Default**
-b *`rate`*	Number	The baud rate to use for the serial console.	*none*

Description

The **baudrate** command sets the baud rate for the system serial console.

If no value is provided, then the current value of the console baud rate is displayed.

If the system supports non-volatile configuration data via the **fconfig** command (see the section called “Persistent State Flash-based Configuration and Control ”), then the value will be saved and used when the system is reset.

Examples

Show the current baud rate.

```
RedBoot> baudrate
Baud rate = 38400
```

Change the console baud rate. In order to make this operation safer, there will be a slight pause after the first message to give you time to change to the new baud rate. If it doesn't work, or a less than affirmative answer is given to the "continue" prompt, then the baud rate will revert to the current value. Only after the baud rate has been firmly established will *RedBoot* give you an opportunity to save the value in persistent storage.

```
RedBoot> baudrate -b 57600
Baud rate will be changed to 57600 - update your settings
Device baud rate changed at this point
Baud rate changed to 57600 - continue (y/n)? y
Update RedBoot non-volatile configuration - continue (y/n)? n
```

Name

cache — Control hardware caches

Synopsis

`cache` [[on] | [off]]

Arguments

Name	**Type**	**Description**	**Default**
on		Turn the caches on	*none*
off		Turn the caches off	*none*

Description

The **cache** command is used to manipulate the caches on the processor.

With no options, this command specifies the state of the system caches.

When an option is given, the caches are turned off or on appropriately.

Examples

Show the current cache state.

```
RedBoot> cache
Data cache: On, Instruction cache: On
```

Disable the caches.

```
RedBoot> cache off
RedBoot> cache
Data cache: Off, Instruction cache: Off
```

Enable the caches.

```
RedBoot> cache on
RedBoot> cache
Data cache: On, Instruction cache: On
```

Name

channel — Select the system console channel

Synopsis

`channel` [[-1] | [*`channel_number`*]]

Arguments

Name	**Type**	**Description**	**Default**
-1		Reset the console channel	*none*
channel_number	Number	Select a channel	*none*

Description

With no arguments, the **channel** command displays the current console channel number.

When passed an argument of 0 upward, this command switches the console channel to that channel number. The mapping between channel numbers and physical channels is platform specific but will typically be something like channel 0 is the first serial port, channel 1 is the second, etc.

When passed an argument of -1, this command reverts RedBoot to responding to whatever channel receives input first, as happens when RedBoot initially starts execution.

Examples

Show the current channel.

```
RedBoot> channel
Current console channel id: 0
```

Change to an invalid channel.

```
RedBoot> channel 99
**Error: bad channel number '99'
```

Revert to the default channel setting (any console mode).

```
RedBoot> channel -1
```

Name

cksum — Compute POSIX checksums

Synopsis

`cksum` {-b *`location`*} {-l *`length`*}

Arguments

Name	**Type**	**Description**	**Default**
-b *`location`*	Memory address	Location in memory for stat of data.	*none*
-l *`length`*	Number	Length of data	*none*

Description

Computes the POSIX checksum on a range of memory (either RAM or FLASH). The values printed (decimal cksum, decimal length, hexadecimal cksum, hexadecimal length) can be compared with the output from the Linux program 'cksum'.

Examples

Checksum a buffer.

```
RedBoot> cksum -b 0x100000 -l 0x100
POSIX cksum = 3286483632 256 (0xc3e3c2b0 0x00000100)
```

Checksum an area of memory after loading a file. Note that the base address and length parameters are provided by the preceding load command.

```
RedBoot> load -r -b %{FREEMEMLO} redboot.bin
Raw file loaded 0x06012800-0x0602f0a8
RedBoot> cksum
Computing cksum for area 0x06012800-0x0602f0a8
POSIX cksum = 2092197813 116904 (0x7cb467b5 0x0001c8a8)
```

Name

disks — List available disk partitions.

Synopsis

```
disks
```

Arguments

None.

Description

The **disks** command is used to list disk partitions recognized by RedBoot.

Examples

Show what disk partitions are available.

```
RedBoot> disks
hda1     Linux Swap
hda2     Linux
00100000: 00 3E 00 06 00 06 00 06  00 00 00 00 00 00 00 00  |.>..............|
00100010: 00 00 00 78 00 70 00 60  00 60 00 60 00 60 00 60  |...x.p.`.`.`.`.`|
```

Name

dump — Display memory.

Synopsis

`dump` {-b *`location`*} [-l *`length`*] [-s] [[-1] | [-2] | [-4]]

Arguments

Name	Type	Description	Default
-b *`location`*	Memory address	Location in memory for start of data.	*none*
-l *`length`*	Number	Length of data	32
-s	Boolean	Format data using Motorola S-records.	
-1		Access one byte (8 bits) at a time. Only the least significant 8 bits of the pattern will be used.	-1
-2		Access two bytes (16 bits) at a time. Only the least significant 16 bits of the pattern will be used.	-1
-4		Access one word (32 bits) at a time.	-1

Description

Display a range of memory on the system console.

The **x** is a synonym for **dump**.

Note that this command could be detrimental if used on memory mapped hardware registers.

The memory is displayed at most sixteen bytes per line, first as the raw hex value, followed by an ASCII interpretation of the data.

Examples

Display a buffer, one byte at a time.

```
RedBoot> mfill -b 0x100000 -l 0x20 -p 0xDEADFACE
RedBoot> x -b 0x100000
00100000: CE FA AD DE CE FA AD DE  CE FA AD DE CE FA AD DE  |................|
00100010: CE FA AD DE CE FA AD DE  CE FA AD DE CE FA AD DE  |................|
```

Display a buffer, one short (16 bit) word at a time. Note in this case that the ASCII interpretation is suppressed.

```
RedBoot> dump -b 0x100000 -2
00100000: FACE DEAD FACE DEAD  FACE DEAD FACE DEAD
00100010: FACE DEAD FACE DEAD  FACE DEAD FACE DEAD
```

Display a buffer, one word (32 bit) word at a time. Note in this case that the ASCII interpretation is suppressed.

```
RedBoot> dump -b 0x100000 -4
00100000: DEADFACE DEADFACE DEADFACE DEADFACE
00100010: DEADFACE DEADFACE DEADFACE DEADFACE
```

Display the same buffer, using Motorola S-record format.

```
RedBoot> dump -b 0x100000 -s
```

```
S31500100000CEFAADDECEFAADDECEFAADDECEFAADDE8E
S31500100010CEFAADDECEFAADDECEFAADDECEFAADDE7E
```

Display a buffer, with visible ASCII strings.

```
RedBoot> d -b 0xfe00b000 -l 0x80
0xFE00B000: 20 25 70 0A 00 00 00 00  41 74 74 65 6D 70 74 20 | %p.....Attempt |
0xFE00B010: 74 6F 20 6C 6F 61 64 20  53 2D 72 65 63 6F 72 64 |to load S-record|

```

Name

help — Display help on available commands

Synopsis

`help[ topic ]`

Arguments

Name	Type	Description	Default
topic	String	Which command to provide help for.	All commands

Description

The **help** command displays information about the available RedBoot commands. If a *topic* is given, then the display is restricted to information about that specific command.

If the command has sub-commands, e.g. **fis**, then the topic specific display will print additional information about the available sub-commands. special (ICMP) packets to a specific host. These packets should be automatically returned by that host. The command will indicate how many of these round-trips were successfully completed.

Examples

Show generic help. Note that the contents of this display will depend on the various configuration options for RedBoot when it was built.

```
RedBoot> help
Manage aliases kept in FLASH memory
   alias name [value]
Manage machine caches
   cache [ON | OFF]
Display/switch console channel
   channel [-1|<channel number>]
Compute a 32bit checksum [POSIX algorithm] for a range of memory
   cksum -b <location> -l <length>
Display (hex dump) a range of memory
   dump -b <location> [-l <length>] [-s] [-1|-2|-4]
Manage FLASH images
   fis {cmds}
Manage configuration kept in FLASH memory
   fconfig [-i] [-l] [-n] [-f] [-d] | [-d] nickname [value]
Execute code at a location
   go [-w <timeout>] [entry]
Uncompress GZIP compressed data
   gunzip -s <location> -d <location>
Help about help?
   help [<topic>]
Read I/O location
   iopeek [-b <location>] [-1|2|4]
Write I/O location
   iopoke [-b <location>] [-1|2|4] -v <value>
Set/change IP addresses
   ip_address [-l <local_ip_address>[/<mask_length>]] [-h <server_address>]
Load a file
   load [-r] [-v] [-d] [-h <host>] [-m {TFTP | HTTP | {x|y}MODEM -c <channel_number>}]
        [-f <flash_address>] [-b <base_address>]  <file_name>
Compare two blocks of memory
   mcmp -s <location> -d <location> -l <length> [-1|-2|-4]
```

```
Fill a block of memory with a pattern
   mfill -b <location> -l <length> -p <pattern>
  [-1|-2|-4]
Network connectivity test
   ping [-v] [-n <count>] [-l <length>] [-t <timeout>] [-r <rate>]
        [-i <IP_addr>] -h <IP_addr>
Reset the system
   reset
Display RedBoot version information
   version
Display (hex dump) a range of memory
   x -b <location> [-l <length>] [-s] [-1|-2|-4]
```

Help about a command with sub-commands.

```
RedBoot> help fis
Manage FLASH images
   fis {cmds}
Create an image
  fis create -b <mem_base> -l <image_length> [-s <data_length>]
      [-f <flash_addr>] [-e <entry_point>] [-r <ram_addr>] [-n] <name>
Display an image from FLASH Image System [FIS]
  fis delete name
Erase FLASH contents
  fis erase -f <flash_addr> -l <length>
Display free [available] locations within FLASH Image System [FIS]
  fis free
Initialize FLASH Image System [FIS]
  fis init [-f]
Display contents of FLASH Image System [FIS]
  fis list [-c] [-d]
Load image from FLASH Image System [FIS] into RAM
  fis load [-d] [-b <memory_load_address>] [-c] name
Write raw data directly to FLASH
  fis write -f <flash_addr> -b <mem_base> -l <image_length>
```

Name

iopeek — Read I/O location

Synopsis

`iopeek` [-b *location*] [[-1] | [-2] | [-4]]

Arguments

Name	Type	Description	Default
-b *location*	I/O address	I/O Location.	*none*
-1		Access a one byte (8 bit) I/O location.	-1
-2		Access a two byte (16 bit) I/O location.	-1
-4		Access a one word (32 bit) I/O location.	-1

Description

Reads a value from the I/O address space.

Examples

Examine 8 bit value at I/O location 0x3F8.

```
RedBoot> iopeek -b 0x3f8
0x03f8 = 0x30
```

Examine 32 bit value at I/O location 0x3f8.

```
RedBoot> iopeek -b 0x3f8 -4
0x03f8 = 0x03c10065
```

Name

iopoke — Write I/O location

Synopsis

`iopoke` [-b *`location`*] [[-1] | [-2] | [-4]] [-v *`value`*]

Arguments

Name	Type	Description	Default
-b *`location`*	I/O address	I/O Location.	*none*
-1		Access a one byte (8 bit) I/O location. Only the 8 least significant bits of value will be used	-1
-2		Access a two byte (16 bit) I/O location. Only the 16 least significant bits of value will be used	-1
-4		Access a one word (32 bit) I/O location.	-1

Description

Writes a value to the I/O address space.

Examples

Write 0x0123 to 16 bit I/O location 0x200.

```
RedBoot> iopoke -b 0x200 -v 0x123 -2
```

Name

gunzip — Uncompress GZIP compressed data

Synopsis

`gunzip` {-s *source*} {-d *destination*}

Arguments

Name	**Type**	**Description**	**Default**
-s *location1*	Memory address	Location of GZIP compressed data to uncompress.	Value set by last **load** or **fis load** command.
-d *location2*	Memory address	Destination to write uncompressed data to.	*none*

Description

Uncompress GZIP compressed data.

Examples

Uncompress data at location 0x100000 to 0x200000.

```
RedBoot> gunzip -s 0x100000 -d 0x200000
Decompressed 38804 bytes
```

Name

ip_address — Set IP addresses

Synopsis

`ip_address` [-b] [-l *local_IP_address* [/ *netmask_length*]] [-h *server_IP_address*] [-d *DNS_server_IP_address*]

Arguments

Name	Type	Description	Default
-b	Boolean	Obtain an IP address using BOOTP or DHCP.	don't use BOOTP/ DHCP
-l *local_IP_address*[*/netmask_length*]	Numeric IP or DNS name	The IP address RedBoot should use, optionally with the network mask length.	*none*
-h *server_IP_address*	Numeric IP or DNS name	The IP address of the default server. Use of this address is implied by other commands, such as **load**.	*none*
-d *DNS_server_IP_address*	Numeric IP or DNS name	The IP address of the DNS server.	*none*

Description

The **ip_address** command is used to show and/or change the basic IP addresses used by RedBoot. IP addresses may be given as numeric values, e.g. 192.168.1.67, or as symbolic names such as www.ecoscentric.com if DNS support is enabled.

The `-b` option is used to cause the target to perform a bootp or dhcp negotiation to get an IP address.

The `-l` option is used to set the IP address used by the target device. The network mask length can also be specified

The `-h` option is used to set the default server address, such as is used by the **load** command.

The `-d` option is used to set the default DNS server address which is used for resolving symbolic network addresses. Note that an address of 0.0.0.0 will disable DNS lookups.

Examples

Display the current network settings.

```
RedBoot> ip_address
IP: 192.168.1.31, Default server: 192.168.1.101, DNS server IP: 0.0.0.0, DNS domain name:
```

Change the DNS server address.

```
RedBoot> ip_address -d 192.168.1.101
IP: 192.168.1.31, Default server: 192.168.1.101, DNS server IP: 192.168.1.101, DNS domain name:
```

Change the DNS domain name.

```
RedBoot> ip_address -D example.com
IP: 192.168.1.31, Default server: 192.168.1.101, DNS server IP: 192.168.1.101, DNS domain name: example.com
```

Change the default server address.

```
RedBoot> ip_address -h 192.168.1.104
IP: 192.168.1.31, Default server: 192.168.1.104, DNS server IP: 192.168.1.101, DNS domain name:
```

Set the IP address to something new, with a 255.255.255.0 netmask

```
RedBoot> ip_address -l 192.168.1.32/24
IP: 192.168.1.32, Default server: 192.168.1.104, DNS server IP: 192.168.1.101, DNS domain name:
```

Name

load — Download programs or data to the RedBoot platform

Synopsis

`load` [-v] [-d] [-r] [-m [{[[xmodem] | [ymodem] | [tftp] | [disk] | [file]]}]] [-h *`IP_address`*] [-f *`location`*] [-b *`location`*] [-c *`channel`*] [*`file_name`*]

Arguments

Name	Type	Description	Default
-v	Boolean	Display a small spinner (indicator) while the download is in progress. This is just for feedback, especially during long loads. Note that the option has no effect when using a serial download method since it would interfere with the protocol.	*quiet*
-d	Boolean	Decompress data stream (gzip data)	*non-compressed data*
-r	Boolean	Raw (or binary) data. -b or -f must be used	*formatted (S-records, ELF image, etc)*
-m tftp		Transfer data via the network using TFTP protocol.	TFTP
-m http		Transfer data via the network using HTTP protocol.	TFTP
-m xmodem		Transfer data using *X-modem* protocol.	TFTP
-m ymodem		Transfer data using *Y-modem* protocol.	TFTP
-m disk		Transfer data from a local disk.	TFTP
-m file		Transfer data from a local filesystem such as JFFS2 or FAT.	TFTP
-m mem		Load data from a memory address. Enabled with the configuration option `CYGFUN_REDBOOT_LOAD_FROM_MEM`. Supply the memory address and length to load from by using a “filename” in the format: *`ADDRESS`*,*`LENGTH`* For example **`0x10000400,0x54350`**	TFTP
-h *`IP_address`*	Numeric IP or DNS name	The IP address of the TFTP or HTTP server.	Value set by **ip_address**
-b *`location`*	Number	Address in memory to load the data. Formatted data streams will have an implied load address which this option may override.	*Depends on data format*
-f *`location`*	Number	Address in flash to load the data. Formatted data streams will have an implied load address which this option may override.	*Depends on data format*
-c *`channel`*	Number	Specify which I/O channel to use for download. This option is only supported when using either xmodem or ymodem protocol.	*Depends on data format*
`file_name`	String	The name of the file on the TFTP or HTTP server or the local disk. Details of how this is specified for TFTP are host- specific. For local disk files, the name must be in *disk*: *filename* format. The disk portion must match one of the disk names listed by the **disks** command.	*None*

Description

The **load** command is used to download data into the target system. Data can be loaded via a network connection, using either the TFTP or HTTP protocols, or the console serial connection using the X/Y modem protocol. Files may also be loaded directly from local filesystems on disk. Files to be downloaded may either be executable images in ELF executable program format, Motorola S-record (SREC) format or raw data.

Note

When downloading an ELF image, RedBoot will forcibly terminate the transfer once all the relevant (loadable) ELF sections have been received. This behaviour reduces download time when using the X/Y modem protocol over a slow serial connection. However, the terminal emulator may report that the transfer is incomplete and has been cancelled. Such messages are normal and may be ignored.

Examples

Download a Motorola S-record (or ELF) image, using TFTP, specifying the base memory address.

```
RedBoot> load redboot.ROM -b 0x8c400000
Address offset = 0x0c400000
Entry point: 0x80000000, address range: 0x80000000-0x8000fe80
```

Download a Motorola S-record (or ELF) image, using HTTP, specifying the host [server] address.

```
RedBoot> load /redboot.ROM -m HTTP -h 192.168.1.104
Address offset = 0x0c400000
Entry point: 0x80000000, address range: 0x80000000-0x8000fe80
```

Load an ELF file from /dev/hda1 which should be an EXT2 partition:

```
RedBoot> load -mode disk hda1:hello.elf
Entry point: 0x00020000, address range: 0x00020000-0x0002fd70
```

Load an ELF file from /jffs2/applications which should be a directory in a JFFS2 filesystem:

```
RedBoot> load -mode file /jffs2/applications/hello.elf
Entry point: 0x00020000, address range: 0x00020000-0x0002fd70
```

Name

mcmp — Compare two segments of memory

Synopsis

`mcmp` {-s *`location1`*} {-d *`location1`*} {-l *`length`*} [[-1] | [-2] | [-4]]

Arguments

Name	**Type**	**Description**	**Default**
-s *`location1`*	Memory address	Location for start of data.	*none*
-d *`location2`*	Memory address	Location for start of data.	*none*
-l *`length`*	Number	Length of data	*none*
-1		Access one byte (8 bits) at a time. Only the least significant 8 bits of the pattern will be used.	-4
-2		Access two bytes (16 bits) at a time. Only the least significant 16 bits of the pattern will be used.	-4
-4		Access one word (32 bits) at a time.	-4

Description

Compares the contents of two ranges of memory (RAM, ROM, FLASH, etc).

Examples

Compare two buffers which match (result is *quiet*).

```
RedBoot> mfill -b 0x100000 -l 0x20 -p 0xDEADFACE
RedBoot> mfill -b 0x200000 -l 0x20 -p 0xDEADFACE
RedBoot> mcmp -s 0x100000 -d 0x200000 -l 0x20
```

Compare two buffers which don't match.

Only the first non-matching element is displayed.

```
RedBoot> mcmp -s 0x100000 -d 0x200000 -l 0x30 -2
Buffers don't match - 0x00100020=0x6000, 0x00200020=0x0000
```

Name

mcopy — Copy memory

Synopsis

`mcopy` {-s *`source`*} {-d *`destination`*} {-l *`length`*} [[-1] | [-2] | [-4]]

Arguments

Name	**Type**	**Description**	**Default**
-s *`location1`*	Memory address	Location of data to copy.	*none*
-d *`location2`*	Memory address	Destination for copied data.	*none*
-l *`length`*	Number	Length of data	*none*
-1		Copy one byte (8 bits) at a time.	-4
-2		Copy two bytes (16 bits) at a time.	-4
-4		Copy one word (32 bits) at a time.	-4

Description

Copies memory (RAM, ROM, FLASH, etc) from one area to another.

Examples

Copy 16 bits at a time.

```
RedBoot> mfill -b 0x100000 -l 0x20 -2 -p 0xDEAD
RedBoot> mfill -b 0x200000 -l 0x20 -2 -p 0x0
RedBoot> dump  -b 0x200000 -l 0x20 -2
00200000: 0000 0000 0000 0000  0000 0000 0000 0000
00200010: 0000 0000 0000 0000  0000 0000 0000 0000
RedBoot> mcopy -s 0x100000 -d 0x200000 -2 -l 0x20
RedBoot> dump  -b 0x200000 -l 0x20 -2
00200000: DEAD DEAD DEAD DEAD  DEAD DEAD DEAD DEAD
00200010: DEAD DEAD DEAD DEAD  DEAD DEAD DEAD DEAD
```

Name

mfill — Fill RAM with a specified pattern

Synopsis

`mfill` {-b *`location`*} {-l *`length`*} {-p *`value`*} {-a *`mask`*} [[-1] | [-2] | [-4]]

Arguments

Name	Type	Description	Default
-b *`location`*	Memory address	Location in memory for start of data.	*none*
-l *`length`*	Number	Length of data	*none*
-p *`pattern`*	Number	Data value to fill with	0
-a *`mask`*	Number	Use location address ANDed with mask as pattern, overrides -p	0
-1		Access one byte (8 bits) at a time. Only the least significant 8 bits of the pattern will be used.	-4
-2		Access two bytes (16 bits) at a time. Only the least significant 16 bits of the pattern will be used.	-4
-4		Access one word (32 bits) at a time.	-4

Description

Fills a range of memory with the given pattern.

Examples

Fill a buffer with zeros.

```
RedBoot> x -b 0x100000 -l 0x20
00100000: 00 3E 00 06 00 06 00 06  00 00 00 00 00 00 00 00  |.>..............|
00100010: 00 00 00 78 00 70 00 60  00 60 00 60 00 60 00 60  |...x.p.`.`.`.`.`|
RedBoot> mfill -b 0x100000 -l 0x20
RedBoot> x -b 0x100000 -l 0x20
00100000: 00 00 00 00 00 00 00 00  00 00 00 00 00 00 00 00  |................|
00100010: 00 00 00 00 00 00 00 00  00 00 00 00 00 00 00 00  |................|
```

Fill a buffer with a pattern.

```
RedBoot> mfill -b 0x100000 -l 0x20 -p 0xDEADFACE
RedBoot> x -b 0x100000 -l 0x20
00100000: CE FA AD DE CE FA AD DE  CE FA AD DE CE FA AD DE  |................|
00100010: CE FA AD DE CE FA AD DE  CE FA AD DE CE FA AD DE  |................|
```

Fill a buffer with masked address.

```
RedBoot> mfill -b 0x01000000 -l 0x20 -a 0x0FFF -2
RedBoot> x -b 0x01000000 -l 0x20 -2
01000000: 0000 0002 0004 0006  0008 000A 000C 000E
01000010: 0010 0012 0014 0016  0018 001A 001C 001E
```

Name

ping — Verify network connectivity

Synopsis

`ping` [-v] [-i *local_IP_address*] [-l *length*] [-n *count*] [-t *timeout*] [-r *rate*] {-h *server_IP_address*}

Arguments

Name	**Type**	**Description**	**Default**
-v	Boolean	Be verbose, displaying information about each packet sent.	*quiet*
-n *local_IP_address*	Number	Controls the number of packets to be sent.	10
-i *local_IP_address*	Numeric IP or DNS name	The IP address RedBoot should use.	Value set by **ip_address**
-h *server_IP_address*	Numeric IP or DNS name	The IP address of the host to contact.	*none*
-l *length*	Number	The length of the ICMP data payload.	64
-r *length*	Number	How fast to deliver packets, i.e. time between successive sends. A value of 0 sends packets as quickly as possible.	1000ms (1 second)
-t *length*	Number	How long to wait for the round-trip to complete, specified in milliseconds.	1000ms (1 second)

Description

The **ping** command checks the connectivity of the local network by sending special (ICMP) packets to a specific host. These packets should be automatically returned by that host. The command will indicate how many of these round-trips were successfully completed.

Examples

Test connectivity to host 192.168.1.101.

```
RedBoot> ping -h 192.168.1.101
Network PING - from 192.168.1.31 to 192.168.1.101
PING - received 10 of 10 expected
```

Test connectivity to host 192.168.1.101, with verbose reporting.

```
RedBoot> ping -h 192.168.1.101 -v -n 4
Network PING - from 192.168.1.31 to 192.168.1.101
 seq: 1, time: 1 (ticks)
 seq: 2, time: 1 (ticks)
 seq: 3, time: 1 (ticks)
 seq: 4, time: 1 (ticks)
PING - received 10 of 10 expected
```

Test connectivity to a non-existent host (192.168.1.109).

```
RedBoot> ping -h 192.168.1.109 -v -n 4
PING: Cannot reach server '192.168.1.109' (192.168.1.109)
```

Name

reset — Reset the device

Synopsis

```
reset
```

Arguments

None

Description

The **reset** command causes the target platform to be reset. Where possible (hardware support permitting), this will be equivalent to a power-on reset condition.

Examples

Reset the platform.

```
RedBoot> reset
... Resetting.+... Waiting for network card: .
Socket Communications, Inc: Low Power Ethernet CF Revision C 5V/3.3V 08/27/98
Ethernet eth0: MAC address 00:c0:1b:00:ba:28
IP: 192.168.1.29, Default server: 192.168.1.101

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 10:41:41, May 14 2002

Platform: Compaq iPAQ Pocket PC (StrongARM 1110)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x01fc0000, 0x00014748-0x01f71000 available
FLASH: 0x50000000 - 0x51000000, 64 blocks of 0x00040000 bytes each.
RedBoot>
```

Name

version — Display RedBoot version information

Synopsis

`version`

Arguments

None

Description

The **version** command simply displays version information about RedBoot.

Examples

Display RedBoot's version.

```
RedBoot> version
RedBoot(tm) debug environment - built 09:12:03, Feb 12 2001
Platform: XYZ (PowerPC 860)
Copyright (C) 2000, 2001, Free Software Foundation, Inc.
RAM: 0x00000000-0x00400000
```

Flash Image System (FIS)

If the platform has flash memory, RedBoot can use this for image storage. Executable images, as well as data, can be stored in flash in a simple file store. The **fis** command (fis is short for Flash Image System) is used to manipulate and maintain flash images.

Name

fis init — Initialize Flash Image System (FIS)

Synopsis

```
fis init[ -f ]
```

Arguments

Name	Type	Description	Default
-f		All blocks of flash memory (except for the boot blocks) will be erased as part of the initialization procedure.	

Description

This command is used to initialize the Flash Image System (FIS). It should normally only be executed once, when RedBoot is first installed on the hardware. If the reserved images or their sizes in the FIS change, due to a different configuration of RedBoot being used, it may be necessary to issue the command again though.

Note

Subsequent executions will cause loss of previously stored information in the FIS.

Examples

Initialize the FIS directory.

```
RedBoot> fis init
About to initialize [format] flash image system - continue (y/n)? y
*** Initialize FLASH Image System
    Warning: device contents not erased, some blocks may not be usable
... Erase from 0x00070000-0x00080000: .
... Program from 0x0606f000-0x0607f000 at 0x00070000: .
```

Initialize the FIS directory and all of flash memory, except for first blocks of the flash where the boot monitor resides.

```
RedBoot> fis init -f
About to initialize [format] flash image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x00020000-0x00070000: .....
... Erase from 0x00080000-0x00080000:
... Erase from 0x00070000-0x00080000: .
... Program from 0x0606f000-0x0607f000 at 0x00070000: .
```

Name

fis list — List Flash Image System directory

Synopsis

`fis list` [-*c*] [-*d*]

Arguments

Name	Type	Description	Default
-c		Show image checksum instead of memory address (column `Mem addr` is replaced by `Checksum`).	
-d		Show image data length instead of amount of flash occupied by image (column `Length` is replaced by `Datalen`).	

Description

This command lists the images currently available in the FIS. Certain images used by RedBoot have fixed names and have reserved slots in the FIS (these can be seen after using the **fis init** command). Other images can be manipulated by the user.

Note

The images are listed in the order they appear in the FIS directory, not by name or creation time.

Examples

List the FIS directory.

```
RedBoot> fis list
Name              FLASH addr  Mem addr    Length      Entry point
RedBoot           0x00000000  0x00000000  0x00020000  0x00000000
RedBoot config    0x0007F000  0x0007F000  0x00001000  0x00000000
FIS directory     0x00070000  0x00070000  0x0000F000  0x00000000
```

List the FIS directory, with image checksums substituted for memory addresses.

```
RedBoot> fis list -c
Name              FLASH addr  Checksum    Length      Entry point
RedBoot           0x00000000  0x00000000  0x00020000  0x00000000
RedBoot config    0x0007F000  0x00000000  0x00001000  0x00000000
FIS directory     0x00070000  0x00000000  0x0000F000  0x00000000
```

List the FIS directory with image data lengths substituted for flash block reservation lengths.

```
RedBoot> fis list -d
Name              FLASH addr  Mem addr    Datalen     Entry point
RedBoot           0x00000000  0x00000000  0x00000000  0x00000000
RedBoot config    0x0007F000  0x0007F000  0x00000000  0x00000000
FIS directory     0x00070000  0x00070000  0x00000000  0x00000000
```

Name

fis free — Free flash image

Synopsis

```
fis free
```

Description

This command shows which areas of the flash memory are currently not in use. When a block contains non-erased contents it is considered in use. Since it is possible to force an image to be loaded at a particular flash location, this command can be used to check whether that location is in use by any other image.

Note

There is currently no cross-checking between actual flash contents and the FIS directory, which mans that there could be a segment of flash which is not erased that does not correspond to a named image, or vice-versa.

Examples

Show free flash areas.

```
RedBoot> fis free
        0xA0040000 .. 0xA07C0000
        0xA0840000 .. 0xA0FC0000
```

Name

fis create — Create flash image

Synopsis

`fis create` {-b *`data address`*} {-l *`length`*} [-f *`flash address`*] [-e *`entry`*] [-r *`relocation address`*] [-s *`data length`*] [-n] [*`name`*]

Arguments

Name	Type	Description	Default
-b	Number	Address of data to be written to the flash.	Address of last loaded file. If not set in a load operation, it must be specified.
-l	Number	Length of flash area to occupy. If specified, and the named image already exists, the length must match the value in the FIS directory.	Length of area reserved in FIS directory if the image already exists, or the length of the last loaded file. If neither are set, it must be specified.
-f	Number	Address of flash area to occopy.	The address of an area reserved in the FIS directory for extant images. Otherwise the first free block which is large enough will be used.
-e	Number	Entry address for an executable image, used by the **fis load** command.	The entry address of last loaded file.
-r	Number	Address where the image should be relocated to by the **fis load** command. This is only relevant for images that will be loaded with the **fis load** command.	The load address of the last loaded file.
-s	Number	Actual length of data written to image. This is used to control the range over which the checksum is made.	It defaults to the length of the last loaded file.
-n		When set, no image data will be written to the flash. Only the FIS directory will be updated.	
`name`	String	Name of flash image.	

Description

This command creates an image in the FIS directory. The data for the image must exist in RAM memory before the copy. Typically, you would use the RedBoot **load** command to load file into RAM and then the **fis create** command to write it to a flash image.

Examples

Trying to create an extant image, will require the action to be verified.

```
RedBoot> fis create RedBoot -f 0xa0000000 -b 0x8c400000 -l 0x20000
An image named ’RedBoot, exists - continue (y/n)? n
```

Create a new test image, let the command find a suitable place.

```
RedBoot> fis create junk -b 0x8c400000 -l 0x20000
... Erase from 0xa0040000-0xa0060000: .
... Program from 0x8c400000-0x8c420000 at 0xa0040000: .
... Erase from 0xa0fe0000-0xa1000000: .
... Program from 0x8c7d0000-0x8c7f0000 at 0xa0fe0000: .
```

Update the RedBoot[RAM] image.

```
RedBoot> load redboot_RAM.img
Entry point: 0x060213c0, address range: 0x06020000-0x06036cc0
RedBoot> fis create RedBoot[RAM]
No memory address set.
An image named 'RedBoot[RAM]' exists - continue (y/n)? y
* CAUTION * about to program 'RedBoot[RAM]'
            at 0x00020000..0x00036cbf from 0x06020000 - continue (y/n)? y
... Erase from 0x00020000-0x00040000: ..
... Program from 0x06020000-0x06036cc0 at 0x00020000: ..
... Erase from 0x00070000-0x00080000: .
... Program from 0x0606f000-0x0607f000 at 0x00070000: .
```

Name

fis load — Load flash image

Synopsis

`fis load` [-b *`load address`*] [-c] [-d] [*`name`*]

Arguments

Name	Type	Description	Default
-b	Number	Address the image should be loaded to. Executable images normally load at the location to which the file was linked. This option allows the image to be loaded to a specific memory location, possibly overriding any assumed location.	If not specified, the address associated with the image in the FIS directory will be used.
-c		Compute and print the checksum of the image data after it has been loaded into memory.	
-d		Decompress gzipped image while copying it from flash to RAM.	
`name`	String	The name of the file, as shown in the FIS directory.	

Description

This command is used to transfer an image from flash memory to RAM.

Once the image has been loaded, it may be executed using the **go** command.

Examples

Load and run RedBoot[RAM] image.

```
RedBoot> fis load RedBoot[RAM]
RedBoot> go
```

Name

fis delete — Delete flash image

Synopsis

`fis delete` { *name* }

Arguments

Name	Type	Description	Default
name	Number	Name of image that should be deleted.	

Description

This command removes an image from the FIS. The flash memory will be erased as part of the execution of this command, as well as removal of the name from the FIS directory.

Note

Certain images are reserved by RedBoot and cannot be deleted. RedBoot will issue a warning if this is attempted.

Examples

```
RedBoot> fis list
Name              flash addr   Mem addr    Length    Entry point
RedBoot          0xA0000000   0xA0000000  0x020000  0x80000000
RedBoot config   0xA0FC0000   0xA0FC0000  0x020000  0x00000000
FIS directory    0xA0FE0000   0xA0FE0000  0x020000  0x00000000
junk             0xA0040000   0x8C400000  0x020000  0x80000000
RedBoot> fis delete junk
Delete image ’junk, - continue (y/n)? y
... Erase from 0xa0040000-0xa0060000: .
... Erase from 0xa0fe0000-0xa1000000: .
... Program from 0x8c7d0000-0x8c7f0000 at 0xa0fe0000: .
```

Name

fis lock — Lock flash area

Synopsis

`fis lock` {-f *flash_address*} {-l *length*}

Arguments

Name	Type	Description	Default
flash_address	Number	Address of area to be locked.	
length	Number	Length of area to be locked.	

Description

This command is used to write-protect (lock) a portion of flash memory, to prevent accidental overwriting of images. In order to make any modifications to the flash, a matching **fis unlock** command must be issued. This command is optional and will only be provided on hardware which can support write-protection of the flash space.

Note

Depending on the system, attempting to write to write-protected flash may generate errors or warnings, or be benignly quiet.

Examples

Lock an area of the flash

```
RedBoot> fis lock -f 0xa0040000 -l 0x20000
... Lock from 0xa0040000-0xa0060000: .
```

Name

fis unlock — Unlock flash area

Synopsis

`fis unlock` {-f *flash_address*} {-l *length*}

Arguments

Name	Type	Description	Default
flash_address	Number	Address of area to be unlocked.	
length	Number	Length of area to be unlocked.	

Description

This command is used to unlock a portion of flash memory forcibly, allowing it to be updated. It must be issued for regions which have been locked before the FIS can reuse those portions of flash.

Note

Some flash devices power up in locked state and always need to be manually unlocked before they can be written to.

Examples

Unlock an area of the flash

```
RedBoot> fis unlock -f 0xa0040000 -l 0x20000
... Unlock from 0xa0040000-0xa0060000: .
```

Name

fis erase — Erase flash area

Synopsis

`fis erase` {-f *`flash_address`*} {-l *`length`*}

Arguments

Name	**Type**	**Description**	**Default**
`flash_address`	Number	Address of area to be erased.	
`length`	Number	Length of area to be erased.	

Description

This command is used to erase a portion of flash memory forcibly. There is no cross-checking to ensure that the area being erased does not correspond to an existing image.

Examples

Erase an area of the flash

```
RedBoot> fis erase -f 0xa0040000 -l 0x20000
... Erase from 0xa0040000-0xa0060000: .
```

Name

fis read — Read flash area

Synopsis

`fis read` {-b *mem_address*} {-l *length*} {-f *flash_address*}

Arguments

Name	Type	Description	Default
mem_address	Number	Address data should be written to.	
length	Number	Length of data to be read.	
flash_address	Number	Address in flash to read from.	

Description

This command is used to read data from flash to memory. This command is only present if a flash device does not support direct random access (for example an SPI NOR flash).

Examples

Read an area of flash into memory

```
RedBoot> fis read -b 0x0606f000 -l 0x1000 -f 0x00020000
```

Name

fis write — Write flash area

Synopsis

`fis write` {-b *`mem_address`*} {-l *`length`*} {-f *`flash_address`*}

Arguments

Name	**Type**	**Description**	**Default**
`mem_address`	Number	Address of data to be written to flash.	
`length`	Number	Length of data to be writtem.	
`flash_address`	Number	Address of flash to write to.	

Description

This command is used to write data from memory to flash. There is no cross-checking to ensure that the area being written to does not correspond to an existing image.

Examples

Write an area of data to the flash

```
RedBoot> fis write -b 0x0606f000 -l 0x1000 -f 0x00020000
* CAUTION * about to program FLASH
            at 0x00020000..0x0002ffff from 0x0606f000 - continue (y/n)? y
... Erase from 0x00020000-0x00030000: .

Filesystem Interface

If the platform has access to secondary storage, then RedBoot may be able to access a filesystem stored on this device. RedBoot can access FAT filesystems stored on IDE disks, CompactFlash devices, MMC and SD cards or USB mass storage devices and can use JFFS2 filesystems stored in FLASH memory. The **fs** command is used to manipulate files on filesystems. Applications may be loaded into memory using the *file* mode of the **load** command.

Name

fs info — Print filesystem information

Synopsis

`fs info`

Arguments

The command takes no arguments.

Description

This command prints information about the filesystems that are available. Three lists are produced. The first is a list of the filsystem implementations available in RedBoot; names from this list may be used in the *`-t`* option to the **fs mount** command. The second list describes the block devices and partitions that are available for mounting a filesystem; names from this list may be used in the *`-d`* option to the **fs mount** command. The last list describes the filesystems that are already mounted.

Examples

```
RedBoot> fs info
Filesystems available:
fatfs

Devices available:
/dev/mmcsd0/0
/dev/mmcsd0/1
/dev/mmcsd0/2
/dev/usbms/0/0
/dev/usbms/0/1

Mounted filesystems:
      Mountpoint           Device Filesystem
            /usb   /dev/usbms/0/1 fatfs:sync=write
           /boot    /dev/mmcsd0/1 fatfs:sync=write
RedBoot>
```

Name

fs mount — Mount a filesystem

Synopsis

`fs mount` [-d *`device`*] [-t *`fstype`*] {mountpoint}

Arguments

Name	Type	Description	Default
`device`	String	Device containing filsystem to mount.	undefined
`fstype`	String	Filesystem type.	fatfs:sync=write
`mountpoint`	String	Pathname for filesystem root.	/

Description

This command is used make a filesystem available for access with the filesystem access commands. Three things need to be defined to do this. First, the name of the device on which the filesystem is stored needs to be given to the *`-d`* option. Secondly, the type of filesystem it is needs to be given to the *`-t`* option. Finally, the pathname by which the new filesystem will be accessed needs to be supplied. Following a successful mount, the root of the filesystem will be accessible at the mountpoint.

The *`-t`* option is optional. If not given a default filesystem type is chosen. At present this is "fatfs:sync=write" which chooses a FAT filesystem that writes data back to the device immediately. See the FAT filesystem documentation for more details of the options available.

RedBoot must have been built with the required filesystem support enabled in its eCos configuration in order to be able to access filesystems of the necessary type. On the majority of platforms, no filesystems are included in RedBoot at all due to the extra memory footprint overhead for RedBoot this would otherwise incur.

Examples

The following example mounts a JFFS2 partition identified by the FIS partition name "jffs2test" at location `/flash` :

```
RedBoot> fs info
Filesystems available:
ramfs
jffs2
fatfs

Devices available:
/dev/flash/
/dev/mmcsd0/

Mounted filesystems:
         Device Filesystem Mounted on
    <undefined>      ramfs /
RedBoot> fs mount -d /dev/flash/fis/jffs2test -t jffs2 /flash
RedBoot> fs info
Filesystems available:
ramfs
jffs2
fatfs

Devices available:
/dev/flash/
```

```
/dev/mmcsd0/

Mounted filesystems:
         Device Filesystem Mounted on
    <undefined>      ramfs /
    /dev/flash/fis/jffs2test      jffs2 /flash
RedBoot>
```

Consult the documentation within the generic Flash driver package on Flash I/O devices for further information on configuration and usage of `/dev/flash/` devices for use with JFFS2.

Further examples of mount commands are:

- Mount a JFFS2 partition located at offset 0x40000 in the first flash device, of length 2Mbytes, at location `/jffs2` :

  ```
  RedBoot> fs mount -d /dev/flash/0/0x40000,0x200000 -t jffs2 /jffs2
  ```

- Mount a FAT partition located on the first partition of an SD card at location `/` :

  ```
  RedBoot> fs mount -d /dev/mmcsd0/1 -t fatfs /
  ```

- Mount a ROMfs partition located at address 0x48000000 in flash at location `/romfs` :

  ```
  RedBoot> fs mount -d 0x48000000 -t romfs /romfs
  ```

  Note that ROMfs uses absolute addresses as the device name, and not `/dev/flash/` Flash I/O devices.

Name

fs umount — Unmount filesystem

Synopsis

`fs umount` { *`mountpoint`* }

Arguments

Name	**Type**	**Description**	**Default**
`mountpoint`	String	Mountpoint of filesystem to unmount.	

Description

This command removes a filesystem from being accessible using the filesystem commands. The single argument needs to be the mountpoint that was used when mounting the filesystem. This command will fail if the current directory is currently within the filesystem to be unmounted.

Examples

Unmount a JFF2 partititon:

```
RedBoot> fs info
Filesystems available:
ramfs
jffs2

Devices available:
/dev/flash1

Mounted filesystems:
         Device Filesystem Mounted on
    <undefined>      ramfs /
    /dev/flash1      jffs2 /flash
RedBoot> fs umount /flash
RedBoot> fs info
Filesystems available:
ramfs
jffs2

Devices available:
/dev/flash1

Mounted filesystems:
         Device Filesystem Mounted on
    <undefined>      ramfs /
RedBoot>
```

Name

fs cd — Change filesystem directory

Synopsis

`fs cd [ directory ]`

Arguments

Name	Type	Description	Default
directory	String	Pathname to directory to change to.	Root directory

Description

This command changes the current filesystem directory. Subsequent filesystem commands will be executed in the new directory. If no argument is given, then the current directory is set back to the root of the filesystem name space.

Examples

Change current directory:

```
RedBoot> fs ls
d---------       128 .
d---------       128 ..
d---------        96 tests
----------      4096 image
RedBoot> fs cd tests
RedBoot> fs ls
d---------        96 .
d---------       128 ..
----------     16384 test1
RedBoot>
```

Name

fs mkdir — Create filesystem directory

Synopsis

`fs mkdir { directory }`

Arguments

Name	**Type**	**Description**	**Default**
directory	String	Pathname to directory to delete.	

Description

This command creates (makes) a directory in the filesystem.

Examples

```
RedBoot> fs ls
d---------       128 .
d---------       128 ..
----------      4096 image
RedBoot> fs mkdir tests
RedBoot> fs ls
d---------       128 .
d---------       128 ..
d---------        64 tests
----------      4096 image
RedBoot>
```

Name

fs rmdir — Delete filesystem directory

Synopsis

`fs rmdir` { *`directory`* }

Arguments

Name	Type	Description	Default
`directory`	String	Pathname to directory to delete.	

Description

This command deletes a directory from the filesystem. If the directory contains files or other directories then this command will fail.

Examples

Delete directory:

```
RedBoot> fs ls
d---------       128 .
d---------       128 ..
d---------        96 tests
----------      4096 image
RedBoot> fs rmdir tests
RedBoot> fs ls
d---------       128 .
d---------       128 ..
----------      4096 image
RedBoot>
```

Name

fs rm — Delete file

Synopsis

`fs rm { file }`

Arguments

Name	Type	Description	Default
file	String	Pathname of file to delete.	

Description

This command deletes a file from the filesystem.

Examples

Change current directory:

```
RedBoot> fs ls tests
d---------        96 .
d---------       128 ..
----------     16384 test1
RedBoot> fs rm tests/test1
RedBoot> fs ls tests
d---------        96 .
d---------       128 ..
RedBoot>
```

Name

fs mv — Move file

Synopsis

`fs mv` { *`source`* } { *`dest`* }

Arguments

Name	Type	Description	Default
source	String	Pathname of file to move.	
dest	String	Pathname to new file location.	

Description

This command moves a file within a filesystem. This command will fail if the destination file already exists, or is in a different filesystem.

Examples

Rename a file:

```
RedBoot> fs ls tests
d---------        96 .
d---------       128 ..
----------     12288 test1
RedBoot> fs mv tests/test1 tests/test2
RedBoot> fs ls tests
d---------       128 .
d---------       128 ..
----------     12288 test2
RedBoot>
```

Name

fs cp — Copy file

Synopsis

`fs cp` { *`source`* } { *`dest`* }

Arguments

Name	Type	Description	Default
`source`	String	Pathname of file to copy.	
`dest`	String	Pathname to new file location.	

Description

This command copies a file from one location to another. Source and destination need not be on the same file system. If the destination file already exists it will be overwritten with the new file contents. This command will fail if the source file does not exist.

Examples

Copy a file:

```
RedBoot> fs ls /usb
drwxrwxrwx         0 System Volume Information
drwxrwxrwx         0 TEST
RedBoot> fs cp /boot/LICENCE.broadcom /usb/LICENCE.broadcom
RedBoot> fs ls /usb
drwxrwxrwx         0 System Volume Information
drwxrwxrwx         0 TEST
-rwxrwxrwx      1494 LICENCE.broadcom
RedBoot>
```

Name

fs cat — Display file

Synopsis

`fs cat` { *`file`* }

Arguments

Name	Type	Description	Default
file	String	Pathname of file to display.	

Description

This command displays the contents of the given file on the console. It is useful for examining configuration, script or other text files. The file is sent to the console with no additional interptetation, so applying this to a binary file may result in chaos on screen. The command will fail if the file does not exist.

Examples

Copy a file:

```
RedBoot> fs cat /boot/redboot.txt
# RedBoot init file
#--------------------------------------------------------------------------------
# Network setup

# Optional command to set a specific IP address
#ip_address -l 10.44.44.44/8

#--------------------------------------------------------------------------------
# JTAG setup

# Default ALT4 set
jtag 22 23 24 25 26 27

# ALT5 set, with TRST on pin 22 ALT4
#jtag 4 5 6 12 13 22

# Alternate mixed set used by some earlier JTAG implementations
# jtag 4 22 24 25 27

# All JTAG pins, useful for testing changes to pin settings.
#jtag 4 5 6 12 13 22 23 24 25 26 27

#--------------------------------------------------------------------------------
# EOF
RedBoot>
```

Name

fs ls — List filesystem directory

Synopsis

fs ls[*directory*]

Arguments

Name	**Type**	**Description**	**Default**
directory	String	Pathname to directory to list.	Current directory

Description

This command prints a list of the contents of the named directory. Each line of the listing starts with a set of UNIX-like access flags, the first character of this will be a ”d“ if this entry is a directory. Following this is the size of the file in bytes and the last item is its name.

Examples

List the current directory:

```
RedBoot> fs ls
d---------       128 .
d---------       128 ..
----------      4096 image
d---------        96 tests
RedBoot>
```

List a subdirectory:

```
RedBoot> fs ls tests
d---------        96 .
d---------       128 ..
----------     16384 test1
RedBoot>
```

Name

fs write — Write to filesystem

Synopsis

`fs write` [-b *mem_address*] [-l *length*] {name}

Arguments

Name	Type	Description	Default
mem_address	Number	Address of data to be written to flash.	Address of last loaded file. If not set by a load operation it must be specified.
length	Number	Length of data to be written.	Length of last loaded file.
name	String	Name of file to create.	

Description

This command is used to write data from memory to a file. If the file does not exist it will be created. If it does exist, then it will be overwritten with the new contents.

Examples

Write an area of data to a file

```
RedBoot> fs write -b 0x0606f000 -l 0x1000 image
RedBoot> fs ls
d---------       128 .
d---------       128 ..
----------      4096 image
d---------        96 tests
RedBoot>
```

Persistent State Flash-based Configuration and Control

RedBoot provides flash management support for storage in the flash memory of multiple executable images and of non-volatile information such as IP addresses and other network information.

RedBoot on platforms that support flash based configuration information will report the following message the first time that RedBoot is booted on the target:

```
flash configuration checksum error or invalid key
```

This error can be ignored if no flash based configuration is desired, or can be silenced by running the **fconfig** command as described below. At this point you may also wish to run the **fis init** command. See other fis commands in the section called “Flash Image System (FIS)”.

Certain control and configuration information used by RedBoot can be stored in flash.

The details of what information is maintained in flash differ, based on the platform and the configuration. However, the basic operation used to maintain this information is the same. Using the **fconfig -l** command, the information may be displayed and/or changed.

If the optional flag `-i` is specified, then the configuration database will be reset to its default state. This is also needed the first time RedBoot is installed on the target, or when updating to a newer RedBoot with different configuration keys.

If the optional flag `-l` is specified, the configuration data is simply listed. Otherwise, each configuration parameter will be displayed and you are given a chance to change it. The entire value must be typed - typing just carriage return will leave a value unchanged. Boolean values may be entered using the first letter (`t` for true, `f` for false). At any time the editing process may be stopped simply by entering a period (.) on the line. Entering the caret (^) moves the editing back to the previous item. See “RedBoot Editing Commands”, the section called “RedBoot Editing Commands”.

If any changes are made in the configuration, then the updated data will be written back to flash after getting acknowledgment from the user.

If the optional flag `-n` is specified (with or without `-l`) then “nicknames” of the entries are used. These are shorter and less descriptive than “full” names. The full name may also be displayed by adding the `-f` flag.

The reason for telling you nicknames is that a quick way to set a single entry is provided, using the format

```
  RedBoot> fconfig nickname value
```

If no value is supplied, the command will list and prompt for only that entry. If a value is supplied, then the entry will be set to that value. You will be prompted whether to write the new information into flash if any change was made. For example

```
  RedBoot> fconfig -l -n
  boot_script: false
  bootp: false
  bootp_my_ip: 10.16.19.176
  bootp_server_ip: 10.16.19.66
  dns_ip: 10.16.19.1
  gdb_port: 9000
  net_debug: false
  RedBoot> fconfig bootp_my_ip 10.16.19.177
  bootp_my_ip: 10.16.19.176 Setting to 10.16.19.177
  Update RedBoot non-volatile configuration - continue (y/n)? y
  ... Unlock from 0x507c0000-0x507e0000: .
  ... Erase from 0x507c0000-0x507e0000: .
  ... Program from 0x0000a8d0-0x0000acd0 at 0x507c0000: .
  ... Lock from 0x507c0000-0x507e0000: .
  RedBoot>
```

Additionally, nicknames can be used like aliases via the format %{nickname}. This allows the values stored by **`fconfig`** to be used directly by scripts and commands.

Depending on how your terminal program is connected and its capabilities, you might find that you are unable to use line-editing to delete the ’old, value when using the default behaviour of **fconfig** ***`nickname`*** or just plain **fconfig**, as shown in this example:

```
RedBoot> fco bootp
bootp: false_
```

The user deletes the word “false;” and enters “true” so the display looks like this:

```
RedBoot> fco bootp
bootp: true
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlock from ...
RedBoot> _
```

To edit when you cannot backspace, use the optional flag `-d` (for “dumb terminal”) to provide a simpler interface thus:

```
RedBoot> fco -d bootp
bootp: false ? _
```

and you enter the value in the obvious manner thus:

```
RedBoot> fco -d bootp
bootp: false ? true
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlock from ...
RedBoot> _
```

One item which is always present in the configuration data is the ability to execute a script at boot time. A sequence of RedBoot commands can be entered which will be executed when the system starts up. Optionally, a time-out period can be provided which allows the user to abort the startup script and proceed with normal command processing from the console.

```
RedBoot> fconfig -l
Run script at boot: false
Use BOOTP for network configuration: false
Local IP address: 192.168.1.29
Default server IP address: 192.168.1.101
DNS domain name: example.com
DNS server IP address: 192.168.1.1
GDB connection port: 9000
Network debug at boot time: false
```

The following example sets a boot script and then shows it running.

```
RedBoot> fconfig
Run script at boot: false t
      Boot script:
Enter script, terminate with empty line
>> fi li
    Boot script timeout: 0 10
Use BOOTP for network configuration: false .
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0xa0fc0000-0xa0fe0000: .
... Program from 0x8c021f60-0x8c022360 at 0xa0fc0000: .

RedBoot>
```

Notes

- The bold characters above indicate where something was entered on the console. As you can see, the **fi li** command at the end came from the script, not the console. Once the script is executed, command processing reverts to the console.
- RedBoot supports the notion of a boot script timeout, i.e. a period of time that RedBoot waits before executing the boot time script. This period is primarily to allow the possibility of canceling the script. Since a timeout value of zero (0) seconds would never allow the script to be aborted or canceled, this value is not allowed. If the timeout value is zero, then RedBoot will abort the script execution immediately.

On many targets, RedBoot may be configured to run from ROM or it may be configured to run from RAM. Other configurations are also possible. All RedBoot configurations will execute the boot script, but in certain cases it may be desirable to limit the execution of certain script commands to one RedBoot configuration or the other. This can be accomplished by prepending `{<startup type>}` to the commands which should be executed only by the RedBoot configured for the specified startup type. The following boot script illustrates this concept by having the ROM based RedBoot load and run the RAM based RedBoot. The RAM based RedBoot will then list flash images.

```
RedBoot> fco
Run script at boot: false t
Boot script:
Enter script, terminate with empty line
>> {ROM}fis load RedBoot[RAM]
>> {ROM}go
>> {RAM}fis li
>>

Persistent State in a NAND-based environment

On some boards it is necessary to use NAND flash to store persistent state and configuration. This is normally provided by the config store.

For simplicity, a *bridge driver* has been developed which allows the config store to be used by RedBoot as if it were NOR flash. (The reason for this is that the RedBoot fconfig system has a much lower overhead than the NAND storage system, in order to operate in environments with very limited resources. NAND-based boards have much more flash and RAM available, so the overhead of the extra layers is not an issue.)

To RedBoot, the config store behaves identically to regular (NOR) flash storage. However its use has a number of implications:

- If the NAND is repartitioned or erased, all persistent configuration is likely to be lost.
- The configuration is susceptible to the same wearout and read disturb effects that affect all NAND parts over time. (This is mitigated by allowing multiple NAND blocks for the config store partition, which are used in rotation.)

Even though the bridge driver may be in use, it is still possible to use the config store directly for other options.

Note

Some platform HALs use this mechanism to set the size of the config store partition in such a way that does not depend on RedBoot. Refer to the documentation for those HAL ports for details.

Manipulating persistent state stored on NAND

To modify configuration items managed by RedBoot, use the **`fconfig`** command in the usual way. See the section called “Persistent State Flash-based Configuration and Control ”.

To modify items in the config store which are not managed by RedBoot, use the **`nconfig`** command. See the section called “NAND configuration commands ”. You may also wish to manipulate the NAND array with the **`nand`** command family; see the section called “NAND manipulation commands ”.

Executing Programs from RedBoot

Once an image has been loaded into memory, either via the **load** command or the **fis load** command, execution may be transfered to that image.

Note

The image is assumed to be a stand-alone entity, as RedBoot gives the entire platform over to it. Typical examples would be an eCos application or a Linux kernel.

Name

go — Execute a program

Synopsis

`go` [-w *timeout*] [-c] [-n] [*start_address*]

Arguments

Name	Type	Description	Default
-w *timeout*	Number	How long to wait before starting execution.	0
-c	Boolean	Go with caches enabled.	caches off
-n	Boolean	Go with network interface stopped.	network enabled
start_address	Number	Address in memory to begin execution.	Value set by last **load** or **fis load** command.

Description

The **go** command causes RedBoot to give control of the target platform to another program. This program must execute stand alone, e.g. an eCos application or a Linux kernel.

If the -w option is used, RedBoot will print a message and then wait for a period of time before starting the execution. This is most useful in a script, giving the user a chance to abort executing a program and move on in the script.

Examples

Execute a program - *no explicit output from RedBoot*.

```
RedBoot> go 0x40040
```

Execute a program with a timeout.

```
RedBoot> go -w 10
About to start execution at 0x00000000 - abort with ^C within 10 seconds
^C
RedBoot>
```

Note that the starting address was implied (0x00000000 in this example). The user is prompted that execution will commence in 10 seconds. At anytime within that 10 seconds the user may type Ctrl+C on the console and RedBoot will abort execution and return for the next command, either from a script or the console.

Name

exec — Execute a Linux kernel

Synopsis

`exec` [-w *`timeout`*] [-r *`ramdisk_address`*] [-s *`ramdisk_length`*] [-b *`load_address`* {-l *`load_length`*}] [-c *`kernel_command_line`*] [*`entry_point`*]

Arguments

Name	Type	Description	Default
-w *`timeout`*	Number	Time to wait before starting execution.	0
-r *`ramdisk_address`*	Number	Address in memory of "initrd"-style ramdisk - passed to Linux kernel.	*None*
-s *`ramdisk_length`*	Number	Length of ramdisk image - passed to Linux kernel.	*None*
-b *`load_address`*	Number	Address in memory of the Linux kernel image.	Value set by **load** or **fis load**
-l *`load_length`*	Number	Length of Linux kernel image.	*none*
-c *`kernel_command_line`*	String	Command line to pass to the Linux kernel.	*None*
-x		Boot kernel with endianess opposite of RedBoot endianess.	Boot kernel with same endianess as RedBoot
`entry_address`	Number	Starting address for Linux kernel execution	Implied by architecture

Description

The **exec** command is used to execute a non-eCos application, typically a Linux kernel. Additional information may be passed to the kernel at startup time. This command is quite special (and unique from the **go** command) in that the program being executed may expect certain environmental setups, for example that the MMU is turned off, etc.

The Linux kernel expects to have been loaded to a particular memory location which is architecture dependent(0xC0008000 in the case of the SA1110). Since this memory is used by RedBoot internally, it is not possible to load the kernel to that location directly. Thus the requirement for the "-b" option which tells the command where the kernel has been loaded. When the **exec** command runs, the image will be relocated to the appropriate location before being started. The "-r" and "-s" options are used to pass information to the kernel about where a statically loaded ramdisk (initrd) is located.

The "-c" option can be used to pass textual "command line" information to the kernel. If the command line data contains any punctuation (spaces, etc), then it must be quoted using the double-quote character '"'. If the quote character is required, it should be written as '\"'.

The "-x" option is optionally available on some bi-endian platforms. It is used to boot a kernel built with an endianess opposite of RedBoot.

Examples

Execute a Linux kernel, passing a command line, which needs relocation. The result from RedBoot is normally quiet, with the target platform being passed over to Linux immediately.

```
RedBoot> exec -b 0x100000 -l 0x80000 -c "noinitrd root=/dev/mtdblock3 console=ttySA0"
```

Execute a Linux kernel, default entry address and no relocation required, with a timeout. The *emphasized lines* are output from the loaded kernel.

```
RedBoot> exec -c "console=ttyS0,38400 ip=dhcp nfsroot=/export/elfs-sh" -w 5
Now booting linux kernel:
Base address 0x8c001000 Entry 0x8c210000
Cmdline : console=ttyS0,38400 ip=dhcp nfsroot=/export/elfs-sh
About to start execution at 0x8x210000 - abort with ^C within 5 seconds
Linux version 2.4.10-pre6 (...) (gcc version 3.1-stdsh-010931) #3 Thu Sep 27 11:04:23 BST 2001
```

NAND configuration commands

Note

This section does not cover configuration items managed by RedBoot; for those, use the **`fconfig`** command instead (the section called “Persistent State Flash-based Configuration and Control ”).

The *config store* is the backing store for this persistent information. Data is stored as *(key, value)* pairs; values are *typed*. This section refers only to the RedBoot commands for manipulating the config store.

Note

The config key **`ecos.fakeflash.config`** contains the RedBoot configuration information as managed by the **fconfig** command. Do not edit this key directly; it is automatically managed by RedBoot and the driver stack.

Name

nconfig list — List configuration keys

Synopsis

```
nconfig list
```

Arguments

The command takes no arguments.

Description

This command lists all known configuration keys. The list is output in arbitrary order.

Examples

```
RedBoot> nconfig list
The config store contains:
  nand.partition1.size
  nand.partition1.base
  ecos.fakeflash.config
RedBoot>
```

Note

The config key **`ecos.fakeflash.config`** contains the RedBoot configuration information as managed by the **fconfig** command. Do not edit this key directly; it is automatically managed by RedBoot and the driver stack.

Name

nconfig info — Query metadata for one or more config keys

Synopsis

```
nconfig info <key> [<key>...]
```

Arguments

One or more config keys. Information is returned about each of them in turn.

Description

This command outputs the metadata (type and data size) for the requested configuration key(s) in the form they currently appear in the store.

Note

The type of a data key is not fixed; it may be changed later, either via RedBoot or by an application. Similarly, the reported size of a variable-length type (`string` or `bytes`) only reflects its current size in storage and may change later.

Examples

```
RedBoot> nconfig info nand.partition1.base nand.partition1.size
Key         : nand.partition1.base
  type      : uint
  data size : 4
Key         : nand.partition1.size
  type      : uint
  data size : 4
RedBoot> nconfig info foo
Key foo not found
RedBoot>
```

Name

nconfig types — List all known config data types

Synopsis

```
nconfig types
```

Arguments

This command takes no arguments.

Description

This command lists all data types the config store knows about.

Config store data types

`uint`	Unsigned 32-bit integer
`bool`	Boolean
`string`	A printable, NULL-terminated string of arbitrary length.
`bytes`	A byte array of arbitrary length.

Note

It is possible that data could be present of an unknown type, if support for new types has been added to an application. The config store has been specifically designed to cope with unknown types and not disturb them.

Examples

```
RedBoot> nconfig types
This build supports the following types:
uint, bool, bytes, string
RedBoot>
```

Name

nconfig get — Outputs the current value of one or more config keys

Synopsis

```
nconfig get <key> [<key>...]
```

Arguments

One or more config keys.

Description

This command retrieves and outputs the current values of one or more config keys. Byte arrays are pretty-printed in hex; strings are output without line breaks.

Note

It is possible that data could be present of an unknown type, if support for new types has been added to an application. The **get** logic will not be able to display types it does not know about.

Examples

```
RedBoot> nconfig get nand.partition1.base nand.partition1.size
nand.partition1.base=16
nand.partition1.size=200
RedBoot> nconfig get app1.magic
app1.magic=This is a string example
RedBoot> nconfig get app2.magic
ecos.fakeflash.config: <64 bytes, hex follows>a
 00100000cefaad0b 010c0100626f6f74 5f73637269707400 000000000411010c
 626f6f745f736372 6970745f64617461 00626f6f745f7363 7269707400000000
RedBoot>
```

Name

nconfig put — Writes a config key

Synopsis

```
nconfig put <key> <type> <value>
```

Arguments

The config key, type and the value or data to be written to it.

Description

This command writes a single key to the store. If the key was already present in the store, its existing value is overwritten.

The value of a `bool` variable may be specified as **`true`**, **`True`**, **`t`**, **`T`**, **`1`**; **`false`**, **`False`**, **`f`**, **`F`**, or **`0`**.

Notes

- This interface does not support the `bytes` type yet.
- To write a string containing a space from within RedBoot, it is necessary to surround the string in quote marks.
- This command may be configured out with the `CYGSEM_REDBOOT_CONFIGSTORE_PUT_CMD` option.

Examples

```
RedBoot> nconfig put nand.partition1.size uint 100
Written OK
RedBoot> nconfig put app1.magic string "This is a string"
Written OK
RedBoot> nconfig put baz.qux bool true
Written OK
RedBoot> nconfig get baz.qux
baz.qux=True
RedBoot>
```

Name

nconfig del — Deletes a config key

Synopsis

```
nconfig del <key>
```

Arguments

The config key to delete.

Description

This command deletes a key and its data from the store.

Note

This command may be configured out with the `CYGSEM_REDBOOT_CONFIGSTORE_DEL_CMD` option.

Examples

```
RedBoot> nconfig del foo.bar
Deleted OK
RedBoot> nconfig del foo.bar
Key foo.bar not found
RedBoot>
```

Name

nconfig dump — Diagnostic dump output

Synopsis

`nconfig dump`

Arguments

This command takes no arguments.

Description

This command outputs a diagnostic dump of all the configuration data in the store.

Note

This command is not present by default. It may be configured in, with the `CYGSEM_REDBOOT_CONFIGSTORE_DUMP_CMD` option.

Caution

This command can generate excessive amounts of output, which may take a long time to send over a slow debug channel.

Note

While this command outputs byte arrays in hex, they are not line-wrapped.

Examples

```
RedBoot> nconfig dump
Store serial number 52:
  app1.magic=This is a string
  nand.partition1.size=200
  nand.partition1.base=16
  ecos.fakeflash.config=00100000cefaad0b 010c0100626f6f74 5f73637269707400  626f6f745f736372 6970745f64617461 \
00626f6f745f7363 7269707400000000 0000000000000000 0000000000000000 0000000000000000 0000000000000000 \
0000000000000000 0000000000000000 0000000000000000 0000000000000000 0000000000000000 0000000000000000 \
0000000000000000 0000000000000000 0000000000000000 0000000000000000 0000000000000000 0000000000000000
 (Ends)
RedBoot>
```

NAND manipulation commands

Notes

- These commands are only available when there is at least one NAND driver configured.
- All the **`nand badblocks`** commands may be configured out simultaneously by turning off the `CYGSEM_REDBOOT_NAND_BADBLOCKS_CMD` option.

Name

nand list — List NAND devices

Synopsis

`nand list`

Arguments

The command takes no arguments.

Description

This command lists all known NAND devices for which a driver is loaded in the current eCos configuration. The list is output in arbitrary order.

Examples

```
RedBoot> nand list
NAND devices available:
        onboard
RedBoot>
```

Name

nand info — Output information about a NAND device

Synopsis

```
nand info <dev> [<dev>...]
```

Arguments

Specify the NAND device name(s) to query. If none are given, all available devices will be queried in turn.

Description

This command outputs information about selected NAND devices. The output includes information about the device physical configuration (not including the spare area of each page) as well as the current configured partition table.

Note

For information about how the partition table is defined and controlled on a particular device, refer to the relevant platform HAL documentation. Some devices can be reconfigured dynamically from within RedBoot; others have a static configuration which requires that eCos (and RedBoot) be rebuilt.

Examples

```
RedBoot> nand info
NAND device `onboard':
  2048 bytes/page, 64 pages/block, capacity 2048 blocks x 128 kB = 256 MB
  Partition Start Blocks
       0       6     10
       1      16    200
RedBoot>
```

Name

nand badblocks states — List all current valid BBT states

Synopsis

```
nand badblocks states
```

Arguments

This command takes no arguments.

Description

This command lists the names of the possible states that may be applied to each block within the Bad Block Table.

Examples

```
RedBoot> nand badblocks states
The possible block states are:
        0 : OK
        1 : worn bad
        2 : reserved
        3 : factory bad
RedBoot>
```

Name

nand badblocks summary — Summary of the Bad Block Table

Synopsis

```
nand badblocks summary [-d <device>]
```

Arguments

This command takes an optional device argument. If not specified, and only one device is present, it applies to the single device; if more than one device is present, it must be specified.

Description

This command outputs a human-readable summary of the information held within the Bad Block Table of a device.

Examples

```
RedBoot> nand badblocks summary
Device `onboard' has 2048 blocks, of which 2 are factory bad, 2 reserved. 2044 blocks (99%) are OK.
RedBoot>
```

Name

nand badblocks list — List not-OK blocks in a Bad Block Table

Synopsis

```
nand badblocks list [-d <device>]
```

Arguments

This command takes an optional device argument. If not specified, and only one device is present, it applies to the single device; if more than one device is present, it must be specified.

Description

This command outputs a human-readable list of the numbers of all not-OK blocks in a device, according to its Bad Block Table.

Examples

```
RedBoot> nand badblocks list -d onboard
factory bad: 100, 101. (count: 2 blocks)
worn bad: no blocks
reserved: 2046, 2047. (count: 2 blocks)
RedBoot>
```

Name

nand badblocks mark — Manipulate the Bad Block Table

Synopsis

```
nand badblocks mark [-d <device>] -b <block> -s <state>
```

Arguments

`-b block`

The block number whose state is to be manipulated.

> **Note**
>
> Block numbers to this command are device block numbers, with 0 meaning the first block on the device.

`-s state`

The new state for the given block. This must be a state number, as output by **`nand badblocks states`**.

`-d device`

(Optional.) If not specified, and only one device is present, the command is assumed to apply to the NAND device; if more than one device is present, it must be specified.

Description

This command explicitly manipulates the Bad Block Table.

> **Note**
>
> This command may be configured out with the `CYGSEM_REDBOOT_NAND_BADBLOCKS_MARK_CMD` option.

> **Warning**
>
> Misuse of this command is likely to cause corruption of data you care about!
>
> - Live data in affected blocks can be rendered inaccessible to eCos.
> - Blocks which have been marked as unreliable due to wear can be brought back into circulation but will still be unreliable.

Examples

```
RedBoot> nand badblocks mark -d onboard -b 2000 -s 1
OK
RedBoot> nand badblocks list -d onboard
factory bad: 100, 101. (count: 2 blocks)
worn bad: 2000. (count: 1 blocks)
reserved: 2046, 2047. (count: 2 blocks)
RedBoot> nand badblocks mark -d onboard -b 2000 -s 0
OK
RedBoot> nand badblocks list -d onboard
factory bad: 100, 101. (count: 2 blocks)
worn bad: no blocks
reserved: 2046, 2047. (count: 2 blocks)
RedBoot>
```

Name

nand erase — Erase an entire NAND partition

Synopsis

```
nand erase <device>/<partition>
```

Arguments

This command takes a single argument encoding the device and partition to erase.

Description

This command erases every block of a NAND partition.

Note

This command may be configured out with the `CYGSEM_REDBOOT_NAND_ERASE_CMD` option.

Examples

```
RedBoot> nand info
NAND device `onboard':
  2048 bytes/page, 64 pages/block, capacity 2048 blocks x 128 kB = 256 MB
  Partition Start Blocks
       0       6     10
       1      16    200
RedBoot> nand erase onboard/2
nand erase: partition not found
RedBoot> nand erase onboard/1
Erasing partition blocks 0 to 199...
............................Skipping block 84 (factory bad)
.Skipping block 85 (factory bad)
......................................
Erase complete.
RedBoot>
```

Name

nand eraseblock — Erase a specific NAND block

Synopsis

```
nand eraseblock -d <device> -b <block> [-n <count>]
```

Arguments

-b block The block number to erase (or, if -n is given, the first block).

> ### Note
>
> Block numbers to this command are device block numbers, with 0 meaning the first block on the device.

-n count The number of blocks to erase. This defaults to 1.

-d device The name of the device to affect.

Description

This command erases one or more blocks on a NAND device.

Notes

- This command may be configured out with the `CYGSEM_REDBOOT_NAND_ERASEBLOCK_CMD` option.
- This command ignores the Bad Blocks Table. It will attempt to erase any block on the device, regardless of its state.

Warning

This command is powerful, but potentially dangerous as it will erase data without any safety checks. It is possible to erase RedBoot, other files required for system bootstrap, the Bad Block Table itself, any stored configuration data, etc. Be very sure of the block number before committing!

Examples

```
RedBoot> nand eraseblock -d onboard -b 42 -n 2
Erasing device onboard blocks 42-43...
Erase complete.
RedBoot>
```

Chapter 226. Rebuilding RedBoot

Introduction

Prebuilt images of RedBoot are provided for all target platforms supported by an eCosCentric release, so it is not normally required to rebuild RedBoot in order to be able to begin your software development on eCos/eCosPro and the target platform. However, for later development you may wish to build your own cut down version of RedBoot or custom enhanced version that includes features such as manufacturing tests, initial programming, recovery, security and so on. This chapter describes the process of building, or rebuilding, RedBoot.

RedBoot is built as an application on top of eCos. The makefile rules for building RedBoot are part of the eCos CDL package so building RedBoot may be easily achieved. Typically building involves a command shell and the command line tool ecosconfig, with additional configuration or final build done through the eCos Configuration Tool.

Building RedBoot requires only a few steps: selecting the platform and the RedBoot template, importing a platform specific configuration file, and finally starting the build.

The platform specific configuration file makes sure the settings are correct for building RedBoot for the given target platform. Each target platform supporting RedBoot normally provides at least one configuration file whose name typically indicates the startup mode of RedBoot (see the section called “RedBoot Startup Mode”). For example, `redboot_RAM.ecm` indicates the filename of a RAM mode RedBoot configuration and `redboot_ROM.ecm` or `redboot_ROMRAM.ecm` for a ROM or ROMRAM mode RedBoot configuration filename respectively. There may be additional configuration files according to the requirements of the particular platform. These files are placed into the `install/etc/redboot/<target>` directory of the install tree, or may be found in the `misc` sub-directory of the platform HAL directory for older releases of eCos.

The RedBoot build process results in a number of files in the `install/bin` directory. The ELF file `redboot.elf` is the principal result. Depending on the platform CDL, there will also be generated versions of RedBoot in other file formats, such as `redboot.bin` (binary format, good when doing an update of a primary RedBoot image, see the section called “Update the primary RedBoot flash image”), `redboot.srec` (Motorola S-record format, good when downloading a RAM mode image for execution), and `redboot.img` (stripped ELF format, good when downloading a RAM mode image for execution, smaller than the .srec file). Some platforms may provide additional file formats and also relocate some of these files to a particular address making them more suitable for downloading using a different boot monitor or flash programming tools.

The platform specific information in the relevant platform's HAL documentation must be consulted as there may be other special instructions required to build RedBoot.

Variables

These instructions assume that the *`ECOS_REPOSITORY`* environment variable contains the full pathname of the `packages` subdirectory or directories containing the eCosPro repository or repositories from which RedBoot is to be built.

These instructions also make use of the *`ECOS_TARGET`* and *`REDBOOT_CFG`* environment variables to simplify and provide generic instructions for building RedBoot. Their used is not required and users are free to replace these with their own actual values in the instructions provided.

The instructions provided in this section are for a **bash** shell environment but are also applicable to a Windows **CMD** environment. The only differences between the instructions for either is the appearance of environment variables in the instructions and the different format of directory paths. For example, where you see the use of the *`${REDBOOT_CFG}`* environment variable in the **bash** shell, *`%REDBOOT_CFG%`* must be used in the Windows **CMD** environment.

The setting of an envirnment variable also differs. For example in the **bash** shell a variables may be set as follows:

```
$ export REDBOOT_CFG=redboot_RAM
```

In the windows **CMD** environment a variable is set as follows:

```
C:\users\demo> set REDBOOT_CFG=redboot_RAM
```

The same applies for the *${ECOS_TARGET}* environment variable. In the example below it is set for *at91sam9g45ek* target platform, the AT91SAM9G45-EKES board. For the **bash** shell:

```
$ export ECOS_TARGET=at91sam9g45ek
```

For the Windows **CMD**:

```
C:\users\demo> set ECOS_TARGET=at91sam9g45ek
```

Note

Windows users using eCosPro Developer's Kits may also use the **bash** shell by changing the shell opened from the eCos Configuration Tool using the Tools → Shell menu option by selecting View → Settings (**Ctrl+T**) , selecting the *Viewers/Shell* tab within the resulting dialog and changing the Command Shell to **bash**.

Building RedBoot using ecosconfig

To build RedBoot using the ecosconfig tool in a command line environment:

1. Create a temporary directory for building RedBoot, and change into it. For example:

   ```
   $ mkdir /tmp/${REDBOOT_CFG}
   $ cd /tmp/${REDBOOT_CFG}
   ```

2. Create a partial build tree to instantiate the platform specific configuration files for the chosen platform:

   ```
   $ ecosconfig --noresolve new ${ECOS_TARGET} redboot
   $ ecosconfig --ignore-errors --no-resolve tree
   $ make etc
   ```

   At this point all the relevant RedBoot configuration files should be found in the `install/etc/redboot/`*${ECOS_TARGET}* subdirectory. `install/etc` will become further populated with other configuration files, such as example PEEDI and OpenOCD configuration files, after a complete build of RedBoot.

3. Import the appropriate platform RedBoot configuration file:

   ```
   $ ecosconfig --no-resolve import install/etc/${ECOS_TARGET}/${REDBOOT_CFG}.ecm
   ```

   At this point the eCos configuration in `ecos.ecc` will contain all the unresolved settings required to build a *${REDBOOT_CFG}* for the *${ECOS_TARGET}* platform

4. Resolve any conflicts and create build tree for RedBoot:

   ```
   $ ecosconfig resolve
   $ ecosconfig tree
   ```

5. RedBoot can now be built:

   ```
   $ make
   ```

   The resulting RedBoot files will be in the associated install directory, in this example, `./install/bin`.

Note

Older revisions of eCos or some platforms may not support the `etc` make target. In these instances the RedBoot configuration file will not be found in the `install/etc/`*${ECOS_TARGET}*`/` subdirectory but may be found in the `misc` subdirectory of the platform HAL within *`${ECOS_REPOSITORY}`*. In these instances please refer to the specific platform HAL documentation for instructions on how to build RedBoot using an appropriate configuration file.

To build for another configuration, simply change the *`REDBOOT_CFG`* definition accordingly. For example:

```
export REDBOOT_CFG=redboot_ROM
mkdir /tmp/${REDBOOT_CFG}
cd /tmp/${REDBOOT_CFG}
ecosconfig --no-resolve new ${ECOS_TARGET} redboot
ecosconfig --no-resolve --ignore-errors tree
make etc
ecosconfig --no-resolve import install/etc/${REDBOOT_CFG}.ecm
ecosconfig resolve
ecosconfig tree
make
```

Notes

- The options `--no-resolve` and `--ignore-errors` are essential to certain targets. Their purpose is to delay the libcdl inferrence engine from being applied to a configuration until the required settings for the RedBoot configuration have been imported. This prevents any inferrences from being made during each creation step of the RedBoot configuration which may steer the final outcome to an unresolveable conflict. This is because inferrences cannot currently be implicitly undone within a configuration, and some inferences may need to be reversed by settings imported within *`${REDBOOT_CFG}`*`.ecm`. The final **ecosconfig resolve** command above therefore applies the libcdl inferrence engine to the configuration settings once all the required settings have been made. The options are otherwise harmless for targets which are not sensitive to premature inferrences.

- If the **bash** shell or Windows **CMD** was started from within the eCos Configuration Tool, the environment variable *`ECOS_TARGET`* will be set within the shell to the target of the configuration tool's eCos configuration at the time **bash** or **CMD** was started.

Rebuilding RedBoot from the eCos Configuration Tool

While it is possible to rebuild RedBoot from the eCos Configuration Tool, creating a RedBoot configuration is not always simple due to certain behavioural limitations of the eCos Configuration Tool. Instead, developers are recommended to use the Tools → Shell menu option to create a command shell and follow the instructions in the section called “Building RedBoot using ecosconfig” up to and including the **make etc** step with the inclusion of the `--compat` and `--config=<`*`savefile`*`>.ecc` options to every **ecosconfig** command. For example, assuming a working directory of `/tmp`:

```
cd /tmp
ecosconfig --compat --config=<savefile>.ecc --no-resolve new ${ECOS_TARGET} redboot
ecosconfig --compat --config=<savefile>.ecc --no-resolve --ignore-errors tree
make etc
```

Note

The environment variable *`${ECOS_TARGET}`* will be set by the eCos Configuration Tool to the current configuration's hardware, or profile's default hardware if no configuration has been created. It may therefore not be necessary to set this variable.

At this point the 1st stage RedBoot configuration can be loaded into the eCos Configuration Tool using File → Open to open the file `/tmp/<`*`savefile`*`>.ecc` and the RedBoot settings imported from `/tmp/<`*`savefile`*`>_install/etc/redboot/`*`${ECOS_TARGET}`*`/`*`${REDBOOT_CFG}`*`.ecm`. using File → Import .

Depending on the platform, a number of conflicts may need to be resolved before the build can be started. To resolve conflicts, if any, use the menu item Tools → Resolve Conflicts .

If you wish to switch to a different location or filename, you may now do so using the menu option File → Save As .

Generate a build tree to instantiate the platform specific configuration files for the chosen platform Build → Generate Build Tree .

Then start the build (Build → Library (**F7**)) and wait for it to complete. The resulting RedBoot files will be in the associated install directory, for the example this would be `<savefile>_install/bin`

As noted above, please also refer to the platform's HAL documentation to determine if there are any additional platform specific instructions that must be followed when rebuilding RedBoot.

Chapter 227. Updating RedBoot

Introduction

RedBoot normally resides in internal flash on the CPU or external flash on the board. It is often possible to update RedBoot in situ using a hardware debugger or even Redboot's flash management commands. Occasionally vendor specific software tools such as ATMEL's SAM-BA In- system Programmer may also be required.

The process of updating RedBoot in situ is documented in this section. For this process, it is assumed that the target is connected to a host system and that there is a serial or TCPIP connection giving access to the RedBoot CLI. For platforms with a ROMRAM mode RedBoot, skip to the section called “Update the primary RedBoot flash image”.

Older boards may use EEPROM although this is a lot less common nowadays. In this case of EPROM, updating RedBoot normally necessitates physically removing the part and reprogramming a new RedBoot image into it using prommer hardware.

Note

The addresses and sizes included in the below are examples only, and will differ from those you will see. This is normal and should not cause concern.

Load and start a RedBoot RAM instance

There are a number of choices here. The basic case is where a RAM mode image has been stored in the FIS (flash Image System). To load and execute this image, use the commands:

```
RedBoot> fis load RedBoot[RAM]
RedBoot> go
```

If this image is not available, or does not work, then an alternate RAM mode image can be loaded via one of several other methods:

- TFTP via a network connection:

  ```
  RedBoot> load redboot_RAM.img
  Entry point: 0x060213c0, address range: 0x06020000-0x060369c8
  RedBoot> go
  ```

- X, Y or Z modem: (y modem in this example)

  ```
  RedBoot> load -m y -r -b %{FREEMEMLO}
  ...
  Raw file loaded 0x06046800-0x06062fe8, assumed entry at 0x06046800
  RedBoot> go
  ```

- A filesystem, if available:

  ```
  RedBoot> load hda2:redboot_RAM.img
  Entry point: 0x060213c0, address range: 0x06020000-0x060369c8
  RedBoot> go
  ```

Notes

- Refer to the **load** command for a complete list of options available.
- If you expect to be doing this more than once, it is a good idea to program the RAM mode image into the flash. You do this using the **fis create** command after having downloaded the RAM mode image, but before you start it.

Some platforms support locking (write protecting) certain regions of the flash, while others do not. If your platform does not support locking, simply ignore the **fis unlock** and **fis lock** steps (the commands will not be recognized by RedBoot).

```
RedBoot> fis unlock RedBoot[RAM]
  ... Unlock from 0x00000000-0x00020000: ..
RedBoot> fis create RedBoot[RAM]
An image named 'RedBoot[RAM]' exists - continue (y/n)? y
* CAUTION * about to program 'RedBoot[RAM]'
            at 0x00020000..0x000369c7 from 0x06020000 - continue (y/n)?y
... Erase from 0x00020000-0x00040000: ..
... Program from 0x06020000-0x060369c8 at 0x00020000: ..
... Erase from 0x00070000-0x00080000: .
... Program from 0x0606f000-0x0607f000 at 0x00070000: .
RedBoot> fis lock RedBoot[RAM]
  ... Lock from 0x00000000-0x00020000: ..
```

Update the primary RedBoot flash image

An instance of RedBoot should now be running on the target from RAM. This can be verified by looking for the mode identifier in the banner. It should be either [RAM] or [ROMRAM].

If this is the first time RedBoot is running on the board or if the flash contents has been damaged, initialize the FIS directory:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x00020000-0x00070000: .....
... Erase from 0x00080000-0x00080000:
... Erase from 0x00070000-0x00080000: .
... Program from 0x0606f000-0x0607f000 at 0x00070000: .
```

It is important to understand that the presence of a correctly initialized FIS directory allows RedBoot to automatically determine the flash parameters. Additionally, executing the steps below as stated without loading other data or using other flash commands (than possibly **fis list**) allows RedBoot to automatically determine the image location and size parameters. This greatly reduces the risk of potential critical mistakes due to typographical errors. It is still always possible to explicitly specify parameters, and indeed override these, but it is not advised.

Note

If the new RedBoot image has grown beyond the slot in flash reserved for it, it is necessary to change the RedBoot configuration option CYGBLD_REDBOOT_MIN_IMAGE_SIZE so the FIS is created with adequate space reserved for RedBoot images. In this case, it is necessary to re-initialize the FIS directory as described above, using a RAM mode RedBoot compiled with the updated configuration.

Using the **load** command, download the new flash based image from the host, relocating the image to RAM:

```
RedBoot> load -r -b %{FREEMEMLO} redboot_ROM.bin
Raw file loaded 0x06046800-0x06062fe8, assumed entry at 0x06046800
```

Notes

- This command loads the RedBoot image using the TFTP protocol via a network connection. Other methods of loading are available, refer to the load command for more details.

- The binary version of the image is being downloaded. This is to ensure that the memory after the image is loaded should match the contents of the file on the host. Loading SREC or ELF versions of the image does not guarantee this since these formats may contain holes, leaving bytes in these holes in an unknown state after the load, and thus causing a likely cksum difference. It is possible to use these, but then the step verifying the cksum below may fail.

Once the image is loaded into RAM, it should be checksummed, thus verifying that the image on the target is indeed the image intended to be loaded, and that no corruption of the image has happened. This is done using the cksum command:

```
RedBoot> cksum
Computing cksum for area 0x06046800-0x06062fe8
POSIX cksum = 2535322412 116712 (0x971df32c 0x0001c7e8)
```

Compare the numbers with those for the binary version of the image on the host. If they do not match, try downloading the image again.

Assuming the cksum matches, the next step is programming the image into flash using the FIS commands.

Some platforms support locking (write protecting) certain regions of the flash, while others do not. If your platform does not support locking, simply ignore the **fis unlock** and **fis lock** steps (the commands will not be recognized by RedBoot).

```
RedBoot> fis unlock RedBoot
... Unlock from 0x00000000-0x00020000: ..
RedBoot> fis create RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
* CAUTION * about to program 'RedBoot'
            at 0x00000000..0x0001c7e7 from 0x06046800 - continue (y/n)? y
... Erase from 0x00000000-0x00020000: ..
... Program from 0x06046800-0x06062fe8 at 0x00000000: ..
... Erase from 0x00070000-0x00080000: .
... Program from 0x0606f000-0x0607f000 at 0x00070000: .
RedBoot> fis lock RedBoot
  ... Lock from 0x00000000-0x00020000: ..
```

Reboot; run the new RedBoot image

Once the image has been successfully written into the flash, simply reset the target OR RUN THE **reset** command and the new version of RedBoot should be running.

When installing RedBoot for the first time, or after updating to a newer RedBoot with different configuration keys, it is necessary to update the configuration directory in the flash using the **fconfig** command. See the section called “Persistent State Flash-based Configuration and Control ”.

Chapter 228. Initial Installation

Hardware Installation

Initial installation of RedBoot into the internel or external flash, or EEPROM, of target hardware is described alongside the respective target hardware documentation in the eCos and eCosPro Reference Manual.

Note

The RedBoot installation documentation of outdated hardware and hardware no longer supported has been removed from editions of this document from July 2016 onwards. If the eCos and eCosPro Reference Manual does not contain instructions on installing RedBoot for your hardware, please refer to the [RedBoot User's Guide] or [eCos Reference Manual] accompanying your eCos distribution.

What to Expect

The initial installation of RedBoot into a target's internal or external flash may normally be achieved using a hardware debugger, an application or tools provided by either the target hardware's manufacturer or the chip vendor of the target hardware, or even RedBoot's flash management commands from a revision of RedBoot running on the target hardware. In the latter case, a RAM executable RedBoot would have been loaded into the target hardware's RAM through the use of a hardware debugger from where it would have been started.

For example:

- ATMEL's SAM-BA In-system Programmer is a vendor specific software tool used for, amongst other, programming binary images into internal or external flash of ATMEL components.
- The Ronetix PEEDI is a hardware debugger that may be used to either program the internal or external flash of target hardware, or may be used to load RedBoot into the RAM (internal, external or otherwise) and commence it's execution, thereby allowing RedBoot to program itself into the flash of the target hardware.

Part LXXIII. Robust Boot Loader

Name

CYGPKG_RBL — provide a robust boot service

Description

The Robust Boot Loader (RBL) package provides an alternative to the usual RedBoot facilities for managing flash hardware, the **fis** and **fconfig** commands. It provides the following facilities:

1. An application can be stored in flash memory. This can be loaded and run automatically during RedBoot startup, or it can started manually.
2. The application can be updated in a robust fashion. The RBL code will automatically maintain a backup copy of the previous version of the application in flash. If something goes wrong during the update, for example a power cut, the system can still boot up using the backup.
3. There is also support for a block of persistent data. Applications can save a block of memory to flash and restore it later, possibly after a reboot. Again updates will happen in a robust fashion with a primary and a backup copy.
4. The RBL functionality can be accessed by application code via a suitable API. Some of the functionality is also available via RedBoot commands.

The RBL package is aimed primarily at field deployment of production systems rather than at application development. The code update facility allows the application to be updated when necessary. The persistent data can be used to hold per-unit settings and any state that should be preserved across power failures or anything else that causes a reboot. There is also some control over standard I/O: in a deployed system the serial port may be connected to some other hardware and outputting a RedBoot banner during startup could be confusing.

The package comes in two parts. When building RedBoot for a particular target platform the package detects the presence of CYGPKG_REDBOOT in the configuration and modifies the available functionality. In any other configuration, used for building the application, the package provides a set of library routines that allow access to this functionality.

The RBL code has gone through a number of versions, affecting the protocol used between the RedBoot code and the application. The version is selected via the configuration option CYGNUM_RBL_VERSION. RedBoot and the application must use the same version of RBL: an application linked against a V1 version of the RBL library routines will not work on top of a RedBoot built with the V2 code, and vice versa. By default the latest version of the protocol will be used.

RedBoot Builds

The first step in building RedBoot with RBL support is to create a RedBoot configuration appropriate for the target platform. This is somewhat target specific so the appropriate platform HAL or RedBoot documentation should be consulted for further details. Typically RedBoot should be configured for ROM startup.

Given this initial configuration the RBL package CYGPKG_RBL should now be added to the configuration, using one of the eCos configuration tools. For example with the command line tool this involves using **ecosconfig add rbl**. This involves a conflict related to the configuration option CYGPKG_REDBOOT_FLASH. The RBL code replaces the standard RedBoot flash support, based around the **fis** and **fconfig** commands, so that must be disabled.

It is also possible to enable the configuration option CYGOPT_RBL_FLASH_OVERRIDE to continue to permit use of RedBoot's standard flash management facilities, but use of this option is discouraged as it is possible to use RedBoot's flash management commands in ways that conflict with RBL. In particular RedBoot's FIS will not be aware of the location of the RBL-managed code and data blocks. Also, RBL is not aware of the location of RedBoot's FIS and fconfig data in Flash, so it is strongly recommended to use the CYGDAT_RBL_RESERVED_FLASH_BLOCKS option to reserve the flash area used for FIS and fconfig data, usually the final one or two blocks in flash. As a result of these sorts of complications, caution is strongly advised if considering use of CYGOPT_RBL_FLASH_OVERRIDE.

There are a number of other configuration options which may need to be changed at this point:

`CYGNUM_RBL_VERSION`

This determines the protocol used between the RedBoot code and the application library routines. The default is to use the latest version. If RedBoot should continue to work with existing application binaries using an older version then this configuration option should be updated to match.

`CYGNUM_RBL_FLASH_BASE`

This option is only of interest if the target hardware has multiple banks of flash. The current version of the package requires that all RBL code and data blocks reside in a single bank. By default this will be the same bank of flash that holds RedBoot, either as determined by `CYGNUM_REDBOOT_FLASH_BASE` or the first bank of flash. If `CYGNUM_RBL_FLASH_BASE` is enabled then its value will determine the bank of flash used for the RBL code and data blocks. This may be useful if for example the board has a small NOR flash for holding RedBoot and a much larger serial dataflash for holding the eCos application and its data.

`CYGDAT_RBL_RESERVED_FLASH_BLOCKS`

Some of the flash blocks should not be used by the RBL package to store code or data. On a typical system it will be necessary to reserve at least flash block 0 because that is used to hold RedBoot itself. If a single flash block is too small to hold RedBoot or if there are other blocks which should be reserved then these should be listed in the value of `CYGDAT_RBL_RESERVED_FLASH_BLOCKS`, using a comma-separated list of numbers.

Note that if there are (smaller) boot blocks, RBL will instead consider them merged together as full sized blocks. For example, if the normal block size is 64K, but there are eight 8K boot blocks, those boot blocks will be counted as if they were another single 64K block, and the block numbers used for this option must reflect that.

`CYGNUM_RBL_CODE_BLOCKS`
`CYGNUM_RBL_DATA_BLOCKS`

The RBL code inside RedBoot needs to know how many flash blocks to allocate for the application code and for the persistent data. Because it maintains both primary and backup versions the actual requirements will be double the sum of these two options. These values will be hard-coded into the versions of RedBoot that get deployed in the field and cannot easily be changed, so they should be chosen carefully.

`CYGDAT_REDBOOT_DEFAULT_IP_ADDR`

Because the flash is used for storing RBL blocks there is nowhere for Redboot to store an **fis** directory or any **fconfig** settings. Hence certain settings like the default IP address cannot be managed via **fconfig**. Instead such settings must be configured statically via configuration options. Typically this will not be a problem because RBL will be used primarily in systems deployed in the field and RedBoot is used only to start the application. If application code needs such settings then they can be held in the RBL persistent data.

`CYGDAT_REDBOOT_DEFAULT_BOOT_SCRIPT`
`CYGNUM_REDBOOT_BOOT_SCRIPT_DEFAULT_TIMEOUT`

Usually RedBoot will obtain its boot script, if any, from the **fconfig** data. This is not available when using RBL so instead the boot script should be specified using a configuration option. For a deployed system `CYGDAT_REDBOOT_DEFAULT_BOOT_SCRIPT` should be set to `"rbl boot\n"` (including the double quotes). If the flash contains a valid application then this will be loaded and run automatically.

RedBoot gives users a chance to interrupt the system before running the boot script. Typically this is irrelevant for a deployed system because there will be nothing attached to the terminal port, but it can be useful during development if for example a broken version of the application has been installed by mistake. For a deployed system it may be desirable to reduce the timeout from the default 10 seconds, so that the application restarts more quickly after a power failure.

`CYGGLO_RBL_STDIO`

This provides control over standard I/O behaviour and is described in more detail below.

Once RedBoot has been appropriately configured it can be built and installed as usual for the target platform.

Application Builds

In addition to the RedBoot extensions the RBL package provides a number of functions for use by application code. These functions interact with the main RBL code inside the currently installed RedBoot using the eCos virtual vector mechanism.

The RBL package is not part of any standard eCos configuration so it must be added explicitly to the configuration used for application builds, for example by using **ecosconfig add**. The package's CDL script will detect that `CYGPKG_REDBOOT` is not defined and hence know that the package is being used for an application build rather than for extending RedBoot. The package does not require any special support from other parts of eCos.

The package's `misc` subdirectory contains three example programs that illustrate the use of the RBL API, together with a `README` and various support files.

Standard I/O

The RBL package builds on standard RedBoot functionality such as boot scripts. Some of this functionality is desirable in a development environment but can cause problems for a system deployed in the field. For example during startup RedBoot will usually output a banner message via a serial port, and it will listen on that serial port for an incoming control-C character in case the developer wants to abort the boot script. When a system is deployed that serial port may be connected to other hardware which does not expect the banner message, or which might be sending a stream of data that happens to include the occasional control-C.

When configuring and building RedBoot it is possible to change the default standard I/O behaviour using the configuration option `CYGGLO_RBL_STDIO`. This can take one of three values:

`standard`

RedBoot I/O behaves as usual, so typically the RedBoot banner will be sent out of a serial port and RedBoot will abort the boot script if it detects an incoming control-C. Application standard I/O is also not affected so for example a `printf` call will result in data being sent out of the serial port.

`suppress_redboot`

RedBoot I/O is suppressed. Any RedBoot output such as the banner message will be discarded, and incoming characters will be ignored. When the application is started via **rbl boot** I/O is reset so the application behaves as normal.

`suppress_all`

RedBoot I/O is suppressed as before, but I/O is not reset when the application is started. Hence any `printf` or similar output produced by the application gets discarded as well (at least in the default configuration where output is sent via the HAL diagnostic pseudo-device). The serial port is now available for other purposes, for example it can be accessed via a full serial driver.

Suppressing application I/O in this way will only work if the application uses the HAL virtual vector mechanisms to route I/O activity via RedBoot. If instead the application is configured to ignore the virtual vectors, for example by disabling `CYGSEM_HAL_USE_ROM_MONITOR`, then the RedBoot `CYGGLO_RBL_OUTPUT` setting will have no effect on application I/O.

Manipulating the standard I/O behaviour like this should only be done when the application will be started automatically via an **rbl boot** command in the boot script. If instead applications will be run via a gdb session interacting with RedBoot then suppressing RedBoot I/O will interfere with the gdb traffic.

There is also a common HAL configuration option that application developers should be aware of: `CYGDBG_HAL_DEBUG_GDB_CTRLC_SUPPORT`. By default this will be enabled for a RAM startup application. It causes the system startup code to install an interrupt handler that looks for incoming control-C characters and switch control to the gdb stubs. Usually this is sensible behaviour during development, but the option should be disabled for a deployed system. Note that it is the application configuration that needs to be changed, not the RedBoot configuration.

Name

`rbl` — access RBL functionality via the RedBoot prompt

Synopsis

`rbl info`

`rbl newcode` -b <buffer> -l <length>

`rbl newdata` -b <buffer> -l <length>

`rbl boot`

`rbl condboot`

Description

A RedBoot configured with RBL support will provide a new command **rbl** with various sub-commands. These allow users to access the RBL functionality at the RedBoot prompt.

rbl info can be used to get information about the RBL subsystem, for example how many flash blocks are allocated to each code block. Typical output might look like:

```
RedBoot> rbl info
Code block A : backup
  First flash block 1 (address 0xffe40000)
  Size 52012, sequence number 3
Code block B : primary
  First flash block 3 (address 0xffec0000)
  Size 52028, sequence number 4
Data block A : primary
  First flash block 2 (address 0xffe80000)
  Size 272, sequence number 11
Data block B : backup
  First flash block 5 (address 0xfff40000)
  Size 272, sequence number 10
```

This shows that the code is currently on its fourth revision and is held in flash block 2 at the given address. Here all code and data blocks fit into a single flash block, which will not always be the case. The data is currently on revision 11.

The **rbl newcode** command can be used to install a new revision of the code, although usually this will be done by the application itself via a call to `rbl_update_code`. However the RedBoot command can be used for the initial installation or if the currently installed version is broken somehow. Typically the code will first be loaded into RAM using a RedBoot **load** command, then programmed into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
Raw file loaded 0x0000d400-0x00019f3b, assumed entry at 0x0000d400
xyzModem - CRC mode, 409(SOH)/0(STX)/0(CAN) packets, 3 retries
RedBoot> rbl newcode -b %{freememlo} -l 52028
... Erase from 0xffe40000-0xffe80000: .
... Program from 0x0000d400-0x00019f3c at 0xffe40000: .
... Program from 0x00005728-0x0000573c at 0xffe7ffec: .
```

The loaded program should be a stripped ELF executable appropriate for the target platform. The `-b` option specifies the memory location. Usually the RedBoot `%{freememlo}` variable will be used for this. The `-l` option corresponds to the file length. First the appropriate flash block or blocks are erased. Next the code is written to the flash. Finally the RBL code writes a little trailer at the end of the flash block containing a checksum, a sequence number, and similar information.

The **rbl newdata** command provides the same functionality for persistent data. Again the data is first loaded into RAM, then programmed into flash.

```
RedBoot> load -r -m ymodem -b %{freememlo}
Raw file loaded 0x0000d400-0x0000d5ba, assumed entry at 0x0000d400
xyzModem - CRC mode, 6(SOH)/0(STX)/0(CAN) packets, 3 retries
RedBoot> rbl newdata -b %{freememlo} -l 443
... Erase from 0xfff40000-0xfff80000: .
... Program from 0x0000d400-0x0000d5bb at 0xfff40000: .
... Program from 0x00005728-0x0000573c at 0xfff7ffec: .
```

The **rbl boot** command is used to load and run the current primary code block. The block should contain a stripped ELF executable which still contains the required relocation tables and the entry point, so there is no need for additional options. During development this command can be run manually to try out the current version of the application. In a production system RedBoot can be configured to run this command automatically by setting the configuration option `CYGDAT_REDBOOT_DEFAULT_BOOT_SCRIPT`. The command does not return. If it is necessary to get back to a RedBoot prompt then either the target board should be reset or the loaded application should call `rbl_reset`.

rbl condboot is a variant of **rbl boot**, available only on certain platforms. The command checks a platform-specific condition, for example the state of a jumper or a button. Depending on the condition **condboot** will either proceed to load and run the current primary code block in exactly the same way as **rbl boot**, or it will do nothing. Again in a production system RedBoot can be configured to run this command automatically by setting the configuration option `CYGDAT_REDBOOT_DEFAULT_BOOT_SCRIPT`. Following power up or reset RedBoot will normally run the current application, but if the button is held down then it will provide an interactive session instead (unless of course the boot script runs additional commands after **rbl condboot**). The interactive session allows the usual RedBoot and **rbl** commands to be executed, so for example the user can perform a ymodem transfer and then replace the primary code block via **rbl newcode**.

Jumpers and buttons are inherently platform-specific so **rbl condboot** will only be built if the platform HAL provides a suitable macro `HAL_RBL_CONDBOOT`. Typically this macro would be defined in the header file `cyg/hal/plf_io.h` which is automatically #include'd by the RBL code. The macro should take the following form:

```
#define HAL_RBL_CONDBOOT(_do_boot_)     \
    CYG_MACRO_START                     \
    …                                   \
    CYG_MACRO_END
```

`_do_boot_` should be set to 1 if the system should proceed with the bootstrap, i.e. load and run the primary code block. It should be set to 0 if **rbl condboot** should do nothing. Depending on the complexity of the hardware the macro body may involve just a couple of lines of inline code or it may involve a function call into the main platform HAL code, for example:

```
#define HAL_RBL_CONDBOOT(_do_boot_)                            \
    CYG_MACRO_START                                            \
    extern int hal_alaia_rbl_condboot(void);                   \
    _do_boot_ = hal_alaia_rbl_condboot();                      \
    CYG_MACRO_END
```

Name

RBL functions — allow applications to access RBL services

Synopsis

#include <cyg/rbl/rbl.h>

cyg_bool **rbl_update_data**(*buffer*, *length*);

cyg_bool **rbl_load_data**(*buffer*, *length*);

void **rbl_reset**();

Flash Details

rbl_get_flash_details can be used by application code to get information about the flash hardware and how it is being used by the RBL code inside RedBoot. The function takes a single argument, a pointer to an rbl_flash_details structure.

```
typedef struct rbl_flash_details {
    cyg_uint8*  rbl_flash_base;
    int         rbl_flash_block_size;
    int         rbl_flash_num_blocks;
    int         rbl_code_num_blocks;
    int         rbl_data_num_blocks;
    int         rbl_trailer_size;
} rbl_flash_details;
```

The *rbl_flash_base* field gives the location of the flash in the target's memory map. Application code does not usually need this information since the flash hardware is entirely managed by RedBoot, but it may be useful for debugging purposes.

The *rbl_flash_block_size* and *rbl_flash_num_blocks* provide further information about the flash hardware. Typical sets of values might be 8 blocks of 256K apiece, or 64 blocks of 64K. If the flash chips support smaller boot blocks then the eCos flash management code will usually treat these as a single full-size block.

rbl_code_num_blocks gives the number of flash blocks that will be used for the primary and the backup code blocks. It corresponds to the value of the CYGNUM_RBL_CODE_BLOCKS configuration option used when building RedBoot. *rbl_data_num_blocks* provides the same information for the persistent data blocks, with a value of 0 indicating that the support for persistent data was disabled.

The RBL code uses a small amount of flash memory for management purposes. This amount of memory is given by *rbl_trailer_size*. Application code can determine the maximum size of an executable using:

```
rbl_flash_details details;
if (! rbl_get_flash_details(&details)) {
    fputs("Error: failed to get RBL flash details\n", stderr);
    return false;
 }
size = (details.rbl_flash_block_size * details.rbl_code_num_blocks) -
       details.rbl_trailer_size;
```

The `rbl_get_flash_details` function will return true on success, false on failure. The most likely reason for failure is that the current RedBoot installation does not have RBL support.

Flash Blocks

`rbl_get_flash_block_purpose` can be used to find out how the RBL code inside RedBoot has allocated each flash block. Typically this is used only for debugging purposes. The argument should be a small number between 0 and `details.rbl_flash_num_blocks - 1`. The return value will be one of the following:

`rbl_flash_block_reserved`
: This flash block is reserved, for example it may hold some or all of the RedBoot code. Flash blocks can be reserved using the configuration option `CYGDAT_RBL_RESERVED_FLASH_BLOCKS` when building RedBoot.

`rbl_flash_block_code_A`
`rbl_flash_block_code_B`
`rbl_flash_block_data_A`
`rbl_flash_block_data_B`
: The flash block is used for an RBL code or data block.

`rbl_flash_block_free`
: This flash block is not used by the RBL code. It may be used by application code for other purposes.

`rbl_flash_block_invalid`
: This value will be returned if the argument to `rbl_get_flash_block_purpose` is outside the valid range. It will also be returned if the current RedBoot installation does not have RBL support.

RBL Block Details

`rbl_get_block_details` can be used to get information about a specific RBL block, for example the primary code block. The function takes two arguments. The first identifies the particular RBL block that is of interest:

`rbl_block_code_primary`
`rbl_block_code_backup`
`rbl_block_data_primary`
`rbl_block_data_backup`
: These identify an RBL block by purpose.

`rbl_block_code_A`
`rbl_block_code_B`
`rbl_block_data_A`
`rbl_block_data_B`
: These identify an RBL block by memory location. RedBoot will allocate flash blocks to code and data in the above order.

The second argument should be a pointer to an rbl_block_details structure which will be used for storing the results.

```
typedef struct rbl_block_details {
    cyg_bool    rbl_valid;
    cyg_uint32  rbl_first_flash_block;
    void*       rbl_address;
    cyg_uint32  rbl_size;
    cyg_uint32  rbl_sequence_number;
} rbl_block_details;
```

At any time a particular RBL block may or may not contain valid code or data. For example if the system has an installed application which has not yet been updated then the primary code block will be valid but the backup code block will be invalid. The other fields will only be valid if the *`rbl_valid`* flag is set.

The *`rbl_first_flash_block`* and *`rbl_address`* fields give information about where an RBL block is held in memory. If an RBL block is spread over multiple flash blocks then care has to be taken: there may be one or more reserved flash blocks in the middle of an RBL block.

The *rbl_size* field gives the current size of a code or data block. This is the actual size specified when the block was updated, not the maximum size.

The *rbl_sequence_number* is used by the RBL code to distinguish between primary and backup blocks. It may also prove useful for debugging purposes.

`rbl_get_block_details` returns true on success, false on failure. The function can fail if the current RedBoot installation does not have RedBoot support, or if an invalid argument is passed.

Updating the Code

`rbl_update_code` is used to install a new code image. It takes two arguments, a buffer and a length. The buffer should contain an ELF executable valid for the target platform, usually stripped to remove unnecessary debug information. Filling this buffer is left to application code.

The function returns true on success, false on failure. It can fail if the current RedBoot installation does not have RedBoot support, if an invalid argument is passed, or if the specified size is larger than the flash space available for a code block.

A flash update involves erasing one or more flash blocks and then programming in the new data. It is important that while this is happening no other threads or interrupt handlers access the flash hardware since that would interfere with the update. Hence interrupts will be disabled for some time while the update is happening.

Updating the Data

`rbl_update_data` is used to install a new version of the persistent data. It takes two arguments, a buffer and a length. The RBL code does not care about the contents of the buffer, this is left entirely to application code.

The function returns true on success, false on failure. It can fail if the current RedBoot installation does not have RBL support, if an invalid argument is passed, or if the specified size is larger than the flash space available for a data block. It is also possible that support for persistent data was disabled completely inside RedBoot by setting the configuration option `CYGNUM_RBL_DATA_BLOCKS` to 0.

A flash update involves erasing one or more flash blocks and then programming in the new data. It is important that while this is happening no other threads or interrupt handlers access the flash hardware since that would interfere with the update. Hence interrupts will be disabled for some time while the update is happening.

Loading the Data

`rbl_load_data` is used to load the current version of the persistent data back into memory. It takes two arguments, a buffer and a length. If there is a valid primary data block then the RBL code will transfer that data into the specified buffer. The amount of data transferred will be either the actual block size or the length argument, whichever is smaller.

The function returns true on success, false on failure. It can fail if the current RedBoot installation does not have RBL support, if an invalid argument is passed, or if there is no current primary data block.

Restarting the Hardware

`rbl_reset` can be used to restart the hardware. Typically this is used after a code update. The function takes no arguments and does not return.

Name

`V2 RBL functions` — allow applications to access RBL services

`cyg_bool` **`rbl_load_data_block`**`(`*`where`*`,` *`length`*`);`

`cyg_bool` **`rbl_update_data_end`**`();`

Description

The original V1 API required single buffers for all update and load operations. This proved unduly restrictive, especially when installing a new code image obtained over a network, because there would be no guarantee that a single buffer of the required size could be dynamically allocated when required. Hence the API was extended for V2 with vector functions, allowing the code and data to be spread over multiple buffers, and with transaction functions, allowing new code images to be installed a piece at a time.

Vector Functions

The three vector functions `rbl_update_codeV`, `rbl_update_dataV` and `rbl_load_dataV` work in terms of a series of buffers rather than a single buffer. For example `rbl_load_data` is equivalent to:

```
cyg_bool
rbl_load_data(cyg_uint8* where, cyg_uint32 size)
{
    cyg_uint8    dataV[1];
    cyg_uint32   sizesV[1];

    dataV[0]  = where;
    sizesV[0] = size;
    return rbl_load_dataV(1, dataV, sizesV);
}
```

Obviously the vector functions become rather more useful for counts greater than 1. The update functions still require that all of the new images are resident in memory, but they no longer have to be in a single contiguous buffer.

When updating some flash drivers may impose limitations on the sizes. For example if the target hardware has a single 16-bit wide flash device then the flash driver may require that all flash write operations happen in multiples of 2 bytes, and the entries in the `sizesV` array should satisfy this requirement.

Transaction Functions

The transaction functions begin/block/end allow RBL operations to be performed in stages. For example `rbl_load_dataV` is equivalent to:

```
cyg_bool
rbl_load_dataV(cyg_uint32 count, cyg_uint8* whereV[], cyg_uint32 sizesV[])
{
    cyg_uint32 i;

    if (! rbl_load_data_begin()) {
        return false;
    }
    for (i = 0; i < count; i++) {
        if (! rbl_load_data_block(whereV[i], sizesV[i])) {
            return false;
        }
    }
    return rbl_load_data_end();
}
```

The begin function must be called at the start of a function. At any one time there can be only one code update, one data update, and one data load in progress, and the begin function will block if another thread is performing a conflicting RBL operation. Once the transaction is started the application can perform one or more block operations, and the transaction should normally be committed with an end function call. For an update the begin function will erase the appropriate flash blocks, the block function will write data to the flash, and the end function will write trailer data containing size, checksum and sequence number. At that point the image becomes the new primary code or data RBL block.

As an additional restriction, `rbl_update_data_end` will block if some other thread is currently loading data. This avoids confusion since otherwise that thread would end up loading data that is no longer primary, and it also avoids problems if another update operation is started immediately.

Unlike the simple or vector update functions, the transaction functions do not require that all of the new image is present in memory at the same time. Instead it is possible to begin a transaction, fetch the first part of the image over the network and install that, fetch the next part, and so on. If the application is unable to complete an update, for example because the network connection is lost, then there should be a call to the abort function instead of to the end function. When a transaction is aborted no trailer gets written to flash so the new image remains invalid and the old image stays as the primary.

As with the vector operations the flash driver may impose limitations on the size arguments to `rbl_update_code_block` and `rbl_update_block`. For example if the target hardware uses a 16-bit wide flash chip then the size argument may have to be a multiple of two bytes.

Error Conditions

All of the RBL functions return a simple boolean to indicate failure. In reality failures are unlikely, but can be caused by the following:

1. The currently installed RedBoot was built without RBL functionality so there is no code in the system to keep track of RBL images and install new ones.

2. RedBoot uses a different version of the RBL protocol, for example V1 when the application has been built with V2.
3. The RedBoot RBL code was unable to initialize the system. This can happen if the actual hardware does not match the RedBoot configuration, for example if the flash chips actually present are smaller than expected and cannot hold all the code and data blocks specified by the `CYGDAT_RBL_RESERVED_FLASH_BLOCKS`, `CYGNUM_RBL_CODE_BLOCKS` and `CYGNUM_RBL_DATA_BLOCKS` configuration options.
4. An attempt is made to load or update data when RedBoot has been configured with zero RBL data blocks,
5. An attempt is made to load more data than is actually present in the current data image, or to install a new image that does not fit in the number of configured flash blocks.
6. An unexpected error occurs inside the flash driver, for example an attempt to erase a flash block fails.

For the transaction functions, if an error occurs then the transaction is automatically aborted. There is no need for the application to call `rbl_update_code_abort` or `rbl_update_data_abort` explicitly, or to end a load operation.

Part LXXIV. RedBoot Extra Initialization

Name

CYGPKG_RBINIT — provide extra RedBoot initialization

Description

The RedBoot Extra Initialisation (RBINIT) package provides extra default initialization for RedBoot. This may be used to execute a set of initial commands, or to perform any additional platform or system specific initialization. The RBINIT package is aimed primarily at field deployment of production systems rather than at application development.

Building RedBoot

The first step in building RedBoot with RBINIT support is to create a RedBoot configuration appropriate for the target platform. This is somewhat target specific so the appropriate platform HAL or RedBoot documentation should be consulted for further details. Typically RedBoot should be configured for ROM startup.

Given this initial configuration the RBINIT package `CYGPKG_RBINIT` should now be added to the configuration, using one of the eCos configuration tools. For example with the command line tool this involves using **ecosconfig add rbinit**.

There are a number of other configuration options which may be changed at this point:

`CYGGLO_RBINIT_STDIO_DISABLE`

> This option causes all output generated during the extra initialization to be discarded. Turn this option off to get output for debugging purposes.

`CYGPKG_RBINIT_PRI`

> This option selects the priority of the extra initialization routine. The value of this option may either be `RedBoot_INIT_BEFORE_NET` or `RedBoot_INIT_AFTER_NET` which, as the names imply, cause the extra initialization to occur either before or after any network device is initialized.

Once RedBoot has been appropriately configured it can be built and installed as usual for the target platform.

Extra Initialization Function

The purpose of the extra initialization package is to execute the `rbinit_exec()` function. A default version of this function is contained in the `rbinit_exec.c` file within this package in the source repository.

The default content of this function provides support for loading and executing primary or secondary applications from a filesystem. The default function will first attempt to mount a JFFS2 filesystem named “jffs2” in the RedBoot FIS table. If that fails it will attempt to mount the first partition of an IDE hard disk using a FAT filesystem. Finally if that fails it will attempt to mount a RAM filesystem, although it will be empty. If a filesystem has been successfully mounted, it will attempt to load into RAM and run a program named “`app.primary`” from the root of the filesystem, and if that fails, a program named “`app.secondary`”.

A customized version of this function may be provided instead by using one of the following methods:

- Editing the file directly in the source repository.
- Adding an equivalent function in your application build and ensure its object file is linked into your application. This will cause the default implementation of `rbinit_exec()` provided in this package to be overridden. You may wish to use the version in this package as a template to start with.
- By copying the `rbinit_exec.c` file into the configuration's build tree and editing it there.

Part LXXV. Unity

Chapter 230. Configuration

This chapter shows how to incorporate the Unity support into an eCos configuration, and how to configure it once included.

Configuration Overview

The Unity support is contained in a single eCos package `CYGPKG_UNITY`. However, some functionality is dependant on other eCos features. e.g. the eCos dynamic memory allocator.

Quick Start

Incorporating the Unity support into your application is straightforward. The essential starting point is to incorporate the Unity eCos package (`CYGPKG_UNITY`) into your configuration.

This may be achieved directly using **ecosconfig add** on the command line, or the **Build->Packages…** menu item within the eCos Configuration Tool.

Depending on the Unity package configuration other packages may be required. The package requires that the `CYGPKG_INFRA` packages is included in the eCos application configuration.

Chapter 231. eCos port

Overview

The goal for the `CYGPKG_UNITY` package is to avoid where possible having to have any core Unity source file changes made specifically for eCos. This is to ensure that re-imports of newer versions of the library sources involve minimal effort. The files are as provided in the official Unity release package as imported, with the following exceptions:

1. Files have been moved, unmodified, to create a standard eCos package tree structure to integrate with the eCosPro build environment

   Only **relevant** files from the original project have been included in the eCos package.

The current Unity version provided by the eCos package is the github tagged release `v2.5.2` (released 26th January 2021).

The original project homepage can be found on github: Unity

The release package was downloaded from the github project page: releases/tag/v2.5.2

The following table highlights the files taken from the Unity package and their new location within the eCos `CYGPKG_UNITY` package:

Original github	**eCos package**
`src/unity.h`	`include/unity.h`
`src/unity_internals.h`	`include/unity_internals.h`
`extras/memory/src/unity_internals.h`	`include/unity_memory.h`
`extras/fixture/src/unity_fixture.h`	`include/unity_fixture.h`
`extras/fixture/src/unity_fixture_internals.h`	`include/unity_fixure_internals.h`
`src/unity.c`	`src/unity.c`
`extras/memory/src/unity_memory.c`	`src/unity_memory.c`
`extras/fixture/src/unity_fixture.c`	`src/unity_fixture.c`

Chapter 232. Test Programs

Test Programs

Some Unity specific tests are built and can be used to verify correct operation of the library.

The original Unity `examples` are all very slight variations of the same underlying example for different build environments, so we only provide a single variant for the eCos tests build.

1. `unity_core`

   This test exercises the core Unity functionality.

2. `unity_core_memory`

   This test exercises the extra memory functionality if CYGPKG_UNITY_MEMORY is enabled.

3. `unity_floats`

   This test exercises the single-precision floating point `(float)` support when `UNITY_EXCLUDE_FLOAT` is **not** defined.

4. `unity_doubles`

   This test exercises the double-precision floating point `(double)` support when `UNITY_EXCLUDE_DOUBLE` is **not** defined.

5. `unity_integers`

   This test exercises the basic integer assert functionality.

6. `unity_integers_64`

   This test exercises the 64-bit support when `UNITY_SUPPORT_64` **is** defined, which is the case when using the default eCos `unity_config.h` configuration header.

7. `unity_memory`

   This test exercises the memory equality support. It is not related to the extra `CYGPKG_UNIT_MEMORY` functionality, but tests the core memory buffer assert support.

8. `unity_strings`

   This test exercises the core string functionality.

9. `example_1_1`

   This test is a simple example of using Unity based on the original Unity package `examples/example_1/test/TestProductionCode.c` source.

10. `example_1_2`

    This test is a simple example of using Unity based on the original Unity package `examples/example_1/test/TestProductionCode2.c` source.

Part LXXVI. Synthetic Target Architecture

Table of Contents

Chapter 233. eCos Synthetic Target

Name

The eCos synthetic target — Overview

Description

Usually eCos runs on either a custom piece of hardware, specially designed to meet the needs of a specific application, or on a development board of some sort that is available before the final hardware. Such boards have a number of things in common:

1. Obviously there has to be at least one processor to do the work. Often this will be a 32-bit processor, but it can be smaller or larger. Processor speed will vary widely, depending on the expected needs of the application. However the exact processor being used tends not to matter very much for most of the development process: the use of languages such as C or C++ means that the compiler will handle those details.

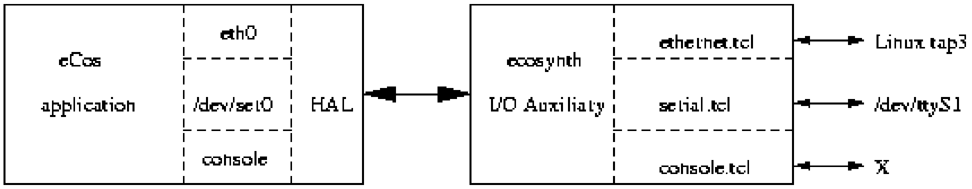
2. There needs to be memory for code and for data. A typical system will have two different types of memory. There will be some non-volatile memory such as flash, EPROM or masked ROM. There will also be some volatile memory such as DRAM or SRAM. Often the code for the final application will reside in the non-volatile memory and all of the RAM will be available for data. However updating non-volatile memory requires a non-trivial amount of effort, so for much of the development process it is more convenient to burn suitable firmware, for example RedBoot, into the non-volatile memory and then use that to load the application being debugged into RAM, alongside the application data and a small area reserved for use by the firmware.

3. The platform must provide certain mimimal I/O facilities. Most eCos configurations require a clock signal of some sort. There must also be some way of outputting diagnostics to the user, often but not always via a serial port. Unless special debug hardware is being used, source level debugging will require bidirectional communication between a host machine and the target hardware, usually via a serial port or an ethernet device.

4. All the above is not actually very useful yet because there is no way for the embedded device to interact with the rest of the world, except by generating diagnostics. Therefore an embedded device will have additional I/O hardware. This may be fairly standard hardware such as an ethernet or USB interface, or special hardware designed specifically for the intended application, or quite often some combination. Standard hardware such as ethernet or USB may be supported by eCos device drivers and protocol stacks, whereas the special hardware will be driven directly by application code.

Much of the above can be emulated on a typical PC running Linux. Instead of running the embedded application being developed on a target board of some sort, it can be run as a Linux process. The processor will be the PC's own processor, for example an x86, and the memory will be the process' address space. Some I/O facilities can be emulated directly through system calls. For example clock hardware can be emulated by setting up a `SIGALRM` signal, which will cause the process to be interrupted at regular intervals. This emulation of real hardware will not be particularly accurate, the number of cpu cycles available to the eCos application between clock ticks will vary widely depending on what else is running on the PC, but for much development work it will be good enough.

Other I/O facilities are provided through an I/O auxiliary process, ecosynth, that gets spawned by the eCos application during startup. When an eCos device driver wants to perform some I/O operation, for example send out an ethernet packet, it sends a request to the I/O auxiliary. That is an ordinary Linux application so it has ready access to all normal Linux I/O facilities. To emulate a device interrupt the I/O auxiliary can raise a `SIGIO` signal within the eCos application. The HAL's interrupt subsystem installs a signal handler for this, which will then invoke the standard eCos ISR/DSR mechanisms. The I/O auxiliary is based around Tcl scripting, making it easy to extend and customize. It should be possible to configure the synthetic target so that its I/O functionality is similar to what will be available on the final target hardware for the application being developed.



A key requirement for synthetic target code is that the embedded application must not be linked with any of the standard Linux libraries such as the GNU C library: that would lead to a confusing situation where both eCos and the Linux libraries attempted to provide functions such as `printf`. Instead the synthetic target support must be implemented directly on top of the Linux kernels' system call interface. For example, the kernel provides a system call for write operations. The actual function `write` is implemented in the system's C library, but all it does is move its arguments on to the stack or into certain registers and then execute a special trap instruction such as `int 0x80`. When this instruction is executed control transfers into the kernel, which will validate the arguments and perform the appropriate operation. Now, a synthetic target application cannot be linked with the system's C library. Instead it contains a function `cyg_hal_sys_write` which, like the C library's `write` function, pushes its arguments on to the stack and executes the trap instruction. The Linux kernel cannot tell the difference, so it will perform the I/O operation requested by the synthetic target. With appropriate knowledge of what system calls are available, this makes it possible to emulate the required I/O facilities. For example, spawning the ecosynth I/O auxiliary involves system calls `cyg_hal_sys_fork` and `cyg_hal_sys_execve`, and sending a request to the auxiliary uses `cyg_hal_sys_write`.

In many ways developing for the synthetic target is no different from developing for real embedded targets. eCos must be configured appropriately: selecting a suitable target such as **`i386linux`** will cause the configuration system to load the appropriate packages for this hardware; this includes an architectural HAL package and a platform-specific package; the architectural package contains generic code applicable to all Linux platforms, whereas the platform package is for specific Linux implementations such as the x86 version and contains any processor-specific code. Selecting this target will also bring in some device driver packages. Other aspects of the configuration such as which API's are supported are determined by the template, by adding and removing packages, and by fine-grained configuration.

In other ways developing for the synthetic target can be much easier than developing for a real embedded target. For example there is no need to worry about building and installing suitable firmware on the target hardware, and then downloading and debugging the actual application over a serial line or a similar connection. Instead an eCos application built for the synthetic target is mostly indistinguishable from an ordinary Linux program. It can be run simply by typing the name of the executable file at a shell prompt. Alternatively you can debug the application using whichever version of gdb is provided by your Linux distribution. There is no need to build or install special toolchains. Essentially using the synthetic target means that the various problems associated with real embedded hardware can be bypassed for much of the development process.

The eCos synthetic target provides emulation, not simulation. It is possible to run eCos in suitable architectural simulators but that involves a rather different approach to software development. For example, when running eCos on the psim PowerPC simulator you need appropriate cross-compilation tools that allow you to build PowerPC executables. These are then loaded into the simulator which interprets every instruction and attempts to simulate what would happen if the application were running on real hardware. This involves a lot of processing overhead, but depending on the functionality provided by the simulator it can give very accurate results. When developing for the synthetic target the executable is compiled for the PC's own processor and will be executed at full speed, with no need for a simulator or special tools. This will be much faster and somewhat simpler than using an architectural simulator, but no attempt is made to accurately match the behaviour of a real embedded target.

Name

Installation — Preparing to use the synthetic target

Host-side Software

To get the full functionality of the synthetic target, users must build and install the I/O auxiliary ecosynth and various support files. It is possible to develop applications for the synthetic target without the auxiliary, but only limited I/O facilities will be available. The relevant code resides in the `host` subdirectory of the synthetic target architectural HAL package, and building it involves the standard **configure**, **make**, and **make install** steps.

There are two main ways of building the host-side software. It is possible to build both the generic host-side software and all package-specific host-side software, including the I/O auxiliary. in a single build tree. This involves using the **configure** script at the toplevel of the eCos repository, which will automatically search the `packages` hierarchy for host-side software. For more information on this, see the `README.host` file at the top of the repository. Note that if you have an existing build tree which does not include the synthetic target architectural HAL package then it will be necessary to rerun the toplevel configure script: the search for appropriate packages happens at configure time.

The alternative is to build just the host-side for this package. This involves creating a suitable build directory and running the **configure** script. Note that building directly in the source tree is not allowed.

```
$ cd <somewhere suitable>
$ mkdir synth_build
$ cd synth_build
$ <repo<>/packages/hal/synth/arch/<version>/host/configure <options>
$ make
$ make install
```

The code makes extensive use of Tcl/TK and requires version 8.3 or later. This is checked by the **configure** script. By default it will use the system's Tcl installation in `/usr`. If a different, more recent Tcl installation should be used then its location can be specified using the options `--with-tcl=<path>`, `--with-tcl-header=<path>` and `--with-tcl-lib=<path>`. For more information on these options see the `README.host` file at the toplevel of the eCos repository.

Some users may also want to specify the install location using a `--prefix=<path>` option. The default install location is `/usr/local`. It is essential that the `bin` subdirectory of the install location is on the user's search `PATH`, otherwise the eCos application will be unable to locate and execute the I/O auxiliary ecosynth.

Because ecosynth is run automatically by an eCos application rather than explicitly by the user, it is not installed in the `bin` subdirectory itself. Instead it is installed below `libexec`, together with various support files such as images. At configure time it is usually possible to specify an alternative location for `libexec` using `--exec-prefix=<path>` or `--libexecdir=<path>`. These options should not be used for this package because the eCos application is built completely separately and does not know how the host-side was configured.

Toolchain

When developing eCos applications for a normal embedded target it is necessary to use a suitable cross-compiler and related tools such as the linker. Developing for the synthetic target is easier because you can just use the standard GNU tools (gcc, g++, ld, …) which were provided with your Linux distribution, or which you used to build your own Linux setup. Any reasonably recent version of the tools, for example gcc 2.96(Red Hat) as shipped with Red Hat Linux 7, should be sufficient.

There is one important limitation when using these tools: current gdb will not support debugging of eCos threads on the synthetic target. As far as gdb is concerned a synthetic target application is indistinguishable from a normal Linux application, so it assumes that any threads will be created by calls to the Linux `pthread_create` function provided by the C library. Obviously this is not the case since the application is never linked with that library. Therefore gdb never notices the eCos thread mechanisms and assumes the application is single-threaded. Fixing this is possible but would involve non-trivial changes to gdb.

Theoretically it is possible to develop synthetic target applications on, for example, a PC running Windows and then run the resulting executables on another machine that runs Linux. This is rarely useful: if a Linux machine is available then usually that machine will also be used for building ecos and the application. However, if for some reason it is necessary or desirable to build on another machine then this requires a suitable cross-compiler and related tools. If the application will be running on a typical PC with an x86 processor then a suitable configure triplet would be **`i686-pc-linux-gnu`**. The installation instructions for the various GNU tools should be consulted for further information.

Hardware Preparation

Preparing a real embedded target for eCos development can be tricky. Often the first step is to install suitable firmware, usually RedBoot. This means creating and building a special configuration for eCos with the RedBoot template, then somehow updating the target's flash chips with the resulting RedBoot image. Typically it will also be necessary to get a working serial connection, and possibly set up ethernet as well. Although usually none of the individual steps are particularly complicated, there are plenty of ways in which things can go wrong and it can be hard to figure out what is actually happening. Of course some board manufacturers make life easier for their developers by shipping hardware with RedBoot preinstalled, but even then it is still necessary to set up communication between host and target.

None of this is applicable to the synthetic target. Instead you can just build a normal eCos configuration, link your application with the resulting libraries, and you end up with an executable that you can run directly on your Linux machine or via gdb. A useful side effect of this is that application development can start before any real embedded hardware is actually available.

Typically the memory map for a synthetic target application will be set up such that there is a read-only ROM region containing all the code and constant data, and a read-write RAM region for the data. The default locations and sizes of these regions depend on the specific platform being used for development. Note that the application always executes out of ROM: on a real embedded target much of the development would involve running RedBoot firmware there, with application code and data loaded into RAM; usually this would change for the final system; the firmware would be replaced by the eCos application itself, configured for ROM bootstrap, and it would perform the appropriate hardware initialization. Therefore the synthetic target actually emulates the behaviour of a final system, not of a development environment. In practice this is rarely significant, although having the code in read-only memory can help catch some problems in application code.

Name

Execution — Arguments and configuration files

Description

The procedure for configuring and building eCos and an application for the synthetic target is the same as for any other eCos target. Once an executable has been built it can be run like any Linux program, for example from a shell prompt,

```
$ ecos_hello <options>
```

or using gdb:

```
$ gdb --nw --quiet --args ecos_hello <options>
(gdb) run
Starting program: ecos_hello <options>
```

By default use of the I/O auxiliary is disabled. If its I/O facilities are required then the option `--io` must be used.

Note

In future the default behaviour may change, with the I/O auxiliary being started by default. The option `--nio` can be used to prevent the auxiliary from being run.

Command-line Arguments

The syntax for running a synthetic target application is:

```
$ <ecos_app> [options] [-- [app_options]]
```

Command line options up to the `--` are passed on to the I/O auxiliary. Subsequent arguments are not passed on to the auxiliary, and hence can be used by the eCos application itself. The full set of arguments can be accessed through the variables `cyg_hal_sys_argc` and `cyg_hal_sys_argv`.

The following options are accepted as standard:

`--io`
This option causes the eCos application to spawn the I/O auxiliary during HAL initialization. Without this option only limited I/O will be available.

`--nio`
This option prevents the eCos application from spawning the I/O auxiliary. In the current version of the software this is the default.

`-nw`, `--no-windows`
The I/O auxiliary can either provide a graphical user interface, or it can run in a text-only mode. The default is to provide the graphical interface, but this can be disabled with `-nw`. Emulation of some devices, for example buttons connected to digital inputs, requires the graphical interface.

`-w`, `--windows`
The `-w` causes the I/O auxiliary to provide a graphical user interface. This is the default.

`-v`, `--version`
The `-v` option can be used to determine the version of the I/O auxiliary being used and where it has been installed. Both the auxiliary and the eCos application will exit immediately.

`-h`, `--help`
`-h` causes the I/O auxiliary to list all accepted command-line arguments. This happens after all devices have been initialized, since the host-side support for some of the devices may extend the list of recognised options. After this both the auxiliary and the eCos application will exit immediately. This option implies `-nw`.

`-k`, `--keep-going`

If an error occurs in the I/O auxiliary while reading in any of the configuration files or initializing devices, by default both the auxiliary and the eCos application will exit. The `-k` option can be used to make the auxiliary continue in spite of errors, although obviously it may not be fully functional.

`-nr`, `--no-rc`

Normally the auxiliary processes two user configuration files during startup: `initrc.tcl` and `mainrc.tcl`. This can be suppressed using the `-nr` option.

`-x`, `--exit`

When providing a graphical user interface the I/O auxiliary will normally continue running even after the eCos application has exited. This allows the user to take actions such as saving the current contents of the main text window. If run with `-x` then the auxiliary will exit as soon the application exits.

`-nx`, `--no-exit`

When the graphical user interface is disabled with `-nw` the I/O auxiliary will normally exit immediately when the eCos application exits. Without the graphical frontend there is usually no way for the user to interact directly with the auxiliary, so there is no point in continuing to run once the eCos application will no longer request any I/O operations. Specifying the `-nx` option causes the auxiliary to continue running even after the application has exited.

`-V`, `--verbose`

This option causes the I/O auxiliary to output some additional information, especially during initialization.

`-l <file>`, `--logfile <file>`

Much of the output of the eCos application and the I/O auxiliary is simple text, for example resulting from eCos `printf` or `diag_printf` calls. When running in graphical mode this output goes to a central text window, and can be saved to a file or edited via menus. The `-l` can be used to automatically generate an additional logfile containing all the text. If graphical mode is disabled then by default all the text just goes to the current standard output. Specifying `-l` causes most of the text to go into a logfile instead, although some messages such as errors generated by the auxiliary itself will still go to stdout as well.

`-t <file>`, `--target <file>`

During initialization the I/O auxiliary reads in a target definition file. This file holds information such as which Linux devices should be used to emulate the various eCos devices. The `-t` option can be used to specify which target definition should be used for the current run, defaulting to `default.tdf`. It is not necessary to include the `.tdf` suffix, this will be appended automatically if necessary.

`-geometry <geometry>`

This option can be used to control the size and position of the main window, as per X conventions.

The I/O auxiliary loads support for the various devices dynamically and some devices may accept additional command line arguments. Details of these can be obtained using the `-h` option or by consulting the device-specific documentation. If an unrecognised command line argument is used then a warning will be issued.

The Target Definition File

The eCos application will want to access devices such as `eth0` or `/dev/ser0`. These need to be mapped on to Linux devices. For example some users may all traffic on the eCos `/dev/ser0` serial device to go via the Linux serial device `/dev/ttyS1`, while ethernet I/O for the eCos `eth0` device should be mapped to the Linux ethertap device `tap3`. Some devices may need additional configuration information, for example to limit the number of packets that should be buffered within the I/O auxiliary. The target definition file provides all this information.

By default the I/O auxiliary will look for a file `default.tdf`. An alternative target definition can be specified on the command line using `-t`, for example:

```
$ bridge_app --io -t twineth
```

A .tdf suffix will be appended automatically if necessary. If a relative pathname is used then the I/O auxiliary will search for the target definition file in the current directory, then in ~/.ecos/synth/, and finally in its install location.

A typical target definition file might look like this:

```
synth_device console {
    # appearance -foreground white -background black
    filter trace {^TRACE:.*} -foreground HotPink1 -hide 1
}

synth_device ethernet {
    eth0 real eth1
    eth1 ethertap tap4 00:01:02:03:FE:06

    ## Maximum number of packets that should be buffered per interface.
    ## Default 16
    #max_buffer 32

    ## Filters for the various recognised protocols.
    ## By default all filters are visible and use standard colours.
    filter ether  -hide 0
    #filter arp    -hide 1
    #filter ipv4   -hide 1
    #filter ipv6   -hide 1
}
```

A target definition file is actually a Tcl script that gets run in the main interpreter of the I/O auxiliary during initialization. This provides a lot of flexibility if necessary. For example the script could open a socket to a resource management server of some sort to determine which hardware facilities are already in use and adapt accordingly. Another possibility is to adapt based on command line arguments. Users who are not familiar with Tcl programming should still be able to edit a simple target definition file without too much difficulty, using a mixture of cut'n'paste, commenting or uncommenting various lines, and making small edits such as changing tap4 to eth2.

Each type of device will have its own entry in the target definition file, taking the form:

```
synth_device <device type> {
    <options>
}
```

The documentaton for each synthetic target device should provide details of the options available for that device, and often a suitable fragment that can be pasted into a target definition file and edited. There is no specific set of options that a given device will always provide. However in practice many devices will use common code exported by the main I/O auxiliary, or their implementation will involve some re-use of code for an existing device. Hence certain types of option are common to many devices.

A good example of this is filters, which control the appearance of text output. The above target definition file defines a filter trace for output from the eCos application. The regular expression will match output from the infrastructure package's tracing facilities when CYGDBG_USE_TRACING and CYGDBG_INFRA_DEBUG_TRACE_ASSERT_SIMPLE are enabled. With the current settings this output will not be visible by default, but can be made visible using the menu item System Filters. If made visible the trace output will appear in an unusual colour, so users can easily distinguish the trace output from other text. All filters accept the following options:

-hide [0|1]

This controls whether or not text matching this filter should be invisible by default or not. At run-time the visibility of each filter can be controlled using the System Filters menu item.

-foreground <colour>

This specifies the foreground colour for all text matching this filter. The colour can be specified using an RGB value such as #F08010, or a symbolic name such as "light steel blue". The X11 utility showrgb can be used to find out about the available colours.

-background <colour>

This specifies the background colour for all text matching the filter. As with -foreground the colour can be specified using a symbolic name or an RGB value.

Some devices may create their own subwindows, for example to monitor ethernet traffic or to provide additional I/O facilities such as emulated LED's or buttons. Usually the target definition file can be used to control the layout of these windows.

The I/O auxiliary will not normally warn about **synth_device** entries in the target definition file for devices that are not actually needed by the current eCos application. This makes it easier to use a single file for several different applications. However it can lead to confusion if an entry is spelled incorrectly and hence does not actually get used. The `-V` command line option can be used to get warnings about unused device entries in the target definition file.

If the body of a **synth_device** command contains an unrecognised option and the relevant device is in use, the I/O auxiliary will always issue a warning about such options.

User Configuration Files

During initialization the I/O auxiliary will execute two user configuration files, `initrc.tcl` and `mainrc.tcl`. It will look for these files in the directory `~/.ecos/synth/`. If that directory does not yet exist it will be created and populated with initial dummy files.

Both of these configuration files are Tcl scripts and will be run in the main interpreter used by the I/O auxiliary itself. This means that they have full access to the internals of the auxiliary including the various Tk widgets, and they can perform file or socket I/O if desired. The section Writing New Devices - host contains information about the facilities available on the host-side for writing new device drivers, and these can also be used in the initialization scripts.

The `initrc.tcl` script is run before the auxiliary has processed any requests from the eCos application, and hence before any devices have been instantiated. At this point the generic command-line arguments has been processed, the target definition file has been read in, and the hooks functionality has been initialized. If running in graphical mode the main window will have been created, but has been withdrawn from the screen to allow new widgets to be added without annoying screen flicker. A typical `initrc.tcl` script could add some menu or toolbar options, or install a hook function that will be run when the eCos application exits.

The `mainrc.tcl` script is run after eCos has performed all its device initialization and after C++ static constructors have run, and just before the call to `cyg_start` which will end up transferring control to the application itself. A typical `mainrc.tcl` script could look at what interrupt vectors have been allocated to which devices and create a little monitor window that shows interrupt activity.

Session Information

When running in graphical mode, the I/O auxiliary will read in a file `~/.ecos/synth/guisession` containing session information. This file should not normally be edited manually, instead it gets updated automatically when the auxiliary exits. The purpose of this file is to hold configuration options that are manipulated via the graphical interface, for example which browser should be used to display online help.

Warning

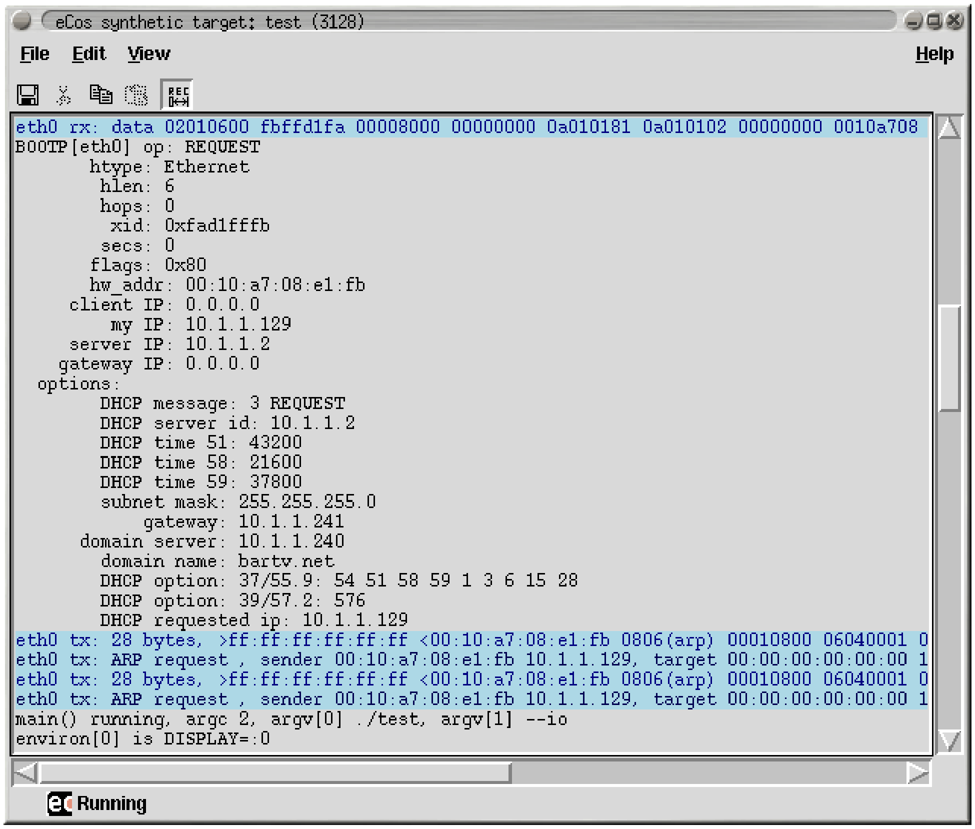
GUI session functionality is not yet available in the current release. When that functionality is fully implemented it is possible that some target definition file options may be removed, to be replaced by graphical editing via a suitable preferences dialog, with the current settings saved in the session file.

Name

User Interface — Controlling the I/O Auxiliary

Description

The synthetic target auxiliary is designed to support both extensions and user customization. Support for the desired devices is dynamically loaded, and each device can extend the user interface. For example it is possible for a device to add menu options, place new buttons on the toolbar, create its own sub-window within the overall layout, or even create entire new toplevel windows. These subwindows or toplevels could show graphs of activity such as interrupts or packets being transferred. They could also allow users to interact with the eCos application, for example by showing a number of buttons which will be mapped on to digital inputs in the eCos application. Different applications will have their own I/O requirements, changing the host-side support files that get loaded and that may modify the user interface. The I/O auxiliary also reads in user configuration scripts which can enhance the interface in the same way. Therefore the exact user interface will depend on the user and on the eCos application being run. However the overall layout is likely to remain the same.



```

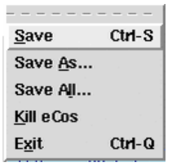
The title bar identifies the window as belonging to an eCos synthetic target application and lists both the application name and its process id. The latter is especially useful if the application was started directly from a shell prompt and the user now wants to attach a gdb session. The window has a conventional menu bar with the usual entries, plus a toolbar with buttons for common operations such as cut and paste. Balloon help is supported.

There is a central text window, possibly surrounded by various sub-windows for various devices. For example there could be a row of emulated LED's above the text window, and monitors of ethernet traffic and interrupt activity on the right. At the bottom of the window is a status line, including a small animation that shows whether or not the eCos application is still running.

Menus and the Toolbar

Usually there will be four menus on the menu bar: File , Edit, View and Help.

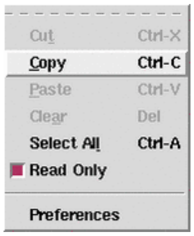


On the File menu there are three entries related to saving the current contents of the central text window. Save is used to save the currently visible contents of the text window. Any text that is hidden because of filters will not be written to the savefile. If there has been a previous Save or Save As operation then the existing savefile will be re-used, otherwise the user will be asked to select a suitable file. Save As also saves just the currently visible contents but will always prompt the user for a filename. Save All can be used to save the full contents of the text window, including any text that is currently hidden. It will always prompt for a new filename, to avoid confusion with partial savefiles.

Usually the eCos application will be run from inside gdb or from a shell prompt. Killing off the application while it is being debugged in a gdb session is not a good idea, it would be better to use gdb's own **kill** command. Alternatively the eCos application itself can use the `CYG_TEST_EXIT` or `cyg_hal_sys_exit` functionality. However it is possible to terminate the application from the I/O auxiliary using Kill eCos . A clean shutdown will be attempted, but that can fail if the application is currently halted inside gdb or if it has crashed completely. As a last resort `SIGKILL` will be used.

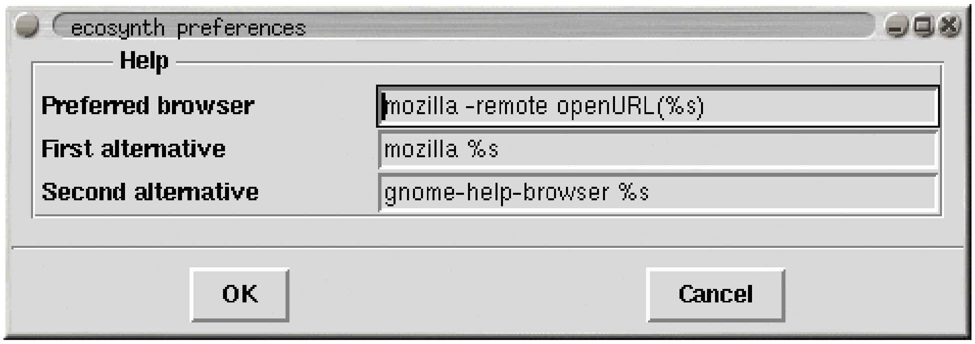
When operating in graphical mode the I/O auxiliary will normally continue to run even after the eCos application has exited. This allows the user to examine the last few lines of output, and perhaps perform actions such as saving the output to a file. The Exit menu item can be used to shut down the auxiliary. Note that this behaviour can be changed with command line arguments `--exit` and `--no-exit`.

If Exit is used while the eCos application is still running then the I/O auxiliary will first attempt to terminate the application cleanly, and then exit.



The Edit menu contains the usual entries for text manipulation: Cut, Copy , Paste, Clear and Select All. These all operate on the central text window. By default this window cannot be edited so the cut, paste and clear operations are disabled. If the user wants to edit the contents of the text window then the Read Only checkbutton should be toggled.

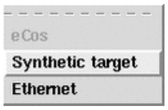
The Preferences menu item brings up a miscellaneous preferences dialog. One of the preferences relates to online help: the I/O auxiliary does not currently have a built-in html viewer; instead it will execute an external browser of some sort. With the example settings shown, the I/O auxiliary will first attempt to interact with an existing mozilla session. If that fails it will try to run a new mozilla instance, or as a last result use the Gnome help viewer.



Preferred browser: mozilla -remote openURL(%s)
First alternative: mozilla %s
Second alternative: gnome-help-browser %s

The View menu contains the System Filters entry, used to edit the settings for the current filters.

The Help menu can be used to activate online help for eCos generally, for the synthetic target as a whole, and for specific devices supported by the generic target. The Preferences dialog can be used to select the browser that will be used.



Note

At the time of writing there is no well-defined toplevel index file for all eCos documentation. Hence the relevant menu item is disabled. Documentation for the synthetic target and the supported devices is stored as part of the package itself so can usually be found fairly easily. It may be necessary to set the `ECOS_REPOSITORY` environment variable.

The Main Text Window

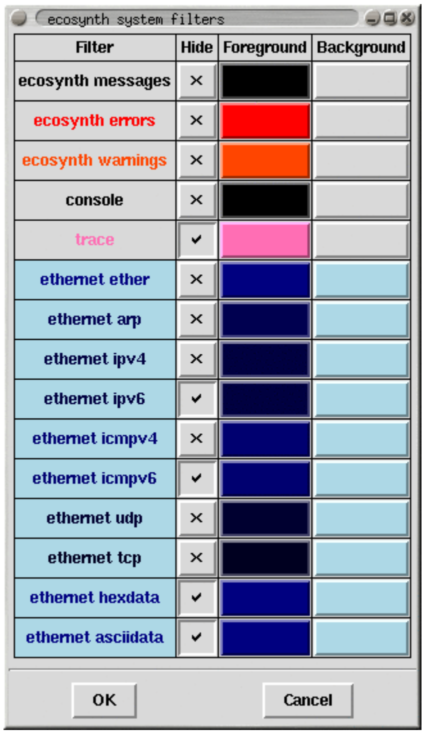
The central text window holds the console output from the eCos application: the screen shot above shows DHCP initialization data from the TCP/IP stack, and some output from the `main` thread at the bottom. Some devices can insert text of their own, for example the ethernet device support can be configured to show details of incoming and outgoing packets. Mixing the output from the eCos application and the various devices can make it easier to understand the order in which events occur.

The appearance of text from different sources can be controlled by means of filters, and it is also possible to hide some of the text. For example, if tracing is enabled in the eCos configuration then the trace output can be given its own colour scheme, making it stand out from the rest of the output. In addition the trace output is generally voluminous so it can be hidden by default, made visible only to find out more about what was happening when a particular problem occurred. Similarly the ethernet device support can output details of the various packets being transferred, and using a different background colour for this output again makes it easier to distinguish from console output.

The default appearance for most filters is controlled via the target definition file. An example entry might be:

```
filter trace {^TRACE:.*} -foreground HotPink1 -hide 1
```

The various colours and the hide flag for each filter can be changed at run-time, using the System Filters item on the View menu. This will bring up a dialog like the following:



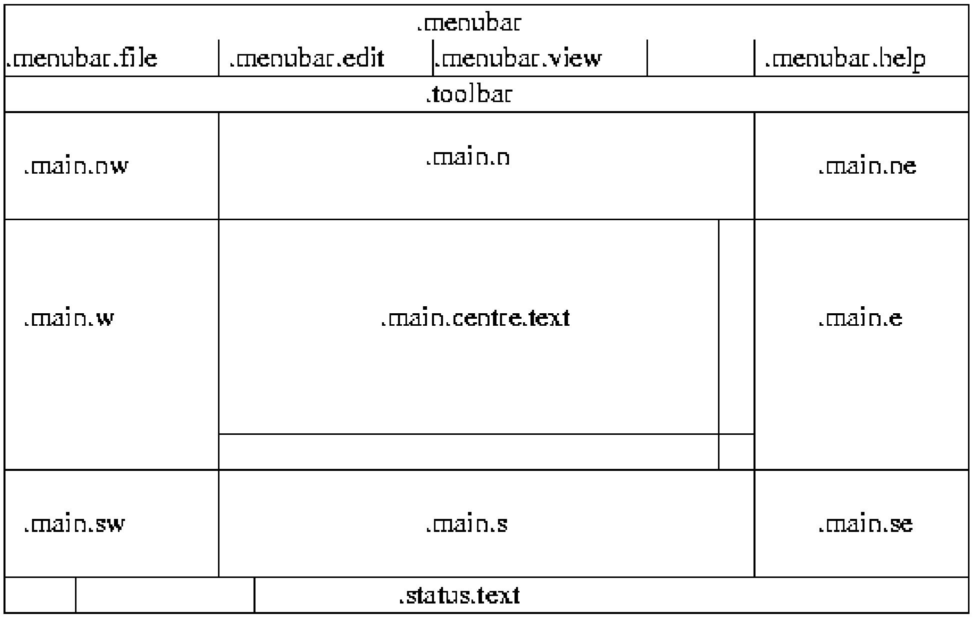
Filter	Hide	Foreground	Background
ecosynth messages	✕	⬛	⬜
ecosynth errors	✕	🟥	⬜
ecosynth warnings	✕	🟧	⬜
console	✕	⬛	⬜
trace	✓	🟪	⬜
ethernet ether	✕	🟦	🟦
ethernet arp	✕	🟦	🟦
ethernet ipv4	✕	⬛	🟦
ethernet ipv6	✓	⬛	🟦
ethernet icmpv4	✕	🟦	🟦
ethernet icmpv6	✓	🟦	🟦
ethernet udp	✕	⬛	🟦
ethernet tcp	✕	⬛	🟦
ethernet hexdata	✓	🟦	🟦
ethernet asciidata	✓	🟦	🟦

It should be noted that the text window is line-oriented, not character-oriented. If an eCos application sends a partial line of text then that will remain buffered until a newline character is received, rather than being displayed immediately. This avoids confusion when there is concurrent output from several sources.

By default the text window is read-only. This means it will not allow cut, paste and clear operations, and keyboard input will be ignored. The Edit menu has a checkbutton Read Only which can be toggled to allow write operations. For example, a user could type in a reminder of what was happening at this time, or paste in part of a gdb session. Such keyboard input does not get forwarded to the eCos application: if the latter requires keyboard input then that should happen via a separate keyboard device.

Positioning Optional Windows

Some devices may create their own subwindows, for example to monitor ethernet traffic or to provide additional I/O facilities such as emulated LED's or buttons. Usually the target definition file can be used to control the layout of these windows. This requires an understanding of the overall layout of the display.



Subwindows are generally packed in one of eight frames surrounding the central text window: `.main.nw`, `.main.n`, `.main.ne`, `.main.w`, `.main.e`, `.main.sw`, `.main.s`, and `.main.se`. To position a row of LED's above the text window and towards the left, a target definition file could contain an entry such as:

```
synth_device led {
    pack -in .main.n -side left
    …
}
```

Similarly, to put a traffic monitor window on the right of the text window would involve something like:

```
    …
    monitor_pack -in .main.e -side bottom
    …
```

Often it will be sufficient to specify a container frame and one of `left`, `right`, `top` or `bottom`. Full control over the positioning requires an understanding of Tcl/Tk and in particular the packing algorithm, and an appropriate reference work should be consulted.

Global Settings

Note

This section still to be written - it should document the interaction between X resources and ecosynth, and how users can control settings such as the main foreground and background colours.

Name

The console device — Show output from the eCos application

Description

The eCos application can generate text output in a variety of ways, including calling `printf` or `diag_printf`. When the I/O auxiliary is enabled the eCos startup code will instantiate a console device to process all such output. If operating in text mode the output will simply go to standard output, or to a logfile if the `-l` command line option is specified. If operating in graphical mode the output will go to the central text window, and optionally to a logfile as well. In addition it is possible to control the appearance of the main text via the target definition file, and to install extra filters for certain types of text.

It should be noted that the console device is line-oriented, not character-oriented. This means that outputting partial lines is not supported, and some functions such as `fflush` and `setvbuf` will not operate as expected. This limitation prevents much possible confusion when using filters to control the appearance of the text window, and has some performance benefits - especially when the eCos application generates a great deal of output such as when tracing is enabled. For most applications this is not a problem, but it is something that developers should be aware of.

The console device is output-only, it does not provide any support for keyboard input. If the application requires keyboard input then that should be handled by a separate eCos device package and matching host-side code.

Installation

The eCos side of the console device is implemented by the architectural HAL itself, in the source file `synth_diag.c`, rather than in a separate device package. Similarly the host-side implementation, `console.tcl`, is part of the architectural HAL's host-side support. It gets installed automatically alongside the I/O auxiliary itself, so no separate installation procedure is required.

Target Definition File

The target definition file can contain a number of entries related to the console device. These are all optional, they only control the appearance of text output. If such control is desired then the relevant options should appear in the body of a **synth_device** entry:

```
synth_device console {
    …
}
```

The first option is **appearance**, used to control the appearance of any text generated by the eCos application that does not match one of the installed filters. This option takes the same argument as any other filter, for example:

```
synth_device console {
    appearance -foreground white -background black
    …
}
```

Any number of additional filters can be created with a **filter** option, for example:

```
synth_device console {
    …
    filter trace {^TRACE:.*} -foreground HotPink1 -hide 1
    …
}
```

The first argument gives the new filter a name which will be used in the filters dialog. Filter names should be unique. The second argument is a Tcl regular expression. The console support will match each line of eCos output against this regular expression, and if a match is found then the filter will be used for this line of text. The above example matches any line of output that begins with `TRACE:`, which corresponds to the eCos infrastructure's tracing facilities. The remaining options control the desired appearance for matched text. If some eCos output matches the regular expressions for several different filters then only the first match will be used.

Target-side Configuration Options

There are no target-side configuration options related to the console device.

Command Line Arguments

The console device does not use any command-line arguments.

Hooks

The console device does not provide any hooks.

Additional Tcl Procedures

The console device does not provide any additional Tcl procedures that can be used by other scripts.

Name

cyg_hal_sys_xyz — Access Linux system facilities

Synopsis

#include <cyg/hal/hal_io.h>

```
int cyg_hal_sys_xyzzy(...);
```

Description

On a real embedded target eCos interacts with the hardware by peeking and poking various registers, manipulating special regions of memory, and so on. The synthetic target does not access hardware directly. Instead I/O and other operations are emulated by making appropriate Linux system calls. The HAL package exports a number of functions which allow other packages, or even application code, to make these same system calls. However this facility must be used with care: any code which calls, for example, `cyg_hal_sys_write` will only ever run on the synthetic target; that functionality is obviously not provided on any real hardware because there is no underlying Linux kernel to implement it.

The synthetic target only provides a subset of the available system calls, specifically those calls which have proved useful to implement I/O emulation. This subset can be extended fairly easily if necessary. All of the available calls, plus associated data structures and macros, are defined in the header file `cyg/hal/hal_io.h`. There is a simple convention: given a Linux system call such as `open`, the synthetic target will prefix `cyg_hal_sys` and provide a function with that name. The second argument to the `open` system call is a set of flags such as `O_RDONLY`, and the header file will define a matching constant `CYG_HAL_SYS_O_RDONLY`. There are also data structures such as cyg_hal_sys_sigset_t, matching the Linux data structure sigset_t.

In most cases the functions provided by the synthetic target behave as per the documentation for the Linux system calls, and section 2 of the Linux man pages can be consulted for more information. There is one important difference: typically the documentation will say that a function returns `-1` to indicate an error, with the actual error code held in `errno`; the actual underlying system call and hence the `cyg_hal_sys_xyz` provided by eCos instead returns a negative number to indicate an error, with the absolute value of that number corresponding to the error code; usually it is the C library which handles this and manipulates errno, but of course synthetic target applications are not linked with that Linux library.

However, there are some exceptions. The Linux kernel has evolved over the years, and some of the original system call interfaces are no longer appropriate. For example the original `select` system call has been superseded by `_newselect`, and that is what the `select` function in the C library actually uses. The old call is still available to preserve binary compatibility but, like the C library, eCos makes use of the new one because it provides the appropriate functionality. In an attempt to reduce confusion the eCos function is called `cyg_hal_sys__newselect`, in other words it matches the official system call naming scheme. The authoritive source of information on such matters is the Linux kernel sources themselves, and especially its header files.

eCos packages and applications should never `#include` Linux header files directly. For example, doing a `#include </usr/include/fcntl.h>` to access additional macros or structure definitions, or alternatively manipulating the header file search path, will lead to problems because the Linux header files are likely to duplicate and clash with definitions in the eCos headers. Instead the appropriate functionality should be extracted from the Linux headers and moved into either `cyg/hal/hal_io.h` or into application code, with suitable renaming to avoid clashes with eCos names. Users should be aware that large-scale copying may involve licensing complications.

Adding more system calls is usually straightforward and involves adding one or more lines to the platform-specific file in the appropriate platform HAL, for example `syscall-i386-linux-1.0.S`. However it is necessary to do some research first about the exact interface implemented by the system call, because of issues such as old system calls that have been superseded. The required information can usually be found fairly easily by searching through the Linux kernel sources and possibly the GNU C library sources.

Name

Writing New Devices — extending the synthetic target, target-side

Synopsis

#include <cyg/hal/hal_io.h>

`int` **`synth_auxiliary_instantiate`**`(`*`package`*`, `*`version`*`, `*`device`*`, `*`instance`*`, `*`data`*`);`

Description

In some ways writing a device driver for the synthetic target is very similar to writing one for a real target. Obviously it has to provide the standard interface for that class of device, so for example an ethernet device has to provide `can_send`, `send`, `recv` and similar functions. Many devices will involve interrupts, so the driver contains ISR and DSR functions and will call `cyg_drv_interrupt_create`, `cyg_drv_interrupt_acknowledge`, and related functions.

In other ways writing a device driver for the synthetic target is very different. Usually the driver will not have any direct access to the underlying hardware. In fact for some devices the I/O may not involve real hardware, instead everything is emulated by widgets on the graphical display. Therefore the driver cannot just peek and poke device registers, instead it must interact with host-side code by exchanging message. The synthetic target HAL provides a function `synth_auxiliary_xchgmsg` for this purpose.

Initialization of a synthetic target device driver is also very different. On real targets the device hardware already exists when the driver's initialization routine runs. On the synthetic target it is first necessary to instantiate the device inside the I/O auxiliary, by a call to `synth_auxiliary_instantiate`. That function performs a special message exchange with the I/O auxiliary, causing it to load a Tcl script for the desired type of device and run an instantiation procedure within that script.

Use of the I/O auxiliary is optional: if the user does not specify `--io` on the command line then the auxiliary will not be started and hence most I/O operations will not be possible. Device drivers should allow for this possibility, for example by just discarding any data that gets written. The HAL exports a flag `synth_auxiliary_running` which should be checked.

Instantiating a Device

Device instantiation should happen during the C++ prioritized static constructor phase of system initialization, before control switches to `cyg_user_start` and general application code. This ensures that there is a clearly defined point at which the I/O auxiliary knows that all required devices have been loaded. It can then perform various consistency checks and clean-ups, run the user's `mainrc.tcl` script, and make the main window visible.

For standard devices generic eCos I/O code will call the device initialization routines at the right time, iterating through the `DEVTAB` table in a static constructor. The same holds for network devices and file systems. For more custom devices code like the following can be used:

```
#include <cyg/infra/cyg_type.h>
class mydev_init {
  public:
    mydev_init() {
        …
    }
};
static mydev_init mydev_init_object CYGBLD_ATTRIB_INIT_PRI(CYG_INIT_IO);
```

Some care has to be taken because the object `mydev_init_object` will typically not be referenced by other code, and hence may get eliminated at link-time. If the code is part of an eCos package then problems can be avoided by putting the relevant file in `libextras.a`:

```
cdl_package CYGPKG_DEVS_MINE {
    …
    compile -library=libextras.a init.cxx
}
```

For devices inside application code the same can be achieved by linking the relevant module as a `.o` file rather than putting it in a `.a` library.

In the device initialization routine the main operation is a call to `synth_auxiliary_instantiate`. This takes five arguments, all of which should be strings:

`package`
: For device drivers which are eCos packages this should be a directory path relative to the eCos repository, for example `devs/eth/synth/ecosynth`. This will allow the I/O auxiliary to find the various host-side support files for this package within the install tree. If the device is application-specific and not part of an eCos package then a NULL pointer can be used, causing the I/O auxiliary to search for the support files in the current directory and then in `~/.ecos/synth` instead.

`version`
: For eCos packages this argument should be the version of the package that is being used, for example `current`. A simple way to get this version is to use the `SYNTH_MAKESTRING` macro on the package name. If the device is application-specific then a NULL pointer should be used.

`device`
: This argument specifies the type of device being instantiated, for example `ethernet`. More specifically the I/O auxiliary will append a `.tcl` suffix, giving the name of a Tcl script that will handle all I/O requests for the device. If the application requires several instances of a type of device then the script will only be loaded once, but the script will contain an instantiation procedure that will be called for each device instance.

`instance`
: If it is possible to have multiple instances of a device then this argument identifies the particular instance, for example `eth0` or `eth1`. Otherwise a NULL pointer can be used.

`data`
: This argument can be used to pass additional initialization data from eCos to the host-side support. This is useful for devices where eCos configury must control certain aspects of the device, rather than host-side configury such as the target definition file, because eCos has compile-time dependencies on some or all of the relevant options. An example might be an emulated frame buffer where eCos has been statically configured for a particular screen size, orientation and depth. There is no fixed format for this string, it will be interpreted only by the device-specific host-side Tcl script. However the string length should be limited to a couple of hundred bytes to avoid possible buffer overflow problems.

Typical usage would look like:

```
    if (!synth_auxiliary_running) {
      return;
    }
    id = synth_auxiliary_instantiate("devs/eth/synth/ecosynth",
             SYNTH_MAKESTRING(CYGPKG_DEVS_ETH_ECOSYNTH),
             "ethernet",
             "eth0",
             (const char*) 0);
```

The return value will be a device identifier which can be used for subsequent calls to `synth_auxiliary_xchgmsg`. If the device could not be instantiated then `-1` will be returned. It is the responsibility of the host-side software to issue suitable diagnostics explaining what went wrong, so normally the target-side code should fail silently.

Once the desired device has been instantiated, often it will be necessary to do some additional initialization by a message exchange. For example an ethernet device might need information from the host-side about the MAC address, the interrupt vector, and whether or not multicasting is supported.

Communicating with a Device

Once a device has been instantiated it is possible to perform I/O by sending messages to the appropriate Tcl script running inside the auxiliary, and optionally getting back replies. I/O operations are always initiated by the eCos target-side, it is not possible for the host-side software to initiate data transfers. However the host-side can raise interrupts, and the interrupt handler inside the target can then exchange one or more messages with the host.

There is a single function to perform I/O operations, `synth_auxiliary_xchgmsg`. This takes the following arguments:

`device_id`
: This should be one of the identifiers returned by a previous call to `synth_auxiliary_instantiate`, specifying the particular device which should perform some I/O.

`request`
: Request are just signed 32-bit integers that identify the particular I/O operation being requested. There is no fixed set of codes, instead each type of device can define its own.

`arg1`
`arg2`
: For some requests it is convenient to pass one or two additional parameters alongside the request code. For example an ethernet device could define a multicast-all request, with `arg1` controlling whether this mode should be enabled or disabled. Both `arg1` and `arg2` should be signed 32-bit integers, and their values are interpreted only by the device-specific Tcl script.

`txdata`
`txlen`
: Some I/O operations may involve sending additional data, for example an ethernet packet. Alternatively a control operation may require many more parameters than can easily be encoded in `arg1` and `arg2`, so those parameters have to be placed in a suitable buffer and extracted at the other end. `txdata` is an arbitrary buffer of `txlen` bytes that should be sent to the host-side. There is no specific upper bound on the number of bytes that can be sent, but usually it is a good idea to allocate the transmit buffer statically and keep transfers down to at most several kilobytes.

`reply`
: If the host-side is expected to send a reply message then `reply` should be a pointer to an integer variable and will be updated with a reply code, a simple 32-bit integer. The synthetic target HAL code assumes that the host-side and target-side agree on the protocol being used: if the host-side will not send a reply to this message then the `reply` argument should be a NULL pointer; otherwise the host-side must always send a reply code and the `reply` argument must be valid.

`rxdata`
`rxlen`
: Some operations may involve additional data coming from the host-side, for example an incoming ethernet packet. `rxdata` should be a suitably-sized buffer, and `rxlen` a pointer to an integer variable that will end up containing the number of bytes that were actually received. These arguments will only be used if the host-side is expected to send a reply and hence the `reply` argument was not NULL.

`max_rxlen`
: If a reply to this message is expected and that reply may involve additional data, `max_rxlen` limits the size of that reply. In other words, it corresponds to the size of the `rxdata` buffer.

Most I/O operations involve only some of the arguments. For example transmitting an ethernet packet would use the `request`, `txdata` and `txlen` fields (in addition to `device_id` which is always required), but would not involve `arg1` or `arg2` and no reply would be expected. Receiving an ethernet packet would involve `request`, `rxdata`, `rxlen` and `max_rxlen`; in addition `reply` is needed to get any reply from the host-side at all, and could be used to indicate whether or not any more packets are buffered up. A control operation such as enabling multicast mode would involve `request` and `arg1`, but none of the remaining arguments.

Interrupt Handling

Interrupt handling in the synthetic target is much the same as on a real target. An interrupt object is created using cyg_drv_interrupt_create, attached, and unmasked. The emulated device - in other words the Tcl script running inside the I/O auxiliary - can raise an interrupt. Subject to interrupts being disabled and the appropriate vector being masked, the system will invoke the specified ISR function. The synthetic target HAL implementation does have some limitations: there is no support for nested interrupts, interrupt priorities, or a separate interrupt stack. Supporting those might be appropriate when targetting a simulator that attempts to model real hardware accurately, but not for the simple emulation provided by the synthetic target.

Of course the actual implementation of the ISR and DSR functions will be rather different for a synthetic target device driver. For real hardware the device driver will interact with the device by reading and writing device registers, managing DMA engines, and the like. A synthetic target driver will instead call synth_auxiliary_xchgmsg to perform the I/O operations.

There is one other significant difference between interrupt handling on the synthetic target and on real hardware. Usually the eCos code will know which interrupt vectors are used for which devices. That information is fixed when the target hardware is designed. With the synthetic target interrupt vectors are assigned to devices on the host side, either via the target definition file or dynamically when the device is instantiated. Therefore the initialization code for a target-side device driver will need to request interrupt vector information from the host-side, via a message exchange. Such interrupt vectors will be in the range 1 to 31 inclusive, with interrupt 0 being reserved for the real-time clock.

Name

Writing New Devices — extending the synthetic target, host-side

Description

On the host-side adding a new device means writing a Tcl/Tk script that will handle instantiation and subsequent requests from the target-side. These scripts all run in the same full interpreter, extended with various commands provided by the main I/O auxiliary code, and running in an overall GUI framework. Some knowledge of programming with Tcl/Tk is required to implement host-side device support.

Some devices can be implemented entirely using a Tcl/Tk script. For example, if the final system will have some buttons then those can be emulated in the synthetic target using a few Tk widgets. A simple emulation could just have the right number of buttons in a row. A more advanced emulation could organize the buttons with the right layout, perhaps even matching the colour scheme, the shapes, and the relative sizes. With other devices it may be necessary for the Tcl script to interact with an external program, because the required functionality cannot easily be accessed from a Tcl script. For example interacting with a raw ethernet device involves some `ioctl` calls, which is easier to do in a C program. Therefore the `ethernet.tcl` script which implements the host-side ethernet support spawns a separate program `rawether`, written in C, that performs the low-level I/O. Raw ethernet access usually also requires root privileges, and running a small program `rawether` with such privileges is somewhat less of a security risk than the whole eCos application, the I/O auxiliary, and various dynamically loaded Tcl scripts.

Because all scripts run in a single interpreter, some care has to be taken to avoid accidental sharing of global variables. The best way to avoid problems is to have each script create its own Tcl namespace, so for example the `ethernet.tcl` script creates a namespace `ethernet::` and all variables and procedures reside in this namespace. Similarly the I/O auxiliary itself makes use of a `synth::` namespace.

Building and Installation

When an eCos device driver or application code instantiates a device, the I/O auxiliary will attempt to load a matching Tcl script. The third argument to `synth_auxiliary_instantiate` specifies the type of device, for example `ethernet`, and the I/O auxiliary will append a `.tcl` suffix and look for a script `ethernet.tcl`.

If the device being instantiated is application-specific rather than part of an eCos package, the I/O auxiliary will look first in the current directory, then in `~/.ecos/synth`. If it is part of an eCos package then the auxiliary will expect to find the Tcl script and any support files below `libexec/ecos` in the install tree - note that the same install tree must be used for the I/O auxiliary itself and for any device driver support. The directory hierarchy below `libexec/ecos` matches the structure of the eCos repository, allowing multiple versions of a package to be installed to allow for incompatible protocol changes.

The preferred way to build host-side software is to use **autoconf** and **automake**. Usually this involves little more than copying the `acinclude.m4`, `configure.in` and `Makefile.am` files from an existing package, for example the synthetic target ethernet driver, and then making minor edits. In `acinclude.m4` it may be necessary to adjust the path to the root of the repository. `configure.in` may require a similar change, and the `AC_INIT` macro invocation will have to be changed to match one of the files in the new package. A critical macro in this file is `ECOS_PACKAGE_DIRS` which will set up the correct install directory. `Makefile.am` may require some more changes, for example to specify the data files that should be installed (including the Tcl script). These files should then be processed using **aclocal**, **autoconf** and **automake** in that order. Actually building the software then just involves **configure**, **make** and **make install**, as per the instructions in the toplevel `README.host` file.

To assist developers, if the environment variable `ECOSYNTH_DEVEL` is set then a slightly different algorithm is used for locating device Tcl scripts. Instead of looking only in the install tree the I/O auxiliary will also look in the source tree, and if the script there is more recent than the installed version it will be used in preference. This allows developers to modify the master copy without having to run **make install** all the time.

If a script needs to know where it has been installed it can examine the Tcl variable `synth::device_install_dir` . This variable gets updated whenever a script is loaded, so if the value may be needed later it should be saved away in a device-specific variable.

Instantiation

The I/O auxiliary will **source** the device-specific Tcl script when the eCos application first attempts to instantiate a device of that type. The script should return a procedure that will be invoked to instantiate a device.

```
namespace eval ethernet {
    …
    proc instantiate { id instance data } {
        …
        return ethernet::handle_request
    }
}
return ethernet::instantiate
```

The `id` argument is a unique identifier for this device instance. It will also be supplied on subsequent calls to the request handler, and will match the return value of `synth_auxiliary_instantiate` on the target side. A common use for this value is as an array index to support multiple instances of this types of device. The `instance` and `data` arguments match the corresponding arguments to `synth_auxiliary_instantiate` on the target side, so a typical value for `instance` would be `eth0`, and `data` is used to pass arbitrary initialization parameters from target to host.

The actual work done by the instantiation procedure is obviously device-specific. It may involve allocating an interrupt vector, adding a device-specific subwindow to the display, opening a real Linux device, establishing a socket connection to some server, spawning a separate process to handle the actual I/O, or a combination of some or all of the above.

If the device is successfully instantiated then the return value should be a handler for subsequent I/O requests. Otherwise the return value should be an empty string, and on the target-side the `synth_auxiliary_instantiate` call will return `-1`. The script is responsible for providing diagnostics explaining why the device could not be instantiated.

Handling Requests

When the target-side calls `synth_auxiliary_xchgmsg`, the I/O auxiliary will end up calling the request handler for the appropriate device instance returned during instantiation:

```
namespace eval ethernet {
    …
    proc handle_request { id request arg1 arg2 txdata txlen max_rxlen } {
        …
        if { <some condition> } {
            synth::send_reply <error code> 0 ""
            return
        }
        …
        synth::send_reply <reply code> $packet_len $packet
    }
    …
}
```

The `id` argument is the same device id that was passed to the instantiate function, and is typically used as an array index to access per-device data. The `request`, `arg1`, `arg2`, and `max_rxlen` are the same values that were passed to `synth_auxiliary_xchgmsg` on the target-side, although since this is a Tcl script obviously the numbers have been converted to strings. The `txdata` buffer is raw data as transmitted by the target, or an empty string if the I/O operation does not involve any additional data. The Tcl procedures **binary scan**, **string index** and **string range** may be found especially useful when manipulating this buffer. `txlen` is provided for convenience, although **string length $txdata** would give the same information.

The code for actually processing the request is of course device specific. If the target does not expect a reply then the request handler should just return when finished. If a reply is expected then there should be a call to **synth::send_reply**. The first argument is the reply code, and will be turned into a 32-bit integer on the target side. The second argument specifies the length of the reply data, and the third argument is the reply data itself. For some devices the Tcl procedure **binary format** may prove useful. If the reply involves just a code and no additional data, the second and third arguments should be `0` and an empty string respectively.

Attempts to send a reply when none is expected, fail to send a reply when one is expected, or send a reply that is larger than the target-side expects, will all be detected by the I/O auxiliary and result in run-time error messages.

It is not possible for the host-side code to send unsolicited messages to the target. If host-side code needs attention from the target, for example because some I/O operation has completed, then an interrupt should be raised.

Interrupts

The I/O auxiliary provides a number of procedures for interrupt handling.

```
synth::interrupt_allocate <name>
synth::interrupt_get_max
synth::interrupt_get_devicename <vector>
synth::interrupt_raise <vector>
```

synth::interrupt_allocate is normally called during device instantiation, and returns the next free interrupt vector. This can be passed on to the target-side device driver in response to a suitable request, and it can then install an interrupt handler on that vector. Interrupt vector `0` is used within the target-side code for the real-time clock, so the allocated vectors will start at `1`. The argument identifies the device, for example `eth0`. This is not actually used internally, but can be accessed by user-initialization scripts that provide some sort of interrupt monitoring facility (typically via the `interrupt` hook). It is possible for a single device to allocate multiple interrupt vectors, but the synthetic target supports a maximum of 32 such vectors.

synth::interrupt_get_max returns the highest interrupt vector that has been allocated, or `0` if there have been no calls to **synth::interrupt_allocate**. **synth::interrupt_get_devicename** returns the string that was passed to **synth::interrupt_allocate** when the vector was allocated.

synth::interrupt_raise can be called any time after initialization. The argument should be the vector returned by **synth::interrupt_allocate** for this device. It will activate the normal eCos interrupt handling mechanism so, subject to interrupts being enabled and this particular interrupt not being masked out, the appropriate ISR will run.

Note

At this time it is not possible for a device to allocate a specific interrupt vector. The order in which interrupt vectors are assigned to devices effectively depends on the order in which the eCos devices get initialized, and that may change if the eCos application is rebuilt. A future extension may allow devices to allocate specific vectors, thus making things more deterministic. However that will introduce new problems, in particular the code will have to start worrying about requests for vectors that have already been allocated.

Flags and Command Line Arguments

The generic I/O auxiliary code will process the standard command line arguments, and will set various flag variables accordingly. Some of these should be checked by device-specific scripts.

`synth::flag_gui`

This is set when the I/O auxiliary is operating in graphical mode rather than text mode. Some functionality such as filters and the GUI layout are only available in graphical mode.

```
    if { $synth::flag_gui } {
        …
    }
```

`synth::flag_verbose`

The user has requested additional information during startup. Each device driver can decide how much additional information, if any, should be produced.

`synth::flag_keep_going`

The user has specified `-k` or `--keep-going`, so even if an error occurs the I/O auxiliary and the various device driver scripts should continue running if at all possible. Diagnostics should still be generated.

Some scripts may want to support additional command line arguments. This facility should be used with care since there is no way to prevent two different scripts from trying to use the same argument. The following Tcl procedures are available:

```
synth::argv_defined <name>
synth::argv_get_value <name>
```

synth::argv_defined returns a boolean to indicate whether or not a particular argument is present. If the argument is the name part of a name/value pair, an = character should be appended. Typical uses might be:

```
    if { [synth::argv_defined "-o13"] } {
        …
    }

    if { [synth::argv_defined "-mark="] } {
        …
    }
```

The first call checks for a flag `-o13` or `--o13` - the code treats options with single and double hyphens interchangeably. The second call checks for an argument of the form `-mark=<value>` or a pair of arguments `-mark <value>`. The value part of a name/value pair can be obtained using **synth::argv_get_value**;

```
    variable speed 1
    if { [synth::argv_defined "-mark="] } {
        set mark [synth::argv_get_value "-mark="]
        if { ![string is integer $mark] || ($mark < 1) || ($mark > 9) } {
            <issue diagnostic>
        } else {
            set speed $mark
        }
    }
```

synth::argv_get_value should only be used after a successful call to **synth::argv_defined**. At present there is no support for some advanced forms of command line argument processing. For example it is not possible to repeat a certain option such as `-v` or `--verbose`, with each occurrence increasing the level of verbosity.

If a script is going to have its own set of command-line arguments then it should give appropriate details if the user specifies `--help`. This involves a hook function:

```
namespace eval my_device {
    proc help_hook { } {
        puts " -o13          : activate the omega 13 device"
        puts " -mark <speed> : set speed. Valid values are 1 to 9."
    }

    synth::hook_add "help" my_device::help_hook
}
```

The Target Definition File

Most device scripts will want to check entries in the target definition file for run-time configuration information. The Tcl procedures for this are as follows:

```
synth::tdf_has_device <name>
synth::tdf_get_devices
synth::tdf_has_option <devname> <option>
synth::tdf_get_option <devname> <option>
synth::tdf_get_options <devname> <option>
synth::tdf_get_all_options <devname>
```

synth::tdf_has_device can be used to check whether or not the target definition file had an entry `synth_device <name>`. Usually the name will match the type of device, so the `console.tcl` script will look for a target definition file entry `console`. **synth::tdf_get_devices** returns a list of all device entries in the target definition file.

Once it is known that the target definition file has an entry for a certain device, it is possible to check for options within the entry. **synth::tdf_has_option** just checks for the presence, returning a boolean:

```
    if { [synth::tdf_has_option "console" "appearance"] } {
        …
    }
```

synth::tdf_get_option returns a list of all the arguments for a given option. For example, if the target definition file contains an entry:

```
synth_device console {
    appearance -foreground white -background black
    filter trace {^TRACE:.*} -foreground HotPink1 -hide 1
    filter xyzzy {.*xyzzy.*} -foreground PapayaWhip
}
```

A call **synth::tdf_get_option console appearance** will return the list `{-foreground white -background black}`. This list can be manipulated using standard Tcl routines such as **llength** and **lindex**. Some options can occur multiple times in one entry, for example `filter` in the `console` entry. **synth::tdf_get_options** returns a list of lists, with one entry for each option occurrence. **synth::tdf_get_all_options** returns a list of lists of all options. This time each entry will include the option name as well.

The I/O auxiliary will not issue warnings about entries in the target definition file for devices which were not loaded, unless the `-v` or `--verbose` command line argument was used. This makes it easier to use a single target definition file for different applications. However the auxiliary will issue warnings about options within an entry that were ignored, because often these indicate a typing mistake of some sort. Hence a script should always call **synth::tdf_has_option**, **synth::;tdf_get_option** or **synth::tdf_get_options** for all valid options, even if some of the options preclude the use of others.

Hooks

Some scripts may want to take action when particular events occur, for example when the eCos application has exited and there is no need for further I/O. This is supported using hooks:

```
namespace eval my_device {
    …
    proc handle_ecos_exit { arg_list } {
        …
    }
    synth::hook_add "ecos_exit" my_device::handle_ecos_exit
}
```

It is possible for device scripts to add their own hooks and call all functions registered for those hooks. A typical use for this is by user initialization scripts that want to monitor some types of I/O. The available Tcl procedures for manipulating hooks are:

```
synth::hook_define <name>
synth::hook_defined <name>
synth::hook_add <name> <function>
synth::hook_call <name> <args>
```

synth::hook_define creates a new hook with the specified name. This hook must not already exist. **synth::hook_defined** can be used to check for the existence of a hook. **synth::hook_add** allows other scripts to register a callback function for this hook, and **synth::hook_call** allows the owner script to invoke all such callback functions. A hook must already be defined before a callback can be attached. Therefore typically device scripts will only use standard hooks and their own hooks, not hooks created by some other device, because the order of device initialization is not sufficiently defined. User scripts run from `mainrc.tcl` can use any hooks that have been defined.

synth::hook_call takes an arbitrary list of arguments, for example:

```
    synth::hook_call "ethernet_rx" "eth0" $packet
```

The callback function will always be invoked with a single argument, a list of the arguments that were passed to **synth::hook_call**:

```
    proc rx_callback { arg_list } {
        set device [lindex $arg_list 0]
        set packet [lindex $arg_list 1]
    }
```

Although it might seem more appropriate to use Tcl's **eval** procedure and have the callback functions invoked with the right number of arguments rather than a single list, that would cause serious problems if any of the data contained special characters such as `[` or `$`. The current implementation of hooks avoids such problems, at the cost of minor inconvenience when writing callbacks.

A number of hooks are defined as standard. Some devices will add additional hooks, and the device-specific documentation should be consulted for those. User scripts can add their own hooks if desired.

`exit`
: This hook is called just before the I/O auxiliary exits. Hence it provides much the same functionality as `atexit` in C programs. The argument list passed to the callback function will be empty.

`ecos_exit`
: This hook is called when the eCos application has exited. It is used mainly to shut down I/O operations: if the application is no longer running then there is no point in raising interrupts or storing incoming packets. The callback argument list will be empty.

`ecos_initialized`
: The synthetic target HAL will send a request to the I/O auxiliary once the static constructors have been run. All devices should now have been instantiated. A script could now check how many instances there are of a given type of device, for example ethernet devices, and create a little monitor window showing traffic on all the devices. The `ecos_initialized` callbacks will be run just before the user's `mainrc.tcl` script. The callback argument list will be empty.

`help`
: This hook is also invoked once static constructors have been run, but only if the user specified `-h` or `--help`. Any scripts that add their own command line arguments should add a callback to this hook which outputs details of the additional arguments. The callback argument list will be empty.

`interrupt`
: Whenever a device calls **synth::interrupt_raise** the `interrupt` hook will be called with a single argument, the interrupt vector. The main use for this is to allow user scripts to monitor interrupt traffic.

Output and Filters

Scripts can use conventional facilities for sending text output to the user, for example calling **puts** or directly manipulating the central text widget `.main.centre.text`. However in nearly all cases it is better to use output facilities provided by the I/O auxiliary itself:

```
synth::report <msg>
synth::report_warning <msg>
synth::report_error <msg>
synth::internal_error <msg>
synth::output <msg> <filter>
```

synth::report is intended for messages related to the operation of the I/O auxiliary itself, especially additional output resulting from `-v` or `--verbose`. If running in text mode the output will go to standard output. If running in graphical mode the output will go to the central text window. In both modes, use of `-l` or `--logfile` will modify the behaviour.

synth::report_warning, **synth::report_error** and **synth::internal_error** have the obvious meaning, including prepending strings such as `Warning:` and `Error:`. When the eCos application informs the I/O auxiliary that all static constructors have run, if at that point there have been any calls to **synth::error** then the I/O auxiliary will exit. This can be suppressed with command line arguments `-k` or `--keep-going`. **synth::internal_error** will output some information about the current state of the I/O auxiliary and then exit immediately. Of course it should never be necessary to call this function.

synth::output is the main routine for outputting text. The second argument identifies a filter. If running in text mode the filter is ignored, but if running in graphical mode the filter can be used to control the appearance of this output. A typical use would be:

```
    synth::output $line "console"
```

This outputs a single line of text using the `console` filter. If running in graphical mode the default appearance of this text can be modified with the `appearance` option in the **synth_device console** entry of the target definition file. The System filters menu option can be used to change the appearance at run-time.

Filters should be created before they are used. The procedures available for this are:

```
synth::filter_exists <name>
synth::filter_get_list
synth::filter_add <name> [options]
synth::filter_parse_options <options> <parsed_options> <message>
synth::filter_add_parsed <name> <parsed_options>
```

synth::filter_exists can be used to check whether or not a particular filter already exists: creating two filters with the same name is not allowed. **synth::filter_get_list** returns a list of the current known filters. **synth::filter_add** can be used to create a new filter. The first argument names the new filter, and the remaining arguments control the initial appearance. A typical use might be:

```
    synth::filter_add "my_device_tx" -foreground yellow -hide 1
```

It is assumed that the supplied arguments are valid, which typically means that they are hard-wired in the script. If instead the data comes out of a configuration file and hence may be invalid, the I/O auxiliary provides a parsing utility. Typical usage would be:

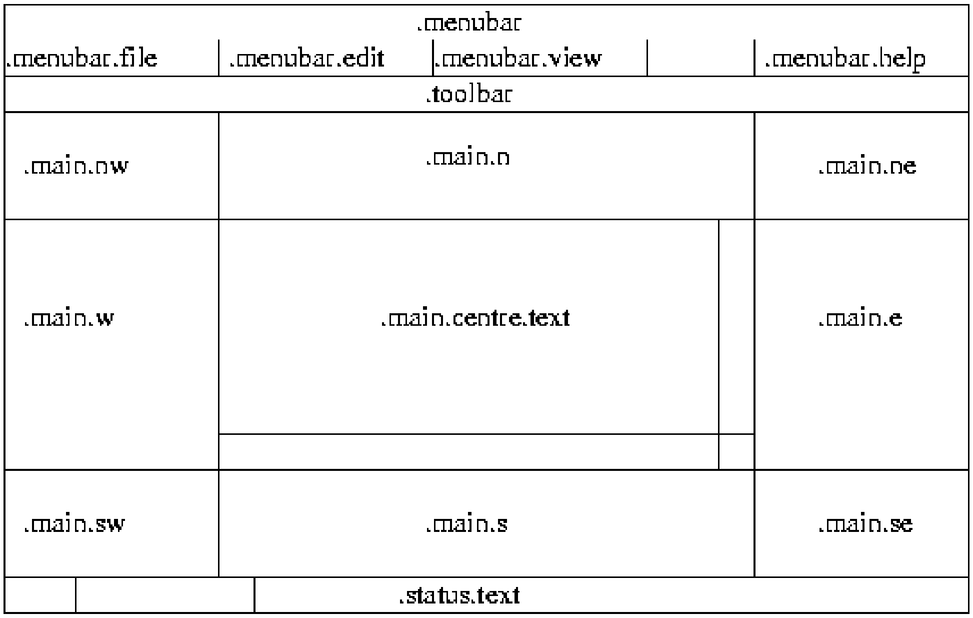
```
    array set parsed_options [list]
    set message ""
    if { ![synth::filter_parse_options $console_appearance parsed_options message] } {
        synth::report_error \
            "Invalid entry in target definition file $synth::target_definition\
             \n  synth_device \"console\", entry \"appearance\"\n$message"
    } else {
        synth::filter_add_parsed "console" parsed_options
    }
```

On success `parsed_options` will be updated with an internal representation of the desired appearance, which can then be used in a call to **synth::filter_add_parsed**. On failure `message` will be updated with details of the parsing error that occurred.

The Graphical Interface

When the I/O auxiliary is running in graphical mode, many scripts will want to update the user interface in some way. This may be as simple as adding another entry to the help menu for the device, or adding a new button to the toolbar. It may also involve adding new subwindows, or even creating entire new toplevel windows. These may be simple monitor windows, displaying additional information about what is going on in the system in a graphical format. Alternatively they may emulate actual I/O operations, for example button widgets could be used to emulate real physical buttons.

The I/O auxiliary does not provide many procedures related to the graphical interface. Instead it is expected that scripts will just update the widget hierarchy directly.



So adding a new item to the Help menu involves a **.menubar.help add** operation with suitable arguments. Adding a new button to the toolbar involves creating a child window in `.toolbar` and packing it appropriately. Scripts can create their own subwindows and then pack it into one of `.main.nw`, `.main.n`, `.main.ne`, `.main.w`, `.main.e`, `.main.sw`, `.main.s` or `.main.se`. Normally the user should be allowed to control this via the target definition file. The central window `.main.centre` should normally be left alone by other scripts since it gets used for text output.

The following graphics-related utilities may be found useful:

```
synth::load_image <image name> <filename>
synth::register_ballon_help <widget> <message>
synth::handle_help <URL>
```

synth::load_image can be used to add a new image to the current interpreter. If the specified file has a `.xbm` extension then the image will be a monochrome bitmap, otherwise it will be a colour image of some sort. A boolean will be returned to indicate success or failure, and suitable diagnostics will be generated if necessary.

synth::register_balloon_help provides balloon help for a specific widget, usually a button on the toolbar.

synth::handle_help is a utility routine that can be installed as the command for displaying online help, for example:

```
    .menubar.help add command -label "my device" -command \
        [list synth::handle_help "file://$path"]
```

Name

Porting — Adding support for other hosts

Description

The initial development effort of the eCos synthetic target happened on x86 Linux machines. Porting to other platforms involves addressing a number of different issues. Some ports should be fairly straightforward, for example a port to Linux on a processor other than an x86. Porting to Unix or Unix-like operating systems other than Linux may be possible, but would involve more effort. Porting to a completely different operating system such as Windows would be very difficult. The text below complements the eCos Porting Guide.

Other Linux Platforms

Porting the synthetic target to a Linux platform that uses a processor other than x86 should be straightforward. The simplest approach is to copy the existing `i386linux` directory tree in the `hal/synth` hierarchy, then rename and edit the ten or so files in this package. Most of the changes should be pretty obvious, for example on a 64-bit processor some new data types will be needed in the `basetype.h` header file. It will also be necessary to update the toplevel `ecos.db` database with an entry for the new HAL package, and a new target entry will be needed.

Obviously a different processor will have different register sets and calling conventions, so the code for saving and restoring thread contexts and for implementing `setjmp` and `longjmp` will need to be updated. The exact way of performing Linux system calls will vary: on x86 linux this usually involves pushing some registers on the stack and then executing an `int 0x080` trap instruction, but on a different processor the arguments might be passed in registers instead and certainly a different trap instruction will be used. The startup code is written in assembler, but needs to do little more than extract the process' argument and environment variables and then jump to the main `linux_entry` function provided by the architectural synthetic target HAL package.

The header file `hal_io.h` provided by the architectural HAL package provides various structure definitions, function prototypes, and macros related to system calls. These are correct for x86 linux, but there may be problems on other processors. For example a structure field that is currently defined as a 32-bit number may in fact may be a 64-bit number instead.

The synthetic target's memory map is defined in two files in the `include/pkgconf` subdirectory. For x86 the default memory map involves eight megabytes of read-only memory for the code at location 0x1000000 and another eight megabytes for data at 0x2000000. These address ranges may be reserved for other purposes on the new architecture, so may need changing. There may be some additional areas of memory allocated by the system for other purposes, for example the startup stack and any environment variables, but usually eCos applications can and should ignore those.

Other HAL functionality such as interrupt handling, diagnostics, and the system clock are provided by the architectural HAL package and should work on different processors with few if any changes. There may be some problems in the code that interacts with the I/O auxiliary because of lurking assumptions about endianness or the sizes of various data types.

When porting to other processors, a number of sources of information are likely to prove useful. Obviously the Linux kernel sources and header files constitute the ultimate authority on how things work at the system call level. The GNU C library sources may also prove very useful: for a normal Linux application it is the C library that provides the startup code and the system call interface.

Other Unix Platforms

Porting to a Unix or Unix-like operating system other than Linux would be somewhat more involved. The first requirement is toolchains: the GNU compilers, gcc and g++, must definitely be used; use of other GNU tools such as the linker may be needed as well, because eCos depends on functionality such as prioritizing C++ static constructors, and other linkers may not implement this or may implement it in a different and incompatible way. A closely related requirement is the use of ELF format for binary executables: if the operating system still uses an older format such as COFF then there are likely to be problems because they do not provide the flexibility required by eCos.

In the architectural HAL there should be very little code that is specific to Linux. Instead the code should work on any operating system that provides a reasonable implementation of the POSIX standard. There may be some problems with program startup, but those could be handled at the architectural level. Some changes may also be required to the exception handling code. However one file which will present a problem is `hal_io.h`, which contains various structure definitions and macros used with the system call interface. It is likely that many of these definitions will need changing, and it may well be appropriate to implement variant HAL packages for the different operating systems where this information can be separated out. Another possible problem is that the generic code assumes that system calls such as `cyg_hal_sys_write` are available. On an operating system other than Linux it is possible that some of these are not simple system calls, and instead wrapper functions will need to be implemented at the variant HAL level.

The generic I/O auxiliary code should be fairly portable to other Unix platforms. However some of the device drivers may contain code that is specific to Linux, for example the `PF_PACKET` socket address family and the ethertap virtual tunnelling interface. These may prove quite difficult to port.

The remaining porting task is to implement one or more platform HAL packages, one per processor type that is supported. This should involve much the same work as a port to another processor running Linux.

When using other Unix operating systems the kernel source code may not be available, which would make any porting effort more challenging. However there is still a good chance that the GNU C library will have been ported already, so its source code may contain much useful information.

Windows Platforms

Porting the current synthetic target code to some version of Windows or to another non-Unix platform is likely to prove very difficult. The first hurdle that needs to be crossed is the file format for binary executables: current Windows implementations do not use ELF, instead they use their own format PE which is a variant of the rather old and limited COFF format. It may well prove easier to first write an ELF loader for Windows executables, rather than try to get eCos to work within the constraints of PE. Of course that introduces new problems, for example existing source-level debuggers will still expect executables to be in PE format.

Under Linux a synthetic target application is not linked with the system's C library or any other standard system library. That would cause confusion, for example both eCos and the system's C library might try to define the `printf` function, and introduce complications such as working with shared libraries. For much the same reasons, a synthetic target application under Windows should not be linked with any Windows DLL's. If an ELF loader has been specially written then this may not be much of a problem.

The next big problem is the system call interface. Under Windows system calls are generally made via DLL's, and it is not clear that the underlying trap mechanism is well-documented or consistent between different releases of Windows.

The current code depends on the operating system providing an implementation of POSIX signal handling. This is used for I/O purposes, for example `SIGALRM` is used for the system clock, and for exceptions. It is not known what equivalent functionality is available under Windows.

Given the above problems a port of the synthetic target to Windows may or may not be technically feasible, but it would certainly require a very large amount of effort.

Part LXXVII. ARM7/ARM9/ XScale/Cortex-A Architecture

Table of Contents

Chapter 234. ARM Architectural Support

Name

`CYGPKG_HAL_ARM` — eCos Support for the ARM Architecture

Description

The ARM architecture HAL provides support for members of the ARM7, ARM9, XScale and Cortex-A families. This includes support for the ARM, Thumb and Thumb2 instruction sets.

The architectural HAL provides support for those features which are common to all members of the ARM family, and for certain features which are present on some, but not all, members. This HAL contains support for CPU initialization, exception and interrupt entry and exit, thread context switching, interrupt masking, timer management, cache management and debugging. A typical eCos configuration will also contain a variant HAL package with support code for a family of processors, possibly a processor HAL package with support for one specific processor, and a platform HAL which contains the code needed for a specific hardware platform. For example the variant or processor HAL may define the exact interrupt controller hardware that is available, and the platform HAL will define the external interrupt vector connections.

If appropriate the variant or platform HAL may also enable support for an ARM architectural hardware Floating Point Unit (FPU). Not all ARM architectures provide hardware floating point as an option, and also not all of the various ARM architectural hardware floating point implementations are currently supported by this architectural HAL.

Support is available for the Advanced SIMD Architecture, commonly known as NEON. Since NEON uses the same registers as the FPU, it is necessary to also have FPU support enabled when NEON support is required.

Support for SMP is available for the Cortex-A processor family based on the ARM MPCore cluster technology. This includes the Generic Interrupt Controller, Snoop Control Unit, private and global timers and the PL310 level 2 cache controller.

Name

Options — Configuring the ARM Architectural HAL Package

Description

The ARM architectural HAL is included in all ecos.db entries for ARM targets, so the package will be loaded automatically when creating a configuration. It should never be necessary to load the package explicitly or to unload it.

The ARM architectural HAL contains a number of configuration points. Few of these should be altered by the user, they are mainly present for the variant and platform HALs to select different architectural features. For example, the CPU family being used, whether the Thumb or Thumb2 instruction sets are supported, if the ARM EABI (Embedded Application Binary Interface) is being used, etc.

CYGINT_HAL_ARM_BIGENDIAN

> This interface controls whether the CPU is capable of being run in big endian mode. It should be implemented by either the variant or platform HAL to reflect the setting of the hardware.

CYGHWR_HAL_ARM_BIGENDIAN

> On targets which are capable of big-endian operation, this option is used to select whether big- or little-endian operation is desired. It provides the main test point for HAL, eCos and application code to test for a big-endian target. It is inactive if `CYGINT_HAL_ARM_BIGENDIAN` is not implemented.

CYGINT_HAL_ARM_FPU

> This interface controls whether the CPU is capable of supporting a hardware FPU (Floating Point Unit). It is the “common” FPU marker and is implemented when either the variant or platform HAL in turn implements a supported FPU type.
>
> For example, a Cortex-A5 target may define `CYGINT_HAL_VFPV4_D16` when it provides the ARMv7 VFPv4-D16 architecture floating point unit.

CYGHWR_HAL_ARM_FPU

> On targets which are capable of hardware FPU operation, this option is used to select whether soft or hard floating point operation is desired. It provides the main test point for HAL, eCos and application code to test for a hard-FP target. It is inactive if `CYGINT_HAL_ARM_FPU` is not implemented.
>
> Even though an architecture may provide a hardware FPU, it is not always suitable for all applications. For example, there is the associated scheduler and RAM cost in preserving FPU context for multi-threaded applications. If `CYGHWR_HAL_ARM_FPU` is enabled then some further configuration options are made available:
>
> CYGHWR_HAL_ARM_FPU_SWITCH
>
> > This option selects the FPU context switching scheme.

Table 234.1. Context Switch

SWITCH	Description
ALL	This mode is the most straightforward, and means that on every context switch, all FPU registers are saved and restored between threads. This mode makes the most sense if you need determinism and/or most or all of your threads will use FP. However if few threads use FP, it can result in a lot of overhead due to saves and restores of unchanged registers.

SWITCH	Description
LAZY	In this mode, if a thread has not used the FPU, the FPU context will not be saved or restored for it. The HAL installs a handler in the ARM undefined instruction exception vector in order to detect the first time the FPU is accessed by that thread. Once the FPU is accessed, the fault handler enables the FPU for that thread, and from then on, the FPU context will be saved and restored when switching from or to that thread. In a system where some or many threads do not use the FPU, this can greatly improve context switch time. However if the system spends most of its time swapping between two or more threads which do both use the FPU, then there may be additional overhead compared to the `ALL` mode (due to the need to check if the FPU was enabled for a particular thread on switch). This means the worst case context switch time is longer than with `ALL` mode. It also reduces determinism as there is an unavoidable latency at the point the thread first accesses the FPU, so that the fault handler can execute to enable the FPU; and determinism is further affected as context switch time depends on whether threads use the FPU. The `LAZY` mode does not save on stack usage, as the number of registers which might need to be saved remains the same.
NONE	In this mode, the FPU is enabled, but no floating point context is stored at any point, which naturally means there is no overhead on context switch. However this means that only one thread or context may use the FPU at a time. If using this mode, either all FP operations must be constrained to a single thread. Or there must be locking to ensure that multiple threads do not access the FPU registers simultaneously. But if you rely on locking, great care must be taken as the compiler has the potential to reorder floating point accesses outside of the critical region if it is still in the same function. The use of the `HAL_REORDER_BARRIER()` call from the `<cyg/hal/hal_arch.h>` HAL header can be useful to prevent reordering across a particular point in the code.

CYGIMP_HAL_ARM_FPU_EXC_SAVE

This option allows the FPU context to be saved over exceptions, including interrupts. Normally this option will be disabled by default, since the hardware FPU instructions will only ever be used from application thread level code.

Disabling this option avoids the unnecessary cost associated with saving the hardware FPU context for interrupt or exception handlers. When disabled this does impose the restriction that the developer should ensure that no attached ISR, DSR or exception handler routine can make use of hardware FPU instructions. For the vast majority of eCos configurations this is *not* an issue.

When this option is enabled the code will preserve the FPU context over exception handlers (including interrupt calls). This option may become a “requirement” if the compiler is configured to make use of hardware FPU registers as temporary storage. However, such use is *not* recommended since the extra performance cost in saving and restoring the FPU context across (for example) *every* interrupt probably far outweighs the gain from being able to use the hardware FPU within such handlers. NOTE: If an interrupt or exception handler does make use of the FPU hardware there is *NO* FPU state preserved across successive handler calls, since each call is a unique instance.

CYGINT_HAL_ARM_NEON

This interface controls whether the CPU contains support for the ARM Advanced SIMD architecture, commonly referred to as NEON. It is usually implemented by the variant or platform HAL to enable NEON support. Since NEON shares registers with the FPU, it is also usually necessary to implement the appropriate FPU option.

For example, a Cortex-A53 target may implement `CYGINT_HAL_VFPV4_D32` when it provides the ARMv7 VFPv4-D32 architecture floating point unit and in addition implement `CYGINT_HAL_ARM_NEON` to indicate that the FPU also implements the NEON architecture.

CYGHWR_HAL_ARM_NEON

On targets which are capable of NEON operation, this option is used to select whether NEON support is enabled. It provides the main test point for HAL, eCos and application code to test for a NEON capable target. It is inactive if either `CYGINT_HAL_ARM_FPU` or `CYGINT_HAL_ARM_NEON` are not implemented. If this option is enabled, then `CYGHWR_HAL_ARM_FPU` will also be enabled automatically. When NEON is enabled, the compiler may generate NEON instructions for data manipulation in any function, including those that may be called from an ISR or DSR. Consequently, `CYGIMP_HAL_ARM_FPU_EXC_SAVE` is also enabled automatically.

Even though an architecture may provide NEON support, it is not always suitable for all applications. NEON shares the FPU registers and the same context save and restore issues apply. Consequently, the FPU options described above for managing the FPU context are active and also apply to NEON applications.

CYGINT_HAL_ARM_SYSTEM_DEBUG_DCC

This interface controls whether the CPU supports the ARM Debug Communications Channel (DCC) feature. It is normally implemented by the variant HAL to reflect the availability of the hardware.

CYGHWR_HAL_ARM_DIAGNOSTICS_INTERFACE

By default the architectural HAL does not implement diagnostic support, with the default `Serial` support being left to the variant or platform HAL implementation.

However, if the CPU variant implements the on-chip Debug Communications Channel feature then selecting `DCC` for this option will configure the system to use the generic architectural HAL DCC diagnostic output support. Accessing DCC diagnostic output will require corresponding support from the hardware debugger host tools being used to connect to the target system.

The `discard` option configures the system so that all diagnostic output is discarded. This can be selected and used when no I/O channel is available for diagnostics.

When DCC is being used for HAL diagnostics the option `CYGDBG_HAL_ARM_DIAGNOSTICS_INTERFACE_DCC_TYPE` should match the attached host debugger interface used to capture the diagnostic output. The `Character` interface simply transfers single characters through the DCC interface, and is compatible with the Linux `ICEDCC` support and with either of the Lauterbach `DCC` and `DCC3` formats. The `LIBDCC` format (as used by OpenOCD for example) uses a specific single character encoding that inter-operates with features not currently supported by eCos.

Compiler Flags

It is normally the responsibility of the platform HAL to define the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

Linker Scripts

The architecture HAL does not provide the main linker script. Instead this must be supplied by the variant HAL, and the makefile rules to generate the final target.ld must be included in the variant's CDL file.

Name

HAL Port — Implementation Details

Description

This documentation explains how the eCos HAL specification has been mapped onto the ARM hardware and should be read in conjunction with the relevant Architecture Reference Manual and the Technical Reference Manual for the revision of the ARM architecture being used. It should be noted that the architectural HAL is usually complemented by a variant HAL and a platform HAL, and those may affect or redefine some parts of the implementation.

Exports

The architectural HAL provides header files `cyg/hal/hal_arch.h`, `cyg/hal/hal_intr.h`, `cyg/hal/hal_io.h` and `cyg/hal/hal_mmu.h`. These header files export the functionality provided by all the ARM HALs for a given target, automatically including headers from the lower-level HALs as appropriate. For example the platform HAL may provide a header `cyg/hal/plf_io.h` containing additional I/O functionality, but that header will be automatically included by `cyg/hal/hal_io.h` so there is no need to include it directly.

Additionally, the architecture HAL provides the `cyg/hal/basetype.h` header, which defines the basic properties of the architecture, including endianness, data type sizes and alignment constraints.

Startup

The architectural HAL provides a default implementation of the low-level startup code which will be appropriate in nearly all scenarios. For a ROM startup this includes copying initialized data from flash to RAM. For all startup types it will involve zeroing BSS regions and setting up the general C environment. It will also set up the initial exception priorities, switches the CPU into the correct execution mode, enables the debug monitor and enables error exception handling.

In addition to the setup it does itself, the initialization code calls out to the variant and platform HALs to perform their own initialization via the `hal_hardware_init()` function.

The architectural HAL also initializes the VSR and virtual vector tables, sets up HAL diagnostics, and invokes C++ static constructors, prior to calling the first application entry point `cyg_start`. This code resides in `src/vectors.S`.

Interrupts and Exceptions

The eCos interrupt and exception architecture is built around a table of pointers to Vector Service Routines that translate hardware exceptions and interrupts into the function calls expected by eCos. The ARM vector table provides exactly this functionality, so it is used directly as the eCos VSR table. The `HAL_VSR_GET` and `HAL_VSR_SET` macros therefore manipulate the vector table directly. The `hal_intr.h` header provides definitions for all the standard ARM exception vectors.

The vector table is constructed at runtime. For ROM, ROMRAM and SRAM startup all entries are initialized. For RAM startup only the interrupt vectors are (re-)initialized to point to the VSR in the loaded code, the exception vectors are left pointing to the VSRs of the loading software, usually RedBoot or GDB stubs.

When an exception occurs it is delivered via the relevant handler provided in `vectors.S`. The handler will save the CPU state and call `exception_handler` in `hal_misc.c`, which passes the exception on to either the kernel or the GDB stub handler. If it returns then the CPU state is restored and the code continued.

When an interrupt occurs it is delivered to a shared VSR, `hal_default_irq_vsr`, which saves some state and calls `hal_IRQ_handler`.

The architectural HAL provides default implementations of `HAL_DISABLE_INTERRUPTS`, `HAL_RESTORE_INTERRUPTS`, `HAL_ENABLE_INTERRUPTS` and `HAL_QUERY_INTERRUPTS`. These involve manipulation of the status register `I` flag. Similarly there are default implementations of the interrupt controller macros HAL_INTERRUPT_MASK, HAL_INTERRUPT_UNMASK, HAL_INTERRUPT_ACKNOWLEDGE and HAL_INTERRUPT_CONFIGURE macros.

HAL_INTERRUPT_SET_LEVEL manipulates the relevant interrupt priority registers. The valid range of interrupts supported depends on the number of interrupt priority bits supported by the CPU variant.

Stacks and Stack Sizes

cyg/hal/hal_arch.h defines values for minimal and recommended thread stack sizes, CYGNUM_HAL_STACK_SIZE_MINIMUM and CYGNUM_HAL_STACK_SIZE_TYPICAL. These values depend on a number of configuration options.

A number of system stacks are provided, and their properties controlled in this package's configuration. By default, the ARM HAL will use a separate stack for calling interrupt handlers. This separate interrupt stack means that the worst case overhead of interrupt handling does not need to be considered when determining each thread's maximum stack usage, which reduces overall stack overhead. The size of this interrupt stack is controlled by the common HAL's configuration (CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE) or can be disabled entirely by turning off CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK.

System startup code will also run on the interrupt stack, if enabled, as it is usually sufficiently large for this. Optionally, a separate startup stack can be enabled in this HAL by disabling CYGIMP_HAL_ARM_INT_STACK_IS_STARTUP_STACK, in which case when control is passed to the application by the cyg_start() or cyg_user_start() entry points, this startup stack will then be used. Alternatively, if the interrupt stack has been disabled entirely then a startup stack must be present, and will be used for all initialisation. Its size can be set with CYGNUM_HAL_ARM_STARTUP_STACK_SIZE. Note that global C++ object constructors defined by either the system, or in application code, will have their constructors run on the interrupt stack. Using the C library startup package's "Invoke default static constructors" option (CYGSEM_LIBC_INVOKE_DEFAULT_STATIC_CONSTRUCTORS) would instead ensure the user application constructors are called in the context of main(), which can be more appropriate.

If including GDB stubs in the application, then a separate GDB stub stack is required in order to guarantee that application problems with stack use will not prevent the GDB stub being able to debug the application. Again the size is controlled via this package's CDL (CYGNUM_HAL_ARM_GDB_STACK_SIZE)

Separate small stacks are also created to do the initial handling of Abort Prefetch, Abort Data, Undefined Instruction exceptions, as well as IRQ and FIQ interrupts. Assuming the default eCos VSRs are in place for these exceptions/interrupts, these small stacks are only used very temporarily until the context is switched to supervisor (SVC) mode.

At that point, in the case of the first three exceptions, if GDB stubs are included, the stack then used will be the GDB stack mentioned above. Alternatively, in the case of the first three exceptions without GDB stubs, the stack used will be that of the supervisor mode (SVC) context at the time of the exception. This is usually the running thread, but can also be a DSR running on the interrupt stack.

In the case of the IRQ and FIQ interrupts, these small stacks are only used by the default eCos VSRs temporarily until the stack is switched to the interrupt stack (or if that is disabled, the stack of the interrupted thread).

The above describes the situation when using the normal eCos VSRs for handling the Abort Data, Abort Prefetch, Undefined Instruction, IRQ and FIQ exceptions/interrupts. However if the user overrides the eCos VSRs with their own VSRs, then it may be necessary to change the stack sizes for these contexts depending on the stack use by those new VSRs. Therefore each of the stack sizes corresponding to these exception/interrupt contexts can be changed in the ARM HAL package configuration.

Thread Contexts and setjmp/longjmp

cyg/hal/hal_arch.h defines a thread context data structure, the context-related macros, and the setjmp/longjmp support. The implementations can be found in src/context.S.

Bit Indexing

The architectural HAL provides implementations in the source file hal_misc.c that are referenced by the HAL_LSBIT_INDEX and HAL_MSBIT_INDEX macros.

Idle Thread Processing

Normally the variant HAL provides the `HAL_IDLE_THREAD_ACTION` implementation. It usually implements code that can be used to put the CPU into a low power mode ready to respond quickly to the next interrupt.

Clock Support

The architectural HAL provides default implementations of the various system clock macros such as HAL_CLOCK_INITIALIZE. The variant or platform HAL are responsible for providing the necessary implementation routines.

HAL I/O

The ARM architecture does not have a separate I/O bus. Instead all hardware is assumed to be memory-mapped. Further it is assumed that all peripherals on the memory bus will switch endianness with the processor and that there is no need for any byte swapping. Hence the various HAL macros for performing I/O simply involve pointers to volatile memory.

The variant and platform files included by the `cyg/hal/hal_io.h` header will typically also provide details of some or all of the peripherals, for example register offsets and the meaning of various bits in those registers.

Cache Handling

The architecture HAL does not provide direct support for dealing with caches, since there is no common mechanism for doing this. The cache support is the responsibility of the variant HAL to, which will supply the `cyg/hal/hal_cache.h` header.

Linker Scripts

The architectural HAL will generate the linker script for eCos applications. This involves the architectural file `src/arm.ld` and a `.ldi` memory layout file, typically provided by the platform HAL. It is the `.ldi` file which places code and data in the appropriate places for the startup type, but most of the hard work is done via macros in the `arm.ld` file.

Diagnostic Support

The architectural HAL implements diagnostic support for DCC output if available, or for discarding all output. However, by default, the diagnostics output is left to the variant or platform HAL, depending on whether suitable peripherals are available on-chip or off-chip. The `CYGHWR_HAL_ARM_DIAGNOSTICS_INTERFACE` can be configured to direct the diagnostic output support used to the appropriate destination.

SMP Support

The ARM architectural HAL provides SMP support for Cortex-A class processors. If the configuration option `CYGPKG_HAL_SMP_SUPPORT` is enabled then the `hal_smp.h` header defines the standard SMP macros described in the HAL documentation. The architectural HAL only provides the SMP components that are common to all CPUs. It is the responsibility of variant and platform HALs to complete SMP support.

The variant HAL needs to supply a number of services for SMP. Access to the interrupt controller needs to be multi-core safe. The design of the standard ARM GIC provides this by default, but other controllers may need a spinlock. MMU and cache support are linked since any memory containing a spinlock must be cached and marked shareable. The variant HAL should also contain `cyg_hal_cpu_start()`, which is used to start up the secondary CPUs and `cyg_hal_smp_start()`, which is the initial entry point for secondary CPUs. It must also supply `cyg_hal_cpu_message()`, and associated ISR and DSR, which are used to pass scheduling messages between CPUs.

The platform HAL (which may comprise more than one layer of hardware specific HALs) is responsible for the memory map and initialization. Initialization will usually involve starting clocks, setting up pin multiplexing and configuring the CPU state. Most of this is common to single and multi-core configurations, although there will be some SMP specific settings. This HAL will also need to supply the PLATFORM_SETUP_CPU macro to initialize the secondary CPUs.

Debug Support

The architectural HAL provides basic support for gdb stubs using the debug monitor exceptions. Breakpoints are implemented using a fixed-size list of breakpoints, as per the configuration option CYGNUM_HAL_BREAKPOINT_LIST_SIZE. When a JTAG device is connected to a ARM device, it will steal breakpoints and other exceptions from the running code. Therefore debugging from RedBoot or the GDB stubs can only be done after detaching any JTAG debugger and power-cycling the board.

HAL_DELAY_US() Macro

The variant or platform HAL is responsible for providing an implementation of the HAL_DELAY_US macro. The system timer must be initialized before this macro is used. The include/hal_intr.h defined HAL_CLOCK_INITIALIZE() macro is called during initialization after the variant and platform initialization functions are called, but before constructors are invoked.

Profiling Support

When using local memory based profiling the ARM architectural HAL implements the mcount function, allowing profiling tools like gprof to determine the application's call graph. It does not implement the profiling timer. Instead that functionality needs to be provided by the variant or platform HAL.

Chapter 235. Atmel AT91 Processor Variant Support

Name

eCos Support for the Atmel AT91 Processor Variant — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Atmel AT91 processor family which includes the AT91R4xxxx series, the M42xxxx and M55xxxx series and the AT91SAM7S, -X and -A series. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, AT91SAM7 variant HAL (where appropriate) and the platform HAL. It provides functionality common to all AT91-based board implementations.

This support is found in the eCos package located at `packages/hal/arm/at91/var` within the eCos source repository.

The AT91 processor HAL package is loaded automatically when eCos is configured for an AT91-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the Atmel AT91 processor within this processor HAL package include:

- AT91-specific hardware definitions
- Interrupt controller
- Timer counters
- Serial UARTs

Support for the interrupt-driven serial, SPI, watchdog and wallclock (RTC) features of the AT91 are also present and can be found in separate packages, outside of this processor HAL.

The watchdog hardware may also used within this HAL to perform software reset.

Name

AT91 hardware definitions — Details on obtaining hardware definitions for AT91

Register definitions

The file `<cyg/hal/var_io.h>` provides definitions related to AT91 subsystems. This file should not be included explicitly, but is included automatically whenever `<cyg/hal/hal_io.h>` is included. This file includes register definitions for the interrupt controller, power management controller, clock generator, memory controller, external bus interface, GPIO, USART, MCI, CAN, TWI (I²C®), Ethernet, timer counter, RTC, and SPI subsystems, depending on the exact model.

Name

AT91 interrupt controller — Advanced Interrupt Controller definitions and usage

Interrupt Controller Support

The AT91 variant HAL contains generic support for the AIC (GIC on SAM7XA1 and -A2). It queries the interrupt controller to identify the current interrupt and vectors to the matching service routine. If the device supports the SYSTEM interrupt then the devices that raise this interrupt will be queried individually and vectored to their own interrupt handlers. The mapping between interrupts and vector numbers is defined in the `hal_platform_ints.h` file in either the platform HAL or the AT91SAM7 variant HAL.

As indicated above, further decoding is performed on the SYSTEM interrupt to identify the cause more specifically. Note that as a result, placing an interrupt handler on the SYSTEM interrupt will not work as expected. Conversely, masking a decoded derivative of the SYSTEM interrupt will not work as this would mask other SYSTEM interrupts, but masking the SYSTEM interrupt itself will work. On the other hand, unmasking a decoded SYSTEM interrupt *will* unmask the SYSTEM interrupt as a whole, thus unmasking interrupts for the other units on this shared interrupt.

Interrupt Controller Functions

The source file `src/at91_misc.c` within this package provides most of the support functions to manipulate the interrupt controller. The `hal_IRQ_handler` queries the IRQ status register to determine the interrupt cause. Functions `hal_interrupt_mask` and `hal_interrupt_unmask` enable or disable interrupts within the interrupt controller.

Interrupts are configured in the `hal_interrupt_configure` function, where the `level` and `up` arguments are interpreted as follows:

level	up	interrupt on
0	0	Falling Edge
0	1	Rising Edge
1	0	Low Level
1	1	High Level

To fit into the eCos interrupt model, interrupts essentially must be acknowledged immediately once decoded, and as a result, the `hal_interrupt_acknowledge` function is empty.

The `hal_interrupt_set_level` is used to set the priority level of the supplied interrupt within the Advanced Interrupt Controller.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (`HAL_INTERRUPT_MASK` et al) or preferably the kernel or driver APIs should be used to control interrupts.

Interrupt handling within standalone applications

For non-eCos standalone applications running under RedBoot, it is possible to install an interrupt handler into the interrupt vector table manually. Memory layouts are platform-dependent and so the platform documentation should be consulted, but in general the address of the interrupt table can be determined by analyzing RedBoot's symbol table, and searching for the address of the symbol name `hal_interrupt_handlers`. Table slots correspond to the interrupt numbers defined in the platform or AT91SAM7 HAL. Pointers inserted in this table should be pointers to a C/C++ function with the following prototype:

```
extern unsigned int isr( unsigned int vector, unsigned int data );
```

For non-eCos applications run from RedBoot, the return value can be ignored. The `vector` argument will also be the interrupt vector number. The `data` argument is extracted from a corresponding table named `hal_interrupt_data` which immediately follows the interrupt vector table. It is still the responsibility of the application to enable and configure the interrupt source appropriately if needed.

Name

Timers — Use of on-chip Timer

Hardware Timer

The eCos kernel system clock is implemented using an on-chip Timer. Depending on the device this will either be a Timer Counter, a Simple Timer, or the Periodic Interval Timer. The kind of device used is determined by the platform HAL. By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option CYGNUM_HAL_RTC_DENOMINATOR which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to CYGNUM_HAL_RTC_DENOMINATOR, then the configuration option CYGNUM_HAL_RTC_NUMERATOR may also be adjusted, and again clock-related settings will automatically be recalculated.

The selected Timer is also used to implement the HAL microsecond delay function, HAL_DELAY_US. This is used by some device drivers, and in non-kernel configurations such as with RedBoot where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Timer-based profiling support

Timer-based profiling support is implemented using timer counter 1 (TC1). If the gprof package, CYGPKG_PROFILE_GPROF, is included in the configuration, then TC1 is reserved for use by the profiler.

Name

Serial UARTs — Configuration and implementation details of serial UART support

Overview

Support is included in this processor HAL package for the AT91's on-chip debug unit UART and serial USART serial devices.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 38400,8,N,1 with no flow control.

HAL diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems. This can operate on any port, according to the configuration settings.

There are several configuration options usually found within a platform HAL which affect the use of this support in the AT91 processor HAL. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, `diag_printf()`. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL` selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the `CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS` CDL option in the HAL. Baud rates for each channel are set with the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD` options.

Interrupt-driven serial driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (`CYGPKG_IO_SERIAL`). This support can be enabled on any port.

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent ctrl-c operation when debugging.

This driver is contained in the `CYGPKG_IO_SERIAL_ARM_AT91` package. That driver package should also be consulted for documentation and configuration options. The driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

The USARTs are named "/dev/ser0", "/dev/ser1" and so on. The DEBUG serial port is given the name "/dev/dbg". These names are all configurable.

Note that unlike the USART devices, the serial debug port does not support modem control signals such as those used for hardware flow control. In addition, USART devices for a particular platform may also not have these control signals brought out to the physical serial port.

Chapter 236. Atmel AT91SAM7 Processor Variant Support

Name

eCos Support for the Atmel AT91SAM7 Processor Variant — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Atmel AT91SAM7 processor family which includes the AT91SAM7S, -X an -A series. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This HAL package complements the ARM architectural HAL, AT91 variant HAL (where appropriate) and the platform HAL. It provides functionality common to all AT91SAM7-based board implementations.

This support is found in the eCos package located at `packages/hal/arm/at91/at91sam7` within the eCos source repository.

The AT91SAM7 HAL package is loaded automatically when eCos is configured for an AT91SAM7-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the Atmel AT91SAM7 within this processor HAL package include:

- AT91SAM7-specific hardware definitions
- Interrupt Vector Definitions

Support for the interrupt-driven serial, SPI, watchdog and wallclock (RTC) features of the AT91SAM7 are also present and can be found in separate packages, outside of this processor HAL.

Name

AT91SAM7 hardware definitions — Details on obtaining hardware definitions for AT91

Device Definitions

The file `<cyg/hal/plf_io.h>` provides definitions related to AT91SAM7 subsystems. This file should not be included explicitly, but is included automatically whenever `<cyg/hal/hal_io.h>` is included. This file mainly includes base address definitions for the interrupt controller, power management controller, clock generator, memory controller, external bus interface, GPIO, USART, MCI, CAN, TWI (I²C®), Ethernet, timer counter, RTC, and SPI subsystems, depending on the exact model.

Name

AT91SAM7 interrupt vector definitions — Advanced Interrupt Controller vector definitions

Interrupt Vector Definitions

The file `<cyg/hal/hal_platform_ints.h>` (located at `hal/arm/arm9/at91sam7/`*`VERSION`*`/include/hal_platform_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs. The exact set of vectors supported depends on the AT91SAM7 model:

For the AT91SAM7S family:

```
#define CYGNUM_HAL_INTERRUPT_FIQ        0       // Advanced Interrupt Controller (FIQ)
#define CYGNUM_HAL_INTERRUPT_SYS        1       // System Peripheral (debug unit, system timer)
#define CYGNUM_HAL_INTERRUPT_PIOA       2       // Parallel IO Controller A
#define CYGNUM_HAL_INTERRUPT_ADC        4       // Analog-to-Digital Converter
#define CYGNUM_HAL_INTERRUPT_SPI        5       // Serial Peripheral Interface
#define CYGNUM_HAL_INTERRUPT_USART0     6       // USART 0
#define CYGNUM_HAL_INTERRUPT_USART1     7       // USART 1
#define CYGNUM_HAL_INTERRUPT_SSC        8       // Serial Synchronous Controller
#define CYGNUM_HAL_INTERRUPT_TWI        9       // Two-Wire Interface (I2C)
#define CYGNUM_HAL_INTERRUPT_PWMC       10      // PWM Controller
#define CYGNUM_HAL_INTERRUPT_UDP        11      // USB Device Port
#define CYGNUM_HAL_INTERRUPT_TC0        12      // Timer Counter 0
#define CYGNUM_HAL_INTERRUPT_TC1        13      // Timer Counter 1
#define CYGNUM_HAL_INTERRUPT_TC2        14      // Timer Counter 2
#define CYGNUM_HAL_INTERRUPT_IRQ0       30      // External IRQ0
#define CYGNUM_HAL_INTERRUPT_IRQ1       31      // External IRQ0

// Interrupts which are multiplexed on to the System Interrupt
#define CYGNUM_HAL_INTERRUPT_PITC       32      // Period Interval Timer
#define CYGNUM_HAL_INTERRUPT_RTTC       33      // Real-Time Timer
#define CYGNUM_HAL_INTERRUPT_PMC        34      // Power Management Controller
#define CYGNUM_HAL_INTERRUPT_MC         35      // Memory Controller
#define CYGNUM_HAL_INTERRUPT_WDTC       36      // Watchdog
#define CYGNUM_HAL_INTERRUPT_RSTC       37      // Reset Controller
#define CYGNUM_HAL_INTERRUPT_DEBUG      38      // Debug Serial Port
```

For the AT91SAM7X family:

```
#define CYGNUM_HAL_INTERRUPT_FIQ        0       // Advanced Interrupt Controller (FIQ)
#define CYGNUM_HAL_INTERRUPT_SYS        1       // System Peripheral (debug unit, system timer)
#define CYGNUM_HAL_INTERRUPT_PIOA       2       // Parallel IO Controller A
#define CYGNUM_HAL_INTERRUPT_PIOB       3       // Parallel IO Controller B
#define CYGNUM_HAL_INTERRUPT_SPI        4       // Serial Peripheral Interface
#define CYGNUM_HAL_INTERRUPT_SPI1       5       // Serial Peripheral Interface 1
#define CYGNUM_HAL_INTERRUPT_USART0     6       // USART 0
#define CYGNUM_HAL_INTERRUPT_USART1     7       // USART 1
#define CYGNUM_HAL_INTERRUPT_SSC        8       // Serial Synchronous Controller
#define CYGNUM_HAL_INTERRUPT_TWI        9       // Two-Wire Interface (I2C)
#define CYGNUM_HAL_INTERRUPT_PWMC       10      // PWM Controller
#define CYGNUM_HAL_INTERRUPT_UDP        11      // USB Device Port
#define CYGNUM_HAL_INTERRUPT_TC0        12      // Timer Counter 0
#define CYGNUM_HAL_INTERRUPT_TC1        13      // Timer Counter 1
#define CYGNUM_HAL_INTERRUPT_TC2        14      // Timer Counter 2
#define CYGNUM_HAL_INTERRUPT_CAN        15      // CAN Controller
#define CYGNUM_HAL_INTERRUPT_EMAC       16      // Ethernet MAC
#define CYGNUM_HAL_INTERRUPT_ADC        17      // Analog-to-Digital Converter
#define CYGNUM_HAL_INTERRUPT_IRQ0       30      // External IRQ0
#define CYGNUM_HAL_INTERRUPT_IRQ1       31      // External IRQ0

// Interrupts which are multiplexed on to the System Interrupt
#define CYGNUM_HAL_INTERRUPT_PITC       32      // Period Interval Timer
#define CYGNUM_HAL_INTERRUPT_RTTC       33      // Real-Time Timer
#define CYGNUM_HAL_INTERRUPT_PMC        34      // Power Management Controller
```

```
#define CYGNUM_HAL_INTERRUPT_MC         35      // Memory Controller
#define CYGNUM_HAL_INTERRUPT_WDTC       36      // Watchdog
#define CYGNUM_HAL_INTERRUPT_RSTC       37      // Reset Controller
#define CYGNUM_HAL_INTERRUPT_DEBUG      38      // Debug Serial Port
```

For the AT91SAM7A3:

```
#define CYGNUM_HAL_INTERRUPT_FIQ        0       // Advanced Interrupt Controller (FIQ)
#define CYGNUM_HAL_INTERRUPT_SYS        1       // System Peripheral (debug unit, system timer)
#define CYGNUM_HAL_INTERRUPT_PIOA       2       // Parallel IO Controller A
#define CYGNUM_HAL_INTERRUPT_PIOB       3       // Parallel IO Controller B
#define CYGNUM_HAL_INTERRUPT_CAN0       4       // CAN Controller 0
#define CYGNUM_HAL_INTERRUPT_CAN1       5       // CAN Controller 1
#define CYGNUM_HAL_INTERRUPT_USART0     6       // USART 0
#define CYGNUM_HAL_INTERRUPT_USART1     7       // USART 1
#define CYGNUM_HAL_INTERRUPT_USART2     8       // USART 2
#define CYGNUM_HAL_INTERRUPT_MCI        9       // Multimedia Card Interface
#define CYGNUM_HAL_INTERRUPT_TWI        10      // Two-Wire Interface (I2C)
#define CYGNUM_HAL_INTERRUPT_SPI        11      // Serial Parallel Interface 0
#define CYGNUM_HAL_INTERRUPT_SPI1       12      // Serial Parallel Interface 1
#define CYGNUM_HAL_INTERRUPT_SSC0       13      // Serial Synchronous Controller 0
#define CYGNUM_HAL_INTERRUPT_SSC1       14      // Serial Synchronous Controller 1
#define CYGNUM_HAL_INTERRUPT_TC0        15      // Timer Counter 0
#define CYGNUM_HAL_INTERRUPT_TC1        16      // Timer Counter 1
#define CYGNUM_HAL_INTERRUPT_TC2        17      // Timer Counter 2
#define CYGNUM_HAL_INTERRUPT_TC3        18      // Timer Counter 3
#define CYGNUM_HAL_INTERRUPT_TC4        19      // Timer Counter 4
#define CYGNUM_HAL_INTERRUPT_TC5        20      // Timer Counter 5
#define CYGNUM_HAL_INTERRUPT_TC6        21      // Timer Counter 6
#define CYGNUM_HAL_INTERRUPT_TC7        22      // Timer Counter 7
#define CYGNUM_HAL_INTERRUPT_TC8        23      // Timer Counter 8
#define CYGNUM_HAL_INTERRUPT_ADC0       24      // Analog-to-Digital Converter 0
#define CYGNUM_HAL_INTERRUPT_ADC1       25      // Analog-to-Digital Converter 1
#define CYGNUM_HAL_INTERRUPT_PWMC       26      // PWM Controller
#define CYGNUM_HAL_INTERRUPT_UDP        27      // USB Device Port
#define CYGNUM_HAL_INTERRUPT_IRQ0       28      // External Interrupt 0
#define CYGNUM_HAL_INTERRUPT_IRQ1       29      // External Interrupt 1
#define CYGNUM_HAL_INTERRUPT_IRQ2       30      // External Interrupt 2
#define CYGNUM_HAL_INTERRUPT_IRQ3       31      // External Interrupt 3

// Interrupts which are multiplexed on to the System Interrupt
#define CYGNUM_HAL_INTERRUPT_PITC       32      // Period Interval Timer
#define CYGNUM_HAL_INTERRUPT_RTTC       33      // Real-Time Timer
#define CYGNUM_HAL_INTERRUPT_PMC        34      // Power Management Controller
#define CYGNUM_HAL_INTERRUPT_MC         35      // Memory Controller
#define CYGNUM_HAL_INTERRUPT_WDTC       36      // Watchdog
#define CYGNUM_HAL_INTERRUPT_RSTC       37      // Reset Controller
#define CYGNUM_HAL_INTERRUPT_DEBUG      38      // Debug Serial Port
```

For the AT91SAM7A1 and AT91SAM7A2:

```
#define CYGNUM_HAL_INTERRUPT_FIQ         0      // Advanced Interrupt Controller (FIQ)
#define CYGNUM_HAL_INTERRUPT_SWIIRQ0     1      // Software Interrupt 0
#define CYGNUM_HAL_INTERRUPT_WD          2      // Watchdog
#define CYGNUM_HAL_INTERRUPT_WT          3      // Watch Timer
#define CYGNUM_HAL_INTERRUPT_USART0      4      // USART 0
#define CYGNUM_HAL_INTERRUPT_USART1      5      // USART 1
#define CYGNUM_HAL_INTERRUPT_CAN3        6      // CAN Controller 3
#define CYGNUM_HAL_INTERRUPT_SPI         7      // Serial Peripheral Interface
#define CYGNUM_HAL_INTERRUPT_CAN1        8      // CAN Controller 1
#define CYGNUM_HAL_INTERRUPT_CAN2        9      // CAN Controller 2
#define CYGNUM_HAL_INTERRUPT_ADC0        10      // Analog-to-Digital Converter 0
#define CYGNUM_HAL_INTERRUPT_ADC1        11      // Analog-to-Digital Converter 1
#define CYGNUM_HAL_INTERRUPT_GPT0CH0     12      // General Purpose Timer 0 Channel 0
#define CYGNUM_HAL_INTERRUPT_GPT0CH1     13      // General Purpose Timer 0 Channel 1
#define CYGNUM_HAL_INTERRUPT_GPT0CH2     14      // General Purpose Timer 0 Channel 2
#define CYGNUM_HAL_INTERRUPT_SWIIRQ1     15      // Software Interrupt 1
```

```
#define CYGNUM_HAL_INTERRUPT_SWIIRQ2     16      // Software Interrupt 2
#define CYGNUM_HAL_INTERRUPT_SWIIRQ3     17      // Software Interrupt 3
#define CYGNUM_HAL_INTERRUPT_GPT1CH0     18      // General Purpose Timer 1 Channel 0
#define CYGNUM_HAL_INTERRUPT_PWM         19      // PWM Controller
#define CYGNUM_HAL_INTERRUPT_CAN0        20      // CAN Controller 0
#define CYGNUM_HAL_INTERRUPT_UPIO        21      // Unified Parallel IO Controller
#define CYGNUM_HAL_INTERRUPT_CAPT0       22      // Capture 0
#define CYGNUM_HAL_INTERRUPT_CAPT1       23      // Capture 1
#define CYGNUM_HAL_INTERRUPT_ST0         24      // Simple Timer 0
#define CYGNUM_HAL_INTERRUPT_ST1         25      // Simple Timer 1
#define CYGNUM_HAL_INTERRUPT_SWIIRQ4     26      // Software Interrupt 4
#define CYGNUM_HAL_INTERRUPT_SWIIRQ5     27      // Software Interrupt 5
#define CYGNUM_HAL_INTERRUPT_IRQ0        28      // External Interrupt 0
#define CYGNUM_HAL_INTERRUPT_IRQ1        29      // External Interrupt 1
#define CYGNUM_HAL_INTERRUPT_SWIIRQ6     30      // Software Interrupt 6
#define CYGNUM_HAL_INTERRUPT_SWIIRQ7     31      // Software Interrupt 7
```

Chapter 237. Atmel AT91SAM7A2-EK Board Support

Name

eCos Support for the Atmel AT91SAM7A2-EK — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel AT91SAM7A2-EK Evaluation Kit. The AT91SAM7A2-EK Evaluation Kit contains the AT91SAM7A2 processor, 512KiB of SRAM, 2MiB of parallel NOR Flash memory, external connections for a singe serial channel, CAN and LIN ports. eCos support for the devices and peripherals on the AT91SAM7A2 is described below.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot into this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. Applications may also be loaded into RAM via a JTAG debugger, or may be programmed into flash.

This documentation is expected to be read in conjunction with the AT91 processor HAL and AT91SAM7 variant HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The parallel NOR flash memory consists of 31 blocks of 16KiBytes each, followed by 8 blocks of 8KiBytes each. In a typical setup, the first 128 KiBytes are reserved for the use of the RedBoot image. The topmost 8 blocks are used to manage the flash and hold RedBoot **fconfig** values. The remaining blocks can be used by application code. There are 30 blocks available between 0x40020000 and 0x401EFFFF.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port can be used for communication. If RedBoot is installed, it uses the Debug Unit serial device. The serial driver package is loaded automatically when configuring for the AT91SAM7A2-EK target.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91`. This driver is also loaded automatically when configuring for the AT91SAM7A2-EK target.

In general, devices (PIO, UARTs, etc.) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM7A2-EK support is intended to work with GNU tools configured for an arm-elf target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM7A2-EK board for eCos Development

Overview

In a typical development environment, the AT91SAM7A2-EK boards boot from the parallel NOR Flash and run the RedBoot ROM monitor directly. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-elf-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
JTAG	RedBoot running from RAM, loaded via JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud.

The ROM version is programmed into flash to boot the system; however, it is not able to reprogram the RedBoot image in flash. The RAM version is provided to allow for updating the resident RedBoot image in Flash. The JTAG version is only used if loading RedBoot into RAM via a JTAG debugger or ICE. The ELF format image of this JTAG version of RedBoot can be loaded and executed from GDB using the Abatron BDI2000 bdiGDB support, to allow it to be debugged.

Initial Installation

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot into this image from reset. Two mechanisms are described below to program RedBoot into Flash. Both of them require a JTAG device. In the following documentation it is assumed that the Abatron BDI2000 is being used. For a different JTAG device, equivalent operations will need to be performed.

Preparing the Abatron BDI2000 JTAG debugger

The BDI2000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.
2. Connect the Abatron BDI2000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI2000.
3. Install the Abatron BDI2000 bdiGDB support software on the host PC.
4. Locate the file `bdi2000.at91sam7a2ek.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/at91/at91sam7a2ek/`*`VERSION`*`/misc` relative to the root of your eCos installation.
5. Locate the file `reg920t.def` within the installation of the BDI2000 bdiGDB support software.
6. Place the bdi2000.at91sam7a2ek.cfg in a location on the PC accessible to the TFTP server. Later you will configure the BDI2000 to load this file via TFTP as its configuration file.
7. Similarly place the file `reg920t.def` in a location accessible to the TFTP server.

8. Open `bdi2000.at91sam7a2ek.cfg` in an editor such as emacs or notepad and if necessary adjust the path of the `reg920t.def` file in the `[REGS]` section to match its location relative to the TFTP server root.

9. Install and configure the Abatron BDI2000 in line with the bdiGDB instruction manual. Configure the BDI2000 to use the `bdi2000.at91sam7a2ek.cfg` configuration file at the appropriate point of this process.

Preparing the AT91SAM7A2-EK board for programming

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to the BDI2000 using a 20-pin ARM/Xscale cable from the JTAG interface connector to the Target A port on the BDI2000.

4. Power up the AT91SAM7A2-EK board.

5. Connect to the BDI2000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

   ```
   SAM7A2>
   ```

6. Confirm correct connection with the BDI2000 with the **reset halt** command as follows:

   ```
   SAM7A2> reset halt
   - TARGET: processing reset request
   - TARGET: BDI asserts TRST and RESET
   - TARGET: BDI removes TRST
   - TARGET: Bypass check 0x000000001 => 0x00000001
   - TARGET: JTAG exists check passed
   - Core#0: ID code is 0x1F0F0F0F
   - TARGET: All ICEBreaker access checks passed
   - TARGET: BDI removes RESET
   - TARGET: BDI waits for RESET inactive
   - TARGET: resetting target passed
   - TARGET: processing target startup ....
   - TARGET: processing target startup passed
   SAM7A2>
   ```

7. Locate the `redboot_ROM.bin` image within the `loaders` subdirectory of the base of the eCos installation.

8. Copy the `redboot_ROM.bin` file into a location on the host computer accessible to its TFTP server.

Using the BDI2000 to directly program RedBoot into Flash

As previously mentioned, there are two methods of programming a RedBoot image into the parallel NOR Flash. This method uses the built-in capabilities of the BDI2000.

This is a three stage process. The relevant Flash blocks must first be unlocked, then erased, and finally programmed. This can be accomplished with the following steps:

1. Connect to the BDI2000 telnet port as before.

2. Erase the 8 initial 8Kbyte sized Flash blocks, and the following 64Kbyte Flash block with the following command:

   ```
   SAM7A>erase
   ```

```
Erasing flash at 0x40000000
Erasing flash at 0x40002000
Erasing flash at 0x40004000
Erasing flash at 0x40006000
Erasing flash at 0x40008000
Erasing flash at 0x4000a000
Erasing flash at 0x4000c000
Erasing flash at 0x4000e000
Erasing flash at 0x40010000
Erasing flash passed
SAM7A>
```

3. Program the RedBoot image into Flash with the following command, replacing */RBPATH* with the location of the redboot_ROM.bin file relative to the TFTP server root directory:

   ```
   SAM7A>prog 0x40000000 /RBPATH/redboot_ROM.bin bin
   Programming redboot_ROM.bin , please wait ....
   Programming flash passed
   SAM7A>
   ```

   This operation can take some time.

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. The RedBoot banner should be visible on the serial port. RedBoot's Flash configuration can be initialized using the same procedure as required in Method 2 below.

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Method 2 - Program RedBoot into Flash with RAM RedBoot

With this approach, the BDI2000 is used to load a RAM RedBoot image, which can then in turn be used to load and program a ROMRAM RedBoot image into Flash.

There are three stages, firstly loading the RAM RedBoot image, then initializing RedBoot's Flash configuration, and finally loading and programming the ROMRAM RedBoot.

Loading a RAM RedBoot

1. Locate the `redboot_JTAG.bin` image within the `loaders` subdirectory of the base of the eCos installation.

2. Copy the `redboot_JTAG.bin` file into a location on the host computer accessible to its TFTP server.

3. With the BDI2000 telnet interface, execute the following command, replacing */RBPATH* with the location of the redboot_JTAG.bin file relative to the TFTP server root directory:

   ```
   SAM7A>load 0x48000000 /RBPATH/redboot_JTAG.bin bin
   Loading /RBPATH/redboot_JTAG.bin , please wait ....
   Loading program file passed
   SAM7A>
   ```

4. Run the loaded RAM RedBoot:

   ```
   SAM7A>go 0x48000040
   SAM7A>
   ```

The terminal emulator connected to the serial debug port should now have displayed the RedBoot banner and prompt similar to the following:

```
**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
```

```
RedBoot(tm) bootstrap and debug environment [JTAG]
Non-certified release, version UNKNOWN - built 11:03:18, Oct 27 2006

Platform: Atmel AT91SAM7A2-EK (ARM7TDMI)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006 eCosCentric Limited

RAM: 0x48000000-0x48040000, [0x48017078-0x4802d000] available
FLASH: 0x40000000-0x401fffff, 31 x 0x10000 blocks, 8 x 0x2000 blocks
RedBoot>
```

Note

It is also possible to use the RAM startup version of RedBoot and the redboot_RAM.bin file instead of redboot_JTAG.bin above. If so, then the address to the **load** command must be 0x48008000, and the start address given to the **go** command should be 0x48008040.

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration. This must be performed when using a RAM RedBoot to program Flash, but is also applicable to initial configuration of a ROM RedBoot loaded using Method 1.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

   ```
   RedBoot> fis init -f
   About to initialize [format] FLASH image system - continue (y/n)? y
   *** Initialize FLASH Image System
   ... Erase from 0x40020000-0x401effff: ............................
   ... Erase from 0x401f0000-0x401fffff: ........
   ... Program from 0x48030000-0x48040000 to 0x401f0000: ........
   RedBoot>
   ```

2. Now configure RedBoot's Flash configuration with the command:

   ```
   RedBoot> fconfig -i
   ```

   The following gives an example configuration:

   ```
   RedBoot> fconfig -i
   Initialize non-volatile configuration - continue (y/n)? y
   ... Erase from 0x401f0000-0x401fffff: ........
   ... Program from 0x48030000-0x48040000 to 0x401f0000: ........
   RedBoot>
   ```

Loading and programming the ROM RedBoot

This section describes the steps required to load the ROM RedBoot from the TFTP server and program it into Flash.

1. Load the RedBoot ROM binary image using Y-Modem protocol over the serial line. First give this command to RedBoot:

   ```
   RedBoot> load -r -m y -b %{freememlo}
   C
   RedBoot>
   ```

   Use the Y-Modem protocol support of your terminal emulator to send the `redboot_ROM.bin` file at this point. When the transfer is finished RedBoot will report:

   ```
   Raw file loaded 0x48017400-0x4802abd3, assumed entry at 0x48017400
   xyzModem - CRC mode, 627(SOH)/0(STX)/0(CAN) packets, 8 retries
   RedBoot>
   ```

2. Finally install the loaded image into Flash:

```
RedBoot> fis create RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x40000000-0x4001ffff: .........
... Program from 0x48017400-0x4802abd4 to 0x40000000: .........
... Erase from 0x401f0000-0x401fffff: .
... Program from 0x48030000-0x48040000 to 0x401f0000: .
RedBoot>
```

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. Output similar to the following should be seen on the serial port.

```
+
RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 11:41:25, Oct 27 2006

Platform: Atmel AT91SAM7A2-EK (ARM7TDMI)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006 eCosCentric Limited

RAM: 0x48000000-0x48040000, [0x48005150-0x4802d000] available
FLASH: 0x40000000-0x401fffff, 8 x 0x2000 blocks, 31 x 0x10000 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM7A2-EK platform HAL package is loaded automatically when eCos is configured for the `at91sam7a2ek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the stubs, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x40000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is an alternative development startup type. The application is loaded into RAM via a JTAG device and is run and debugged from there. The application will be self-contained with no dependencies on services provided by other software. It is expected that hardware setup will have been performed via the JTAG device prior to loading.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB Stubs.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM7A2-EK board contains a quantity of on-chip flash memory. The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2` package contains the code necessary to support this part and the platform HAL package contains definitions necessary to support this part. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Watchdog Driver

The AT91SAM7A2-EK board use the AT91SAM7A2's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

USART Serial Driver

The AT91SAM7A2-EK board use the AT91SAM7A2's internal USART serial support as described in the AT91 processor HAL documentation. One serial ports is available: USART 0 which is mapped to virtual vector channel 0 and "`/dev/ser0`". USART 0 does not support modem control signals such as those used for hardware flow control.

Compiler Flags

The SAM7 variant HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm7tdmi`
: The arm-elf-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm7tdmi` is the correct option for the ARM7TDMI processor in the SAM7A2.

`-mthumb`
: The arm-elf-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded RAM applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The ARM7TDMI core of the AT91SAM7A2 only supports two such hardware breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI2000 notes

On the Abatron BDI2000, the `bdi2000.at91sam7a2ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLL and flash memory controller.

The `bdi2000.at91sam7a2ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI2000 command line interface to make the changes take effect.

On the BDI2000, debugging can be performed either via the telnet interface or using **arm-elf-gdb** and the bdiGDB interface. In the case of the latter, **arm-elf-gdb** needs to connect to TCP port 2001 on the BDI2000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI2000 is powered up, the target will always run the initialization section of the `bdi2000.at91sam7a2ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behaviour is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot from ROM as normal.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
SAM7A2>load 0x00201000 /test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
SAM7A2>go 0x00201000
```

Consult the BDI2000 documentation for information on other formats.

Configuration of RAM applications

If the JTAG device has initialized the processor, such as by using the `bdi2000.at91sam7a2ek.cfg` configuration on the BDI2000, applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Selecting the JTAG startup type in the configuration tool sets these options automatically.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial port.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM7A2-EK hardware, and should be read in conjunction with that specification. The AT91SAM7A2-EK platform HAL package complements the ARM architectural HAL, the AT91 variant HAL and the AT91SAM7 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor or JTAG device for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the PLL and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The AT91SAM7 processor HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash
This is located at address 0x40000000 of the physical memory space.

RAM
This is located at address 0x48000000 of the physical memory space. During booting this memory is only available at this address, but during the boot process it is also remapped to location 0x00000000 in order to allow the hardware exception vectors to be in RAM. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup, all remaining RAM is available. For RAM startup, available RAM starts at location 0x48008000, with the bottom 32KiB reserved for use by RedBoot.

On-chip Peripheral Registers
These are located at address 0xFF000000 in the physical memory space.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 237.1. at91sam7a2ek Real-time characterization

```
            Startup, main stack : stack used   416 size  3920
             Startup :  Interrupt stack used   148 size  4096
             Startup : Idlethread stack used    88 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   61.00 microseconds (57 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  10
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32

                                   Confidence

```

Other Issues

The AT91SAM7A2-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The AT91SAM7 processor HAL, AT91 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 238. Atmel AT91SAM7A3-EK Board Support

Name

eCos Support for the Atmel AT91SAM7A3-EK — Overview

Description

This document covers the configuration and usage of eCos and GDB Stubs on the Atmel AT91SAM7A3-EK Evaluation Kit. The AT91SAM7A3-EK Evaluation Kit contains the AT91SAM7A3 processor, external connections for one serial channel, USB host/device, MMC card. eCos support for the devices and peripherals on the AT91SAM7A3 is described below.

Application development on this board can take one of several approaches. Applications may be loaded into RAM via a JTAG device; however, the application size is limited by the amount of on-chip RAM: 32KiB. Applications may also be loaded into the on-chip flash memory where the RAM limit will only apply to the data portion of the application. Finally, it is possible to program a GDB debugging stub into flash which will then allow applications to be loaded into RAM via the serial port. This allows development to proceed without needing to use a JTAG device, although one will be required to program the debugging stub in the first place, and application size is limited to just 28KiB, since the GDB stub uses the least significant 4KiB.

This documentation is expected to be read in conjunction with the AT91 processor HAL and AT91SAM7 variant HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The on-chip NOR flash is organized into 1024 pages of 256 bytes each.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports the Debug Unit and USART serial devices. The debug serial port at J2 can be used for communication. If the GDB stub ROM is installed, it uses the Debug Unit serial device. The serial driver package is loaded automatically when configuring for the AT91SAM7A3-EK target.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the AT91SAM7A3-EK target.

In general, devices (PIO, UARTs, etc.) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM7A3-EK support is intended to work with GNU tools configured for an arm-elf target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM7A3-EK board for eCos Development

Overview

eCos applications are either programmed into the on-chip flash, or run from RAM using either a JTAG device or the GDB stubs ROM. To install a flash-resident application, or the GDB stubs requires use of a JTAG device to write to the flash. So, in all cases it is necessary to set up a JTAG device for the board. This document describes how to set up an Abatron BDI2000 and then use it to program an application into the flash.

Initial Installation

Preparing the Abatron BDI2000 JTAG debugger

The BDI2000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.

2. Connect the Abatron BDI2000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI2000.

3. Install the Abatron BDI2000 bdiGDB support software on the host PC.

4. Locate the file `bdi2000.at91sam7a3ek.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/at91/at91sam7a3ek/`*`VERSION`*`/misc` relative to the root of your eCos installation.

5. Locate the file `reg920t.def` within the installation of the BDI2000 bdiGDB support software.

6. Place the bdi2000.at91sam7a3ek.cfg in a location on the PC accessible to the TFTP server. Later you will configure the BDI2000 to load this file via TFTP as its configuration file.

7. Similarly place the file `reg920t.def` in a location accessible to the TFTP server.

8. Open `bdi2000.at91sam7a3ek.cfg` in an editor such as emacs or notepad and if necessary adjust the path of the `reg920t.def` file in the `[REGS]` section to match its location relative to the TFTP server root.

9. Install and configure the Abatron BDI2000 in line with the bdiGDB instruction manual. Configure the BDI2000 to use the `bdi2000.at91sam7a3ek.cfg` configuration file at the appropriate point of this process.

Preparing the AT91SAM7A3-EK board for programming

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to the BDI2000 using a 20-pin ARM/Xscale cable from the JTAG interface connector to the Target A port on the BDI2000.

4. Power up the AT91SAM7A3-EK board.

5. Connect to the BDI2000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

   ```
   SAM7A3>
   ```

6. Confirm correct connection with the BDI2000 with the **reset halt** command as follows:

   ```
   SAM7A3> reset halt
   - TARGET: processing reset request
   - TARGET: BDI asserts TRST and RESET
   - TARGET: BDI removes TRST
   - TARGET: Bypass check 0x000000001 => 0x00000001
   - TARGET: JTAG exists check passed
   - Core#0: ID code is 0x3F0F0F0F
   - TARGET: All ICEBreaker access checks passed
   - TARGET: BDI removes RESET
   - TARGET: BDI waits for RESET inactive
   - TARGET: resetting target passed
   - TARGET: processing target startup ....
   - TARGET: processing target startup passed
   SAM7A3>
   ```

Installation into Flash

Installation of an application into the on-chip flash, or the installation of the GDB stubs take exactly the same form:

1. Locate the binary image of the executable to be installed. For the GDB stubs do this by locating the file `gdb.module.bin` within the `loaders` subdirectory of the base of the eCos installation. For applications use **arm-elf-objcopy -O binary** to convert the ELF output of the linker into binary.

2. Copy the file into a location on the host computer accessible to its TFTP server.

3. Connect to the BDI2000 telnet port as before.

4. Give the **unlock** command to ensure that the flash area we want to program is writable:

   ```
   SAM7A3>unlock 0x100000 0x100 256
   Unlocking flash at 0x00100000
   Unlocking flash at 0x00100100
   Unlocking flash at 0x00100200
   ...
   Unlocking flash at 0x0010fe00
   Unlocking flash at 0x0010ff00
   Unlocking flash passed
   SAM7A3>
   ```

   This command unlocks 256 pages, i.e. 64KiB. The number of pages unlocked should match at least the size of the executable to be programmed.

5. Give the **erase** command to clear any previous contents:

   ```
   SAM7A3>erase 0x100000 0x100 256
   Erasing flash at 0x00100000
   Erasing flash at 0x00100100
   Erasing flash at 0x00100200
   ...
   Erasing flash at 0x0010fe00
   Erasing flash at 0x0010ff00
   Erasing flash passed
   SAM7A3>
   ```

As with the **unlock** command, the size of the area erased must be at least the size of the executable to be programmed.

6. Now give the **prog** command to fetch the executable from the TFTP server and program it to the flash.

   ```
   SAM7A3>prog 0x100000 sam7.bin bin
   Programming sam7.bin , please wait ....
   Programming flash passed
   SAM7A3>
   ```

The installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. A ROM based application should start immediately, and any output will be seen on the serial connection. If the GDB stub ROM has been installed, then something similar to the following will be seen on the serial port:

```
+$T050f:cc061000;0d:18082000;#4d
```

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM7A3-EK platform HAL package is loaded automatically when eCos is configured for the `at91sam7a3ek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has GDB stubs programmed into flash and boots into that initially. arm-elf-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the stubs, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x00100000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is an alternative development startup type. The application is loaded into RAM via a JTAG device and is run and debugged from there. The application will be self-contained with no dependencies on services provided by other software. It is expected that hardware setup will have been performed via the JTAG device prior to loading.

GDB Stubs and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB Stubs.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM7A3-EK board contains a quantity of on-chip flash memory. The `CYGPKG_DEVS_FLASH_AT91` package contains all the code and data definitions necessary to support this part. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Watchdog Driver

The AT91SAM7A3-EK board use the AT91SAM7A3's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

Note that on the AT91, the on-chip watchdog peripheral always starts running immediately, and so in configurations that do not include the watchdog driver, it is always disabled via its write-once register. In configurations which include the watchdog driver obviously the watchdog is not disabled otherwise it could not be subsequently re-enabled, and so the application must start and periodically reset the watchdog from the very beginning of execution.

USART Serial Driver

The AT91SAM7A3-EK board use the AT91SAM7A3's internal USART serial support as described in the AT91 processor HAL documentation. Two serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/dbg`" in the interrupt-driven driver; and USART 0 which is mapped to virtual vector channel 1 and "`/dev/ser0`". Only USART 0 supports modem control signals such as those used for hardware flow control.

Compiler Flags

The SAM7 variant HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm7tdmi`

The arm-elf-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm7tdmi` is the correct option for the ARM7TDMI processor in the SAM7A3.

`-mthumb`

The arm-elf-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`

This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded RAM applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The ARM7TDMI core of the AT91SAM7A3 only supports two such hardware breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI2000 notes

On the Abatron BDI2000, the `bdi2000.at91sam7a3ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLL and flash memory controller.

The `bdi2000.at91sam7a3ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI2000 command line interface to make the changes take effect.

On the BDI2000, debugging can be performed either via the telnet interface or using **arm-elf-gdb** and the bdiGDB interface. In the case of the latter, **arm-elf-gdb** needs to connect to TCP port 2001 on the BDI2000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI2000 is powered up, the target will always run the initialization section of the `bdi2000.at91sam7a3ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behaviour is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot from ROM as normal.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
SAM7A3>load 0x00201000 /test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
SAM7A3>go 0x00201000
```

Consult the BDI2000 documentation for information on other formats.

Configuration of RAM applications

If the JTAG device has initialized the processor, such as by using the `bdi2000.at91sam7a3ek.cfg` configuration on the BDI2000, applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Selecting the JTAG startup type in the configuration tool sets these options automatically.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USART 0 can be chosen instead by setting the CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL configuration option in the platform HAL to channel 1.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM7A3-EK hardware, and should be read in conjunction with that specification. The AT91SAM7A3-EK platform HAL package complements the ARM architectural HAL, the AT91 variant HAL and the AT91SAM7 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor or JTAG device for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the PLL and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The AT91SAM7 processor HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

On-chip Flash
This is located at address 0x00100000 of the physical memory space.

On-chip RAM
This is located at address 0x00200000 of the physical memory space. During booting this memory is only available at this address, but during the boot process it is also remapped to location 0x00000000 in order to allow the hardware exception vectors to be in RAM. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup, all remaining RAM is available. For RAM startup, available RAM starts at location 0x00201000, with the bottom 4KiB reserved for use by the GDB stubs.

On-chip Peripheral Registers
These are located at address 0xFF000000 in the physical memory space.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 238.1. at91sam7a3ek Real-time characterization

```
            Startup, main stack : stack used   456 size  3920
             Startup :  Interrupt stack used  4064 size  4096
             Startup : Idlethread stack used   120 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 3 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   47.13 microseconds (141 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   1
   Thread switches:         128
```

```

```

Other Issues

The AT91SAM7A3-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The AT91SAM7 processor HAL, AT91 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 239. Atmel AT91SAM7S-EK Board Support

Name

eCos Support for the Atmel AT91SAM7S-EK — Overview

Description

This document covers the configuration and usage of eCos and GDB Stubs on the Atmel AT91SAM7S-EK Evaluation Kit. The AT91SAM7S-EK Evaluation Kit contains the AT91SAM7S processor, external connections for two serial channels (one debug, one full), USB host/device. eCos support for the devices and peripherals on the AT91SAM7S is described below.

Application development on this board can take one of several approaches. Applications may be loaded into RAM via a JTAG device; however, the application size is limited by the amount of on-chip RAM, which is 64KiB on the AT91SAM7S256 and AT91SAM7S512, and 32KiB on the AT91SAM7S128. Applications may also be loaded into the on-chip flash memory where the RAM limit will only apply to the data portion of the application. Finally, it is possible to program a GDB debugging stub into flash which will then allow applications to be loaded into RAM via the serial port. This allows development to proceed without needing to use a JTAG device and application size is limited to the RAM size less 4KiB used by the stub. It is therefore recommended that JTAG debugging be used to debug applications since memory is limited on this platform.

This documentation is expected to be read in conjunction with the AT91 processor HAL and AT91SAM7 variant HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The on-chip NOR flash is organized into pages of 128 or 256 bytes each. The number of pages is determined by the device variant, from 2048 for the AT91SAM7S512 to 128 for the AT91SAM7S32.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J3 and DTE port at J2 (connected to USART channel 0) can be used for communication. If the GDB stub ROM is installed, it uses the Debug Unit serial device only. The serial driver package is loaded automatically when configuring for the AT91SAM7S-EK target.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the AT91SAM7S-EK target.

In general, devices (PIO, UARTs, etc.) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM7S-EK support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM7S-EK board for eCos Development

Overview

eCos applications are either programmed into the on-chip flash, or run from RAM using either a JTAG device or the GDB stubs ROM. The installation of the GDB stubs or any flash-resident application requires use of a JTAG device to write to the flash, or the Atmel-supplied SAM-BA program that interacts with the on-chip boot program. This document describes how to set up an Abatron BDI2000 Ronetix PEEDI for programming the gdb stubs and applications into the flash, and use the Atmel SAM-BA application to program the gdb stubs into the flash.

Initial Installation with Abatron BDI2000

Preparing the Abatron BDI2000 JTAG debugger

The BDI2000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.
2. Connect the Abatron BDI2000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI2000.
3. Install the Abatron BDI2000 bdiGDB support software on the host PC.
4. Locate the file `bdi2000.at91sam7sek.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/at91/at91sam7sek/`*`VERSION`*`/misc` relative to the root of your eCos installation.
5. Locate the file `regSAM7S.def` within the installation of the BDI2000 bdiGDB support software.
6. Place the `bdi2000.at91sam7sek.cfg` file in a location on the PC accessible to the TFTP server. Later you will configure the BDI2000 to load this file via TFTP as its configuration file.
7. Similarly place the file `regSAM7S.def` in a location accessible to the TFTP server.
8. Open `bdi2000.at91sam7sek.cfg` in an editor such as emacs or notepad and if necessary adjust the path of the `regSAM7S.def` file in the `[REGS]` section to match its location relative to the TFTP server root.
9. Install and configure the Abatron BDI2000 in line with the bdiGDB instruction manual. Configure the BDI2000 to use the `bdi2000.at91sam7sek.cfg` configuration file at the appropriate point of this process.

Preparing the AT91SAM7S-EK board for programming with BDI2000

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.
2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.
3. Connect the board to the BDI2000 using a 20-pin ARM/Xscale cable from the JTAG interface connector to the Target A port on the BDI2000.

4. Power up the AT91SAM7S-EK board.

5. Connect to the BDI2000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

   ```
   SAM7S>
   ```

6. Confirm correct connection with the BDI2000 with the **reset halt** command as follows:

   ```
   SAM7S> reset halt
   - TARGET: processing reset request
   - TARGET: BDI asserts TRST and RESET
   - TARGET: BDI removes TRST
   - TARGET: Bypass check 0x000000001 => 0x00000001
   - TARGET: JTAG exists check passed
   - Core#0: ID code is 0x3F0F0F0F
   - TARGET: All ICEBreaker access checks passed
   - TARGET: BDI removes RESET
   - TARGET: BDI waits for RESET inactive
   - TARGET: resetting target passed
   - TARGET: processing target startup ....
   - TARGET: processing target startup passed
   SAM7S>
   ```

Initial Installation with Ronetix PEEDI

Preparing the Ronetix PEEDI JTAG debugger

The PEEDI must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps give a typical outline of setting up the PEEDI using TFTP. Consult the PEEDI documentation for alternative mechanisms.

1. Prepare a PC to act as a host PC and start a TFTP server on it.

2. Connect the PEEDI JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the PEEDI (straight through, not null modem).

3. Locate the file `peedi.at91sam7sek.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/at91/at91sam7sek/`*`VERSION`*`/misc` relative to the root of your eCos installation.

4. Place the `peedi.at91sam7sek.cfg` file in a location on the PC accessible to the TFTP server. Later you will configure the PEEDI to load this file via TFTP as its configuration file.

5. Open `at91sam7sek.cfg` in an editor such as emacs or notepad and insert your own license information in the `[LICENSE]` section.

6. Install and configure the PEEDI in line with the PEEDI Quick Start Guide or User's Manual, especially configuring PEEDI's RedBoot with the network information. Configure it to use the `peedi.at91sam7sek.cfg` target configuration file on the TFTP server at the appropriate point of the **fconfig** process, for example with a path such as: `tftp://192.168.7.9/peedi.at91sam7sek.cfg`

7. Reset the PEEDI.

8. Connect to the PEEDI's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see output similar to the following:

   ```
   $ telnet 192.168.7.225
   Trying 192.168.7.225...
   Connected to 192.168.7.225.
   Escape character is '^]'.
   ```

```
PEEDI - Powerful Embedded Ethernet Debug Interface

sam7sek>
```

Preparing the AT91SAM7S-EK board for programming with PEEDI

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to the PEEDI using a 20-pin ARM/Xscale cable from the JTAG interface connector on the board to the Target port on the PEEDI.

4. Power up the AT91SAM7S-EK board.

5. Connect to the PEEDI's CLI on port 23 as before.

6. Confirm correct connection with the PEEDI with the **reset** command as follows:

   ```
   sam7sek> reset
   ++ info: user reset
   sam7sek>
   ++ info: RESET and TRST asserted
   ++ info: TRST released
   ++ info: 1 TAP controller(s) detected
   ++ info: TAP : IDCODE = 0x3F0F0F0F, ARM7TDMI compliant
   ++ info: RESET released
   ++ info: core 0: initialized

   sam7sek>
   ```

Installation into Flash

Installation of an application into the on-chip flash, or the installation of the GDB stubs, using a JTAG programmer takes exactly the same form:

1. Locate the binary image of the executable to be installed. For the GDB stubs do this by locating the file `gdb_module.bin` within the `loaders` subdirectory of the base of the eCos installation. For applications use **arm-eabi-objcopy -O binary** to convert the ELF output of the linker into binary.

2. Copy the file into a location on the host computer accessible to its TFTP server.

3. Connect to the JTAG device telnet port as before.

4. The flash must be unlocked to ensure that the flash area we want to program is writable.

   For the BDI2000, use the **unlock** command:

   ```
   SAM7S>unlock 0x100000 0x100 256
   Unlocking flash at 0x00100000
   Unlocking flash at 0x00100100
   Unlocking flash at 0x00100200
   ```

```
...
Unlocking flash at 0x0010fe00
Unlocking flash at 0x0010ff00
Unlocking flash passed
SAM7S>
```

For the PEEDI, use the **flash unlock** command:

```
sam7sek> flash unlock 0x100000 65536
unlocking region #0 at 0x00100000
unlocking region #1 at 0x00104000
unlocking region #2 at 0x00108000
unlocking region #3 at 0x0010C000

sam7sek>
```

This command unlocks 256 pages, i.e. 64KiB on the AT91SAM7S512. The number of pages unlocked should match at least the size of the executable to be programmed. With the PEEDI you can use an unadorned **flash unlock** to unlock the entire flash.

5. Give the **erase** (BDI2000) or **flash erase** (PEEDI) command to clear any previous contents.

   For the BDI2000:

```
SAM7S>erase 0x100000 0x100 256
Erasing flash at 0x00100000
Erasing flash at 0x00100100
Erasing flash at 0x00100200
...
Erasing flash at 0x0010fe00
Erasing flash at 0x0010ff00
Erasing flash passed
SAM7S>
```

   As with the **unlock** command, the size of the area erased must be at least the size of the executable to be programmed.

   For the PEEDI, only full flash erase is supported:

```
sam7sek> flash erase

done.

sam7sek>
```

6. Now give the **prog** (BDI2000) or **flash program** (PEEDI) command to fetch the executable from the TFTP server and program it to the flash.

   For the BDI2000:

```
SAM7S>prog 0x100000 sam7.bin bin
Programming sam7.bin , please wait ....
Programming flash passed
SAM7S>
```

   For the PEEDI:

```
sam7sek> flash program tftp://192.168.7.9/gdb_module.bin bin 0x100000
++ info: Programming directly
++ info: Programming image file: tftp://192.168.7.9/gdb_module.bin
++ info: At absolute addres:     0x00100000
unlocking   at 0x00100000 (region #0)
programming at 0x00100000
programming at 0x00101000
programming at 0x00102000
programming at 0x00103000
unlocking   at 0x00104000 (region #1)
```

```
programming at 0x00104000
programming at 0x00105000
programming at 0x00106000
programming at 0x00107000

++ info: successfully programmed 32.00 KB in 0.93 sec

sam7sek>
```

The installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. A ROM based application should start immediately, and any output will be seen on the serial connection. If the GDB stub ROM has been installed, then something similar to the following will be seen on the serial port:

```
+$T050f:cc061000;0d:18082000;#4d
```

Programming GDB Stubs into Flash using SAM-BA

The following gives the steps needed to program the gdb stubs into Flash using SAM-BA. The user should refer to the SAM-BA documentation for full details of how to run the program.

1. Download the AT91 In-system Programmer software package from the Atmel website. Install it on a suitable PC running Windows or Linux. The remainder of this section documents the behaviour seen under Windows, although the behaviour on Linux should not be too different.

2. Copy `gdb_module.bin` from either the at91sam7sek_256 or at91sam7sek_512 subdirectories, depending on which of the two boards you are using, to a suitable location on the PC.

3. Connect a null-modem serial cable between the DEBUG serial port of the board and a serial port on a convenient host (which need not be the PC running SAM-BA). Run a terminal emulator (Hyperterm or minicom) at 38400 baud. Connect a USB cable between the PC and the AT91SAM7S-EK board.

4. JP5 (TST) jumper needs to be temporarily closed and USB connected into the PC for 10 seconds. This writes the SAM-BA bootstrap into the boot sectors so the board can then be programmed. USB should then be disconnected and JP5 moved to the open position. If you do not do this then the option of connecting SAM-BA to the \usb\ARM0 will not be available when the USB cable is reconnected to the PC.

5. Power up the board by plugging the USB cable from the AT91SAM7S-EK board into the PC and Windows should now recognize the USB device.

6. Start SAM-BA. Select "\usb\ARM0" for the communication interface, and "at91sam7s256-ek" or "at91sam7s512-ek" for the board to match the board you are about to program. If the USB option does not appear, check the cable and look in the Windows Device Manager for the active device. If all is well, click on "Connect".

7. In the SAM-BA main window, select the "FLASH" tab and in the "Send File Name" field, select the `gdb_module.bin`. Ensure that the Address field contains "0x100000" and click "Send File". The following output should be seen:

   ```
   (AT91-ISP v1.12) 1 % send_file {Flash} "gdb_module.bin" 0x100000 0
   -I- Send File gdb_module.bin at address 0x100000
    first_sector 0 last_sector 1
   -I-     Writing: 0x740C bytes at 0x0 (buffer addr : 0x202B68)
   -I-     0x740C bytes written by applet
   (AT91-ISP v1.12) 1 %
   ```

   You may get a popup asking if you want to unlock sectors 0, 1 of flash. Select "Y" if prompted.

   You may also get a pop-up asking "Do you want to lock involved lock region(s) (0 to 1)?". Select "No" if prompted.

8. Shut down SAM-BA, disconnect and reconnect the USB cable. Press the reset button on the board and something similar to the following should be output for a AT91SAM7S256-EK board on the DEBUG serial line:

```
$T050f:cc051000;0d:e8072000;#7f
```

For a AT91SAM7S512-EK board you should see something similar. For example:

```
$T050f:c0051000;0d:e0072000;#44
```

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM7S-EK platform HAL package is loaded automatically when eCos is configured for the `at91sam7sek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has GDB stubs programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the stubs, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x00100000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is an alternative development startup type. The application is loaded into RAM via a JTAG device and is run and debugged from there. The application will be self-contained with no dependencies on services provided by other software. It is expected that hardware setup will have been performed via the JTAG device prior to loading.

GDB Stubs and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB Stubs.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM7S-EK board contains a quantity of on-chip flash memory. The `CYGPKG_DEVS_FLASH_AT91` package contains all the code and data definitions necessary to support this part. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Watchdog Driver

The AT91SAM7S-EK board use the AT91SAM7S's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

Note that on the AT91, the on-chip watchdog peripheral always starts running immediately, and so in configurations that do not include the watchdog driver, it is always disabled via its write-once register. In configurations which include the watchdog driver obviously the watchdog is not disabled otherwise it could not be subsequently re-enabled, and so the application must start and periodically reset the watchdog from the very beginning of execution.

USART Serial Driver

The AT91SAM7S-EK board use the AT91SAM7S's internal USART serial support as described in the AT91 processor HAL documentation. Two serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/dbg`" in the interrupt-driven driver; and USART 0 which is mapped to virtual vector channel 1 and "`/dev/ser0`". Only USART 0 supports modem control signals such as those used for hardware flow control.

Compiler Flags

The SAM7 variant HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm7tdmi`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm7tdmi` is the correct option for the ARM7TDMI processor in the SAM7S.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded RAM applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The ARM7TDMI core of the AT91SAM7S only supports two such hardware breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI2000 notes

On the Abatron BDI2000, the `bdi2000.at91sam7sek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLL and flash memory controller.

The `bdi2000.at91sam7sek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI2000 command line interface to make the changes take effect.

On the BDI2000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the bdiGDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI2000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI2000 is powered up, the target will always run the initialization section of the `bdi2000.at91sam7sek.cfg` file (which configures the CPU clock among other things), and halts the target. This behaviour is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot from ROM as normal.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
SAM7S>load 0x00201000 /test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
SAM7S>go 0x00201000
```

Consult the BDI2000 documentation for information on other formats.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.at91sam7sek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLL and flash memory controller.

The `peedi.at91sam7sek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.at91sam7sek.cfg` file (which configures the CPU clock among other things), and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi.at91sam7sek.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
sam7sek> memory load tftp://192.168.7.9/test.bin bin 0x201000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x00201000
loading at 0x201000
loading at 0x205000

Successfully loaded 28KB (29064 bytes) in 0.1s
sam7sek> go 0x201000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

Configuration of RAM applications

If the JTAG device has initialized the processor, such as by using the `bdi2000.at91sam7sek.cfg` configuration on the BDI2000 or `peedi.at91sam7sek.cfg` configuration on the PEEDI, applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be disabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Selecting the JTAG startup type in the configuration tool sets these options automatically.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USART 0 can be chosen instead by setting the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` configuration option in the platform HAL to channel 1.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM7S-EK hardware, and should be read in conjunction with that specification. The AT91SAM7S-EK platform HAL package complements the ARM architectural HAL, the AT91 variant HAL and the AT91SAM7 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor or JTAG device for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the PLL and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The AT91SAM7 processor HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

On-chip Flash

This is located at address 0x00100000 of the physical memory space.

On-chip RAM

This is located at address 0x00200000 of the physical memory space. During booting this memory is only available at this address, but during the boot process it is also remapped to location 0x00000000 in order to allow the hardware exception vectors to be in RAM. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup, all remaining RAM is available. For RAM startup, available RAM starts at location 0x00201000, with the bottom 4KiB reserved for use by the GDB stubs.

On-chip Peripheral Registers

These are located at address 0xFF000000 in the physical memory space.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 239.1. at91sam7sek Real-time characterization

```
            Startup, main stack : stack used   416 size  3920
             Startup :  Interrupt stack used   148 size  4096
             Startup : Idlethread stack used    84 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 3 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   33.54 microseconds (100 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   2
   Thread switches:         128
```

```

```

Other Issues

The AT91SAM7S-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The AT91SAM7 processor HAL, AT91 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 240. Atmel AT91SAM7X-EK Board Support

Name

eCos Support for the Atmel AT91SAM7X-EK — Overview

Description

This document covers the configuration and usage of eCos and GDB Stubs on the Atmel AT91SAM7X-EK Evaluation Kit. The AT91SAM7X-EK Evaluation Kit contains the AT91SAM7X256 processor, external connections for two serial channels (one debug, one full), ethernet, USB host/device. eCos support for the devices and peripherals on the AT91SAM7X256 is described below.

Application development on this board can take one of several approaches. Applications may be loaded into RAM via a JTAG device; however, the application size is limited by the amount of on-chip RAM, which is 64KiB on the AT91SAM7X256, 32KiB on the AT91SAM7X128 and 128KiB on the AT91SAM7X512. Applications may also be loaded into the on-chip flash memory where the RAM limit will only apply to the data portion of the application. Finally, it is possible to program a GDB debugging stub into flash which will then allow applications to be loaded into RAM via the serial port. This allows development to proceed without needing to use a JTAG device and application size is limited to the RAM size less 4KiB used by the stub. It is therefore recommended that JTAG debugging be used to debug applications since memory is limited on this platform.

This documentation is expected to be read in conjunction with the AT91 processor HAL and AT91SAM7 variant HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The on-chip NOR flash is organized into pages of 256 bytes each. The number of pages is determined by the device variant, from 512 for the AT91SAM7X128 to 2048 for the AT91SAM7X512.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J3 and DTE port at J2 (connected to USART channel 0) can be used for communication. If the GDB stub ROM is installed, it uses the Debug Unit serial device only. The serial driver package is loaded automatically when configuring for the AT91SAM7X-EK target.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the AT91SAM7X-EK target.

The AT91SAM7 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91SAM7X. This type of bus is also known as I²C®.

There is a network driver for the on-chip Ethernet and DM9161A PHY. This is only recommended for use with the lwIP TCP/IP stack due to the low RAM requirements.

The AT91SAM7X-EK on-board dataflash device is accessible at virtual address 0x10000000 and a dataflash card connected at J30 is accessible at virtual address 0x20000000.

In general, devices (PIO, UARTs, etc.) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM7X-EK support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM7X-EK board for eCos Development

Overview

eCos applications are either programmed into the on-chip flash, or run from RAM using either a JTAG device or the GDB stubs ROM. The installation of the GDB stubs or any flash-resident application requires use of a JTAG device to write to the flash, or the Atmel-supplied SAM-BA program that interacts with the on-chip boot program. So, in all cases it is necessary to set up a JTAG device for the board. This document describes how to set up either an Abatron BDI3000 or Ronetix PEEDI and then use them to program an application into the flash.

Initial Installation with Abatron BDI3000

Preparing the Abatron BDI3000 JTAG debugger

The BDI3000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.
2. Connect the Abatron BDI3000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI3000.
3. Install the Abatron BDI3000 bdiGDB support software on the host PC.
4. Locate the file `bdi3000.at91sam7xek.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/at91/at91sam7xek/`*`VERSION`*`/misc` relative to the root of your eCos installation.
5. Locate the file `regSAM7S.def` within the installation of the BDI3000 bdiGDB support software.
6. Place the `bdi3000.at91sam7xek.cfg` file in a location on the PC accessible to the TFTP server. Later you will configure the BDI3000 to load this file via TFTP as its configuration file.
7. Similarly place the file `regSAM7S.def` in a location accessible to the TFTP server.
8. Open `bdi3000.at91sam7xek.cfg` in an editor such as emacs or notepad and if necessary adjust the path of the `regSAM7S.def` file in the `[REGS]` section to match its location relative to the TFTP server root.
9. Install and configure the Abatron BDI3000 in line with the bdiGDB instruction manual. Configure the BDI3000 to use the `bdi3000.at91sam7xek.cfg` configuration file at the appropriate point of this process.

Preparing the AT91SAM7X-EK board for programming with BDI3000

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.
2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.
3. Connect the board to the BDI3000 using a 20-pin ARM/Xscale cable from the JTAG interface connector to the Target A port on the BDI3000.

4. Power up the AT91SAM7X-EK board.

5. Connect to the BDI3000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

   ```
   SAM7X>
   ```

6. Confirm correct connection with the BDI3000 with the **reset halt** command as follows:

   ```
   SAM7X> reset halt
   - TARGET: processing reset request
   - TARGET: BDI asserts TRST and RESET
   - TARGET: BDI removes TRST
   - TARGET: Bypass check 0x000000001 => 0x00000001
   - TARGET: JTAG exists check passed
   - Core#0: ID code is 0x3F0F0F0F
   - TARGET: All ICEBreaker access checks passed
   - TARGET: BDI removes RESET
   - TARGET: BDI waits for RESET inactive
   - TARGET: resetting target passed
   - TARGET: processing target startup ....
   - TARGET: processing target startup passed
   SAM7X>
   ```

Initial Installation with Ronetix PEEDI

Preparing the Ronetix PEEDI JTAG debugger

The PEEDI must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps give a typical outline of setting up the PEEDI using TFTP. Consult the PEEDI documentation for alternative mechanisms.

1. Prepare a PC to act as a host PC and start a TFTP server on it.

2. Connect the PEEDI JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the PEEDI (straight through, not null modem).

3. Locate the file `peedi.at91sam7xek.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/at91/at91sam7xek/`*`VERSION`*`/misc` relative to the root of your eCos installation.

4. Place the `peedi.at91sam7xek.cfg` file in a location on the PC accessible to the TFTP server. Later you will configure the PEEDI to load this file via TFTP as its configuration file.

5. Open `at91sam7xek.cfg` in an editor such as emacs or notepad and insert your own license information in the `[LICENSE]` section.

6. Install and configure the PEEDI in line with the PEEDI Quick Start Guide or User's Manual, especially configuring PEEDI's RedBoot with the network information. Configure it to use the `peedi.at91sam7xek.cfg` target configuration file on the TFTP server at the appropriate point of the **fconfig** process, for example with a path such as: `tftp://192.168.7.9/peedi.at91sam7xek.cfg`

7. Reset the PEEDI.

8. Connect to the PEEDI's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see output similar to the following:

   ```
   $ telnet 192.168.7.225
   Trying 192.168.7.225...
   Connected to 192.168.7.225.
   Escape character is '^]'.
   ```

```

```

Preparing the AT91SAM7X-EK board for programming with PEEDI

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to the PEEDI using a 20-pin ARM/Xscale cable from the JTAG interface connector on the board to the Target port on the PEEDI.

4. Power up the AT91SAM7X-EK board.

5. Connect to the PEEDI's CLI on port 23 as before.

6. Confirm correct connection with the PEEDI with the **reset** command as follows:

```
sam7xek> reset
++ info: user reset
sam7xek>
++ info: RESET and TRST asserted
++ info: TRST released
++ info: 1 TAP controller(s) detected
++ info: TAP : IDCODE = 0x3F0F0F0F, ARM7TDMI compliant
++ info: RESET released
++ info: core 0: initialized

sam7xek>
```

Installation into Flash

Installation of an application into the on-chip flash, or the installation of the GDB stubs, using a JTAG programmer takes exactly the same form:

1. Locate the binary image of the executable to be installed. For the GDB stubs do this by locating the file `gdb.module.bin` within the `loaders` subdirectory of the base of the eCos installation. For applications use **arm-eabi-objcopy -O binary** to convert the ELF output of the linker into binary.

2. Copy the file into a location on the host computer accessible to its TFTP server.

3. Connect to the JTAG device telnet port as before.

4. The flash must be unlocked to ensure that the flash area we want to program is writable.

   For the BDI3000, use the **unlock** command:

```
SAM7X>unlock 0x100000 0x100 256
Unlocking flash at 0x00100000
Unlocking flash at 0x00100100
Unlocking flash at 0x00100200
...
Unlocking flash at 0x0010fe00
Unlocking flash at 0x0010ff00
Unlocking flash passed
SAM7X>
```

For the PEEDI, use the **flash unlock** command:

```
sam7xek> flash unlock 0x100000 65536
unlocking region #0 at 0x00100000
unlocking region #1 at 0x00104000
unlocking region #2 at 0x00108000
unlocking region #3 at 0x0010C000

sam7xek>
```

This command unlocks 256 pages, i.e. 64KiB. The number of pages unlocked should match at least the size of the executable to be programmed. With the PEEDI you can use an unadorned **flash unlock** to unlock the entire flash.

5. Give the **erase** (BDI3000) or **flash erase** (PEEDI) command to clear any previous contents.

   For the BDI3000:

   ```
   SAM7X>erase 0x100000 0x100 256
   Erasing flash at 0x00100000
   Erasing flash at 0x00100100
   Erasing flash at 0x00100200
   ...
   Erasing flash at 0x0010fe00
   Erasing flash at 0x0010ff00
   Erasing flash passed
   SAM7X>
   ```

   As with the **unlock** command, the size of the area erased must be at least the size of the executable to be programmed.

   For the PEEDI, only full flash erase is supported:

   ```
   sam7xek> flash erase

   done.

   sam7xek>
   ```

6. Now give the **prog** (BDI3000) or **flash program** (PEEDI) command to fetch the executable from the TFTP server and program it to the flash.

   For the BDI3000:

   ```
   SAM7X>prog 0x100000 sam7.bin bin
   Programming sam7.bin , please wait ....
   Programming flash passed
   SAM7X>
   ```

   For the PEEDI:

   ```
   sam7xek> flash program tftp://192.168.7.9/gdb_module.bin bin 0x100000
   ++ info: Programming directly
   ++ info: Programming image file: tftp://192.168.7.9/gdb_module.bin
   ++ info: At absolute addres:     0x00100000
   unlocking   at 0x00100000 (region #0)
   programming at 0x00100000
   programming at 0x00101000
   programming at 0x00102000
   programming at 0x00103000
   ```

```
unlocking   at 0x00104000 (region #1)
programming at 0x00104000
programming at 0x00105000
programming at 0x00106000
programming at 0x00107000

++ info: successfully programmed 32.00 KB in 0.93 sec

sam7xek>
```

7. Finally, the processor must be switched to boot from the flash rather than the internal ROM. This is done by programming a General Purpose NVM bit in the flash memory. This can be done using memory write commands in the JTAG device telnet interface. On the BDI3000 this is done using the following commands:

   ```
   SAM7X>md 0xffffff60 3
   ffffff60 : 0x00480100      4718848  ..0.
   ffffff64 : 0x00000000            0  ....
   ffffff68 : 0x00000001            1  ....
   SAM7X>mm 0xffffff64 0x5a00020b
   SAM7X>md 0xffffff60 3
   ffffff60 : 0x00480100      4718848  ..0.
   ffffff64 : 0x00000000            0  ....
   ffffff68 : 0x00000401         1025  ....
   SAM7X>
   ```

   And on the PEEDI:

   ```
   sam7xek> mem read 0xffffff60 3

   0xFFFFFF60: 0x00480100 0x00000000 0x00000001
   sam7xek> mem write 0xffffff64 0x5a00020b
   sam7xek> mem read 0xffffff60 3

   0xFFFFFF60: 0x00480100 0x00000000 0x00000401
   sam7xek>
   ```

The installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. A ROM based application should start immediately, and any output will be seen on the serial connection. If the GDB stub ROM has been installed, then something similar to the following will be seen on the serial port:

```
+$T050f:cc061000;0d:18082000;#4d
```

Programming GDB Stubs into Flash using SAM-BA

The following gives the steps needed to program the gdb stubs into Flash using SAM-BA. The user should refer to the SAM-BA documentation for full details of how to run the program.

1. Download the AT91 In-system Programmer software package from the Atmel website. Install it on a suitable PC running Windows or Linux. The remainder of this section documents the behaviour seen under Windows, although the behaviour on Linux should not be too different.

2. Copy `gdb_module.bin` from either the at91sam7xek_256 or at91sam7xek_512 subdirectories, depending on which of the two boards you are using, to a suitable location on the PC.

3. Connect a null-modem serial cable between the DEBUG serial port of the board and a serial port on a convenient host (which need not be the PC running SAM-BA). Run a terminal emulator (Hyperterm or minicom) at 38400 baud. Connect a USB cable between the PC and the AT91SAM7X-EK board.

4. Power up the board by plugging the USB cable from the AT91SAM7X-EK board into the PC and Windows should recognize the USB device. If it does not, then you will need to erase the existing program that has already been programmed into flash. To do this, disconnect the USB cable from the PC, effectively powering down the device, connect jumper J8 (ERASE) on the

AT91SAM7X-EK board and reconnect the USB cable. This step should have erased the flash. Finally disconnect the USB cable followed by J8, reconnect the USB cable and the board should be recognized now. Windows may ask you to install a new driver, in which case follow the instructions.

5. Start SAM-BA. Select "\usb\ARM0" for the communication interface, and "at91sam7x256-ek" or "at91sam7x512-ek" for the board to match the board you are about to program. If the USB option does not appear, check the cable and look in the Windows Device Manager for the active device. If all is well, click on "Connect".

6. In the SAM-BA main window, select the "FLASH" tab and in the "Send File Name" field, select the `gdb_module.bin`. Ensure that the Address field contains "0x100000" and click "Send File". The following output should be seen:

   ```
   (AT91-ISP v1.13) 1 % send_file {Flash} "gdb_module.bin" 0x100000 0
   -I- Send File gdb_module.bin at address 0x100000
    first_sector 0 last_sector 1
   -I-     Writing: 0x7400 bytes at 0x0 (buffer addr : 0x202BC8)
   -I-     0x7400 bytes written by applet
   (AT91-ISP v1.13) 1 %
   ```

   You may get a pop-up asking "Do you want to lock involved lock region(s) (0 to 1)?". Select "No" if prompted.

7. In the Scripts section, select the script "Boot from Flash (GPNVM2)" and press "Execute". The following output should be seen:

   ```
   (AT91-ISP v1.13) 1 % FLASH::ScriptGPNMV 4
   -I- GPNVM2 set
   (AT91-ISP v1.13) 1 %
   ```

8. Shut down SAM-BA, disconnect and reconnect the USB cable. Press the reset button on the board and something similar to the following should be output for a AT91SAM7X256-EK board on the DEBUG serial line:

   ```
   $T050f:cc051000;0d:e8072000;#7f
   ```

   For a AT91SAM7X512-EK board you should see something similar. For example:

   ```
   $T050f:d0051000;0d:e8072000;#4d
   ```

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM7X-EK platform HAL package is loaded automatically when eCos is configured for the `at91sam7xek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM This is the startup type which is normally used during application development. The board has GDB stubs programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the stubs, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into flash at physical address 0x00100000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG This is an alternative development startup type. The application is loaded into RAM via a JTAG device and is run and debugged from there. The application will be self-contained with no dependencies on services provided by other software. It is expected that hardware setup will have been performed via the JTAG device prior to loading.

GDB Stubs and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB Stubs.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM7X-EK board contains a quantity of on-chip flash memory. The `CYGPKG_DEVS_FLASH_AT91` package contains all the code and data definitions necessary to support this part. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Watchdog Driver

The AT91SAM7X-EK board uses the AT91SAM7X's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

Note that on the AT91, the on-chip watchdog peripheral always starts running immediately, and so in configurations that do not include the watchdog driver, it is always disabled via its write-once register. In configurations which include the watchdog driver obviously the watchdog is not disabled otherwise it could not be subsequently re-enabled, and so the application must start and periodically reset the watchdog from the very beginning of execution.

USART Serial Driver

The AT91SAM7X-EK board use the AT91SAM7X's internal USART serial support as described in the AT91 processor HAL documentation. Two serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/dbg`" in the interrupt-driven driver; and USART 0 which is mapped to virtual vector channel 1 and "`/dev/ser0`". Only USART 0 supports modem control signals such as those used for hardware flow control.

Ethernet Driver

The AT91SAM7X-EK board can use the AT91SAM7X's internal ethernet MAC (EMAC) support. The package `CYGPKG_DEVS_ETH_ARM_AT91` contains the necessary device driver support.

Due to the amount of RAM available, it is not possible to use the BSD-derived TCP/IP stack. Instead either the lwIP TCP/IP stack (in `CYGPKG_NET_LWIP`) should be used, or your application can operate the driver directly in standalone mode. To enable the Ethernet driver in your configuration, either include the “Common Ethernet Support” (`CYGPKG_IO_ETH_DRIVERS`) package in your configuration, or base your configuration on an appropriate template, in particular the “lwip_eth” template.

Support for the Davicom DM9161A PHY (which comes from the `CYGPKG_DEVS_ETH_PHY` package) is automatically configured when ethernet support is enabled.

The AT91 ethernet device driver package in fact includes two separate driver implementations: one standard driver suitable for use in standalone mode, or with various TCP/IP stacks including at least RedBoot, BSD and lwIP; and one specific to lwIP. It is strongly recommended that the lwIP-specific driver is used with lwIP, given the low memory constraints. The lwIP-specific driver is a streamlined efficient version designed for very low RAM overhead. As a result it is implemented intentionally at the expense of features irrelevant to the AT91SAM7X, such as multiple network device support, and network debugging under RedBoot. Instead it has improvements such as zero-copy reception and transmission of data packets, leading to both faster operation, and smaller code and data memory footprint.

The choice between using the standard driver, or the lwIP-specific driver is not made within this package, but is instead made in the generic ethernet I/O package `CYGPKG_IO_ETH_DRIVERS` using the options within the lwIP driver model component (`CYGIMP_IO_ETH_DRIVERS_LWIP_DRIVER_MODEL`). The standard driver is the default, and thus needs to be explicitly changed to select the lwIP-specific driver model.

Careful selection and tuning of the configuration settings within the AT91 Ethernet package, and more especially, the lwIP stack, can result in realistic application use of TCP/IP at high speeds, despite the low RAM availability.

Note that a board design issue has required a workaround to be used in order to correctly initialize the PHY. This has two notable consequences: there is an extra delay of 700ms at startup time; and the programmatic use of the NRST line from the processor can confuse attached JTAG units into believing the processor has reset, which can in turn adversely affect debugging sessions. In the case of the Abatron BDI3000, it has been found that ensuring the last reset command was a "reset run", and then connecting via GDB immediately after target reset results in a stable debug session, albeit at the expense of the processor already having run some of the early HAL startup sequence.

Compiler Flags

The SAM7 variant HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm7tdmi`

The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm7tdmi` is the correct option for the ARM7TDMI processor in the SAM7X.

`-mthumb`

The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`

This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded RAM applications, or even applications resident in ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The ARM7TDMI core of the AT91SAM7X only supports two such hardware breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI3000 notes

On the Abatron BDI3000, the `bdi3000.at91sam7xek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLL and flash memory controller.

The `bdi3000.at91sam7xek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI3000 command line interface to make the changes take effect.

On the BDI3000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the bdiGDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI3000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI3000 is powered up, the target will always run the initialization section of the `bdi3000.at91sam7x-ek.cfg` file (which configures the CPU clock among other things), and halts the target. This behaviour is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot from ROM as normal.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
SAM7X>load 0x00201000 /test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
SAM7X>go 0x00201000
```

Consult the BDI3000 documentation for information on other formats.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.at91sam7xek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLL and flash memory controller.

The `peedi.at91sam7xek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.at91sam7xek.cfg` file (which configures the CPU clock among other things), and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi.at91sam7xek.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
sam7xek> memory load tftp://192.168.7.9/test.bin bin 0x201000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x00201000
loading at 0x201000
loading at 0x205000

Successfully loaded 28KB (29064 bytes) in 0.1s
sam7xek> go 0x201000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

Configuration of RAM applications

If the JTAG device has initialized the processor, such as by using the `bdi3000.at91sam7xek.cfg` configuration on the BDI3000 or `peedi.at91sam7xek.cfg` configuration on the PEEDI, applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be disabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Selecting the JTAG startup type in the configuration tool sets these options automatically.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USART 0 can be chosen instead by setting the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` configuration option in the platform HAL to channel 1.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM7X-EK hardware, and should be read in conjunction with that specification. The AT91SAM7X-EK platform HAL package complements the ARM architectural HAL, the AT91 variant HAL and the AT91SAM7 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor or JTAG device for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the PLL and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The AT91SAM7 processor HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

On-chip Flash
This is located at address 0x00100000 of the physical memory space.

On-chip RAM
This is located at address 0x00200000 of the physical memory space. During booting this memory is only available at this address, but during the boot process it is also remapped to location 0x00000000 in order to allow the hardware exception vectors to be in RAM. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM startup, all remaining RAM is available. For RAM startup, available RAM starts at location 0x00201000, with the bottom 4KiB reserved for use by the GDB stubs.

On-chip Peripheral Registers
These are located at address 0xFF000000 in the physical memory space.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 240.1. at91sam7xek Real-time characterization

```
            Startup, main stack : stack used   416 size  3920
             Startup :  Interrupt stack used   148 size  4096
             Startup : Idlethread stack used    84 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 3 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   33.54 microseconds (100 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   2
   Thread switches:         128
```

```
  Mutexes:                  32
  Mailboxes:                32
  Semaphores:               32
  Scheduler operations:    128
  Counters:                 32
  Flags:                    32
  Alarms:                   32

                               Confidence

Other Issues

The AT91SAM7X-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The AT91SAM7 processor HAL, AT91 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 241. NXP LPC2xxx variant HAL

Name

eCos Support for the NXP LPC2xxx ARM microcontrollers — Overview

Description

The NXP LPC2xxx series of ARM microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for the on-chip serial, watchdog, RTC (wallclock) and Flash devices. In addition it provides common functionality and definitions that LPC2xxx based platform ports may require, as well as definitions useful to application developers.

This documentation covers the LPC2xxx functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the LPC2xxx variant HAL provides. The areas that are specific to platform HALs and not the LPC2xxx variant HAL include:

- memory map and related configuration and setup
- memory remapping
- External Memory Controller (EMC) and Memory Accelerator Module (MAM) setup (if applicable)
- Definitions of clock (OSC) inputs to PLL
- PLL setup
- PINSEL and GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED control

This variant HAL provides helper macros and defines for some of these, but their use or otherwise is governed by the platform HAL.

Name

On-chip subsystems and peripherals — Hardware support

Hardware support

On-chip memory

The NXP LPC2xxx parts include a small amount of on-chip SRAM, and a limited amount of on-chip Flash. Specific capacities vary between parts. The SRAM is generally too small to be useful to RedBoot and some form of external RAM is employed if remote debugging is required, although some limited applications can be run if a GDB stub ROM image is programmed to internal Flash instead. Otherwise for processor models with no external RAM, applications must be programmed directly to internal Flash. The platform HAL may opt to use the SRAM to store the interrupt vectors mapped to address 0, or as a buffer for reprogramming internal flash when using the LPC2xxx Flash driver. The on-chip Flash is generally sufficient to include RedBoot or a GDB stub ROM image, although the on-chip SRAM may not be - again consult the platform HAL documentation. At this time, there is no support for initial programming of the on-chip Flash and so the NXP LPC2000 Flash Utility, Flash Magic or a JTAG/ICE is generally used for this.

Typically, an eCos platform HAL port will expect a RedBoot image to be programmed into the LPC2xxx on-chip Flash memory for development, and the board would boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels.

Serial I/O

The LPC2xxx variant HAL supports basic polled HAL diagnostic I/O over either of the two on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for both on-chip serial devices. The serial driver consists of two eCos packages: `CYGPKG_IO_SERIAL_GENERIC_16X5X` which is a “generic” package for 16x5x compatible serial devices; and `CYGPKG_IO_SERIAL_ARM_LPC2XXX` which provides more specific definitions for the LPC2xxx on-chip serial devices. Using the HAL diagnostic I/O support, either of these devices can be used by RedBoot for communication with the host. If you are only using UART 0, a small amount of memory can be saved by reducing the number of communication channels with the CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS` from 2 to 1 if the platform HAL permits this. It is not possible to enable UART 1 but not UART 0 at this time. If a serial device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication with the HAL I/O support. The alternative serial port should be used instead, if available on the platform. The serial driver supports the line status and modem control (including hardware handshaking) lines on UART 1 only.

Watchdog

A device driver is included for the on-chip watchdog device. This driver allows the use of the standard eCos watchdog API accessible with the `CYGPKG_IO_WATCHDOG` eCos package. If the watchdog is not reset within a time period defined in the watchdog device driver CDL, an interrupt is generated and a user-supplied function called. Alternatively it may be configured to automatically reset the system.

The watchdog device is also used to implement reset functionality, such as required by the RedBoot **reset** command. It may also be called directly by applications using the following function:

```
#include <cyg/hal/hal_diag.h>
extern void hal_lpc2xxx_reset_cpu(void);
```

RTC/Wallclock

Support is provided for the on-chip RTC (wallclock) device. This allows the use of the standard eCos wallclock API accessible with the `CYGPKG_IO_WALLCLOCK` eCos package. The wallclock is also used by other eCos subsystems such as the C library and POSIX compatibility layer to provide calendar time functionality.

Interrupt controller

eCos manages the on-chip Vectored Interrupt Controller (VIC). The VIC is only configured to use interrupts in non-vectored mode.

Timers

Timer 0 is used to implement the eCos system clock. If the gprof package, CYGPKG_PROFILE_GPROF, is included in the configuration, then timer 1 is reserved for use by the profiler. Any remaining timers are available for application use.

I²C Bus

The on-chip I²C bus devices are supported by the NXPI2C driver package, CYGPKG_DEVS_I2C_NXPI2C. Platform HALs need to enable the attached buses and define the clock speed and lines to be used for SDA and SCL.

SPI Bus

The on-chip SSP SPI devices (not the Legacy SPI device) are supported by the PL022 driver package, CYGPKG_DEVS_SPI_ARM_PL022. This needs some configuration in the platform HAL to enable the attached buses and define the GPIO lines used for chip select.

Other

Other on-chip devices (SPI, PWM, A/D converter, etc.) are not touched by the LPC2xxx variant HAL and unless used by the platform HAL are free for use for applications.

Name

HAL Port — Implementation Details

Overview

This section covers any remaining items of note related to the LPC2xxx variant support, not covered in previous sections.

LEDs

If a platform port has support for display values on LEDs, that support is standardised to be accessible from C with the following function:

```
#include <cyg/infra/hal_diag.h>
extern void hal_diag_led(int leds);
```

PLL configuration

CDL variables related to the PLL configuration are standardised across LPC2xxx implementations. The platform HAL must provide the input oscillator frequency (`CYGNUM_HAL_ARM_LPC2XXX_OSC_FREQ`), as well as the desired PLL multipliers and dividers selected by the user and relevant for the chosen part (`CYGNUM_HAL_ARM_LPC2XXX_PLL_MULTIPLIER` and `CYGNUM_HAL_ARM_LPC2XXX_PLL_DIVIDER`). It must also supply the `VPB` divider (`CYGNUM_HAL_ARM_LPC2XXX_VPB_DIVIDER`) which divides down the core clock (`CCLK`) to generate the peripheral clock (`PCLK`). Where applicable a platform may also define a `CCLK` divider (`CYGNUM_HAL_ARM_LPC2XXX_CCLK_DIVIDER`).

As a result, the variant HAL calculates CDL options for the absolute values of `CCLK` (`CYGNUM_HAL_ARM_LPC2XXX_CCLK_SPEED`) and `PCLK` (`CYGNUM_HAL_ARM_LPC2XXX_PCLK_SPEED`) which are exported to the rest of the system, and accessible to applications from `<pkgconf/hal.h>`.

It is still the responsibility of the platform HAL to initialize the PLL, although assembler helper macros are provided in `<cyg/hal/var_io.h` to ease implementation.

LPC2xxx definitions

The LPC2xxx variant HAL port includes the header file `var_io.h` which provides useful register definitions used by eCos, but can also be freely used by applications. It includes register definitions for subsystems unused by eCos.

It may be found in the `include/cyg/hal` directory relative to your configuration's install tree, or alternatively in the source repository at `hal/arm/lpc2xxx/var/`*`VERSION`*`/include/var_io.h`. However it should be properly included by applications by using:

```
#include <cyg/hal/hal_io.h>
```

This will allow for platform HALs to augment or override any relevant definitions.

Power control

The kernel idle thread is scheduled to run when the system has no other tasks able to run. The idle thread can call a HAL supplied macro to place the chip into an appropriate power saving mode instead of just going around a busy loop. The LPC2xxx variant HAL defines the `HAL_IDLE_THREAD_ACTION` macro to use the LPC2xxx power control support to place the chip into `IDLE` mode which will stop the processor clock, without disabling the on-chip peripherals. This state continues until an interrupt is received. This mode has no deleterious effect on program execution, however it has been known to interfere with JTAG/ICE hardware debuggers. Therefore the CDL option `CYGIMP_HAL_ARM_LPC2XXX_IDLE_THREAD_USES_IDLE` exists in the variant HAL to ensure the processor does not enter the idle mode from the idle thread. It is recommended this option be disabled if hardware debugging solutions are used, especially if reliability is erratic.

Unless specified otherwise by the platform HAL port, no other power saving features are used and no peripherals are disabled, even those unsupported by the eCos LPC2xxx variant port. Therefore if the application wishes to conserve power it is its responsibility to place the relevant peripherals into power down modes.

Memory Acceleration Module support

The variant HAL supplies helper macros to the platform HALs to centralise initialisation code for common subsystems, including the Memory Acceleration Module (MAM).

However it is known that there are errata which affect the MAM, and specifically restrict what mode the MAM should operate in. In some cases, such as the LPC2148, there are conflicting errata, that recommend that the MAM be used only in `Full` mode in some cases to avoid one erratum, or only `Partial` mode in others to avoid a different erratum.

Therefore the choice of MAM mode is left to the user and can be set with the CDL option `CYGHWR_HAL_ARM_LPC2XXX_MAM_MODE` in the variant HAL.

Virtual Vector support

As described in the common HAL documentation, virtual vectors are used to abstract certain services which could be shared between a resident ROM monitor, and an application. In the case where an application is entirely stand-alone, and does not use any resident ROM monitor - for example, if it is itself a ROM application - then virtual vector support is unnecessary.

The CDL configuration option `CYGFUN_HAL_LPC2XXX_VIRTUAL_VECTOR_SUPPORT` can be used to control the presence of virtual vectors, although it is expected that the default value will be selected appropriately in any case. Disabling virtual vector support can save both Flash and RAM use, which can be important for targets with restricted memory.

Chapter 242. Ashling EVBA7 Eval Board Support

Name

eCos Support for the Ashling EVBA7 Eval Board — Overview

Description

The Ashling EVBA7 Eval Board is fitted with a Philips LPC2000 processor rated to 60MHz, which contains up to 64KB of SRAM and up to 256KB of FLASH. The board has two 9-pin RS-232 serial interfaces connected to the LPC2000 on-chip UARTs, an LED bank and JTAG/USB debug interfaces. Refer to the board documentation for full details.

The standard EVBA7 is fitted with an LPC2106 microcontroller. Some versions of the EVBA7 board are fitted with an adaptor that either contains a specific LPC2000 part, or a socket into which one of several LPC2000 parts may be fitted.

For typical eCos development, a RedBoot or GDB Stubrom image is programmed into the LPC2000 on-chip flash memory, and the board will boot this image from reset. Both RedBoot and the GDB stub ROM provide GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART 0.

This documentation describes platform-specific elements of the EVBA7 Eval Board support within eCos. Documentation on the Philips LPC2xxx variants is available separately, and should be read in conjunction with this documentation. The LPC2xxx documentation covers various topics including HAL support common to LPC2xxx variants, and on-chip device support. This document complements the LPC2xxx documentation.

Supported Hardware

The EVBA7 Eval Board has up to 128Kbyte of on-chip Flash memory. In a typical setup, RedBoot or the GDB Stubrom will load and run from this internal flash. No support for managing internal Flash is included in this port - the Ashling FlashLPC Utility is required to program the internal Flash. 24Kbytes of internal flash memory should be reserved for the GDB Stubrom, the remainder being free for the application's use. RedBoot will occupy the entire internal ROM.

EVBA7 boards fitted with the PA-EVBA7-144 adaptor also have 1MByte of external RAM on the adaptor. In this case, eCos is configured to use this memory rather than the internal SRAM. These are also the only boards capable of running RedBoot.

The first 64 bytes of on-chip SRAM are mapped by the HAL startup code using the LPC2000 memory mapping control to location 0x00000000 for speed of interrupt vector processing. SRAM from location 0x40000040 to 0x40001000 is used by the GDB Stubrom. The rest of SRAM is available for use by the application.

The Philips LPC2xxx variant HAL includes support for the two LPC2000 on-chip serial devices and is documented in the variant HAL. The interrupt-driven serial driver supports the line status and modem control (including hardware handshaking) lines on UART1 only.

The EVBA7 Eval Board port includes support for the on-chip watchdog, RTC (wallclock), and interrupt controller (VIC). This support is documented in the LPC2xxx variant HAL.

Tools

The EVBA7 Eval Board port is intended to work with GNU tools configured for an arm-eabi target. Thumb mode is supported. The original port was done using arm-elf-gcc version 3.3.3, arm-elf-gdb version 6.1, and binutils version 2.14.

Name

Setup — Preparing the EVBA7 Eval Board for eCos Development

Overview

In a typical development environment, the EVBA7 Eval Board boots from internal flash into the GDB stubrom monitor or RedBoot. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable ROM or RedBoot image into flash memory.

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and rebuilding the stubrom or RedBoot.

Initial Installation

Flash Installation

This process assumes that a Microsoft Windows machine with the Ashling FlashLPC Utility installed is available. The first step is to connect the RS232 cable supplied with the EVBA7 between port 0 of the EVBA7 and the host PC. Now install the jumper labelled “ENABLE SERIAL ISP”. On the base EVBA7 this is jumper JP6; on boards fitted with one of the FA-EVBA7 adaptors, this is JP5 on the adaptor; on boards fitted with a PA-EVBA7 adaptor, this is JP3 on the adaptor. Refer to the board documentation for full details. Apply the power, or press the reset button.

The board is now running a special Philips boot loader. Start the FlashLPC Utility, and ensure that the selected device matches the device installed on the EVBA7. Choose the appropriate COM port that is being used on your PC and select 115200 baud for both the initial and final baud rates. Set the Crystal KHz value to 14745, ensure that the stop bits value is set to 1 and the packet size is set to 100%. Establish communication with the board by pressing the “Connect” button.

Now in the “Flash Programming” section, select the `stubrom.srec` or `redboot.srec` file. Set the file format to “S-Record Format”,select “Erase individual sectors before programming” under the Programming Options and ensure that “Automatically add checksum to vector table” is ticked. Finally press “Program”, or “Program and Verify” to program the ROM image.

When the process completes, remove the “ENABLE SERIAL ISP” jumper. Verify the programming has been successful by starting a terminal emulation application such as HyperTerminal on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Reset the board and the stubrom should start. For boards programmed with GDB stubs the output should be similar to the following:

```
+$T050f:ec070000;0d:28080040;#52
```

This is the stubrom attempting to communicate with GDB and indicates that it is functioning correctly.

For boards fitted with RedBoot, you should see the RedBoot startup messages ending with a RedBoot prompt.

Rebuilding GDB Stubrom

Should it prove necessary to rebuild the Stubrom binary, this is done most conveniently at the command line. Assuming your `PATH` and `ECOS_REPOSITORY` environment variables have been set correctly, the steps needed to rebuild the stubrom are:

```
$ mkdir stub_rom
$ cd stub_rom
$ ecosconfig new evba7 stubs
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `stubrom.srec`.

Rebuilding RedBoot

Should it prove necessary to rebuild the RedBoot binary, this is done most conveniently at the command line. Assuming your PATH and ECOS_REPOSITORY environment variables have been set correctly, the steps needed to rebuild RedBoot are:

```
$ mkdir evba7_redboot
$ cd evba7_redboot
$ ecosconfig new evba7_2294 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/lpc2000/evba7/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the install/bin subdirectory should contain the file redboot.srec.

Name

Configuration — Platform-specific Configuration Options

Overview

The evba7 platform HAL package is loaded automatically when eCos is configured for a `evba7` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The evba7 platform HAL package supports two separate startup types:

RAM This is the startup type which is normally used during application development. The board has the GDB stubrom or RedBoot programmed into flash at location 0x0 in internal on-chip Flash and boots from that location. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the ROM monitor. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the ROM monitor, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into internal flash at location 0x0. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

The ROM Monitor and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB Stubrom or RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, or as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port UART0 will be claimed for HAL diagnostics.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The PLL multipliers and dividers may be configured to allow a core clock (CCLK) speed of up to 60MHz. The description of the clock-related CDL options may be found in the LPC2xxx variant HAL documentation.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

However there are two flags that are used if Thumb mode is to be supported:

`-mthumb` The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used.

`-mthumb-interwork` This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the EVBA7 Eval Board hardware, and should be read in conjunction with that specification. The EVBA7 Eval Board platform HAL package complements the ARM architectural HAL and the LPC2xxx variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. This includes the PINSEL functions and LED bank. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including PLL (for the clocks), Memory Mapping control registers to map SRAM to 0x0, and Memory Acceleration Module (MAM). The details of the early hardware startup may be found in the header `cyg/hal/hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

on-chip Flash

This is located at address 0x0 of the memory space, although after hardware initialization, the start of internal SRAM is mapped over locations 0x0 to 0x40. This region ends at 0x20000. No flash driver is provided for the on-chip Flash. The MAM is enabled to accelerate memory reads from this area.

internal SRAM

This is located at address 0x40000000 of the memory space, and is 16, 32 or 64k in size, depending on the chip fitted. The first 64 bytes are mapped to location 0x0000000. When this is the only RAM available, the virtual vector table starts at 0x40000050 and extends to 0x40000150. The remainder of SRAM is available for use by ROM based applications. For RAM startup applications, SRAM below 0x40001000 is reserved for the GDB stubrom and the remainder is available for the application.

On boards fitted with the PA-EVBA7-144 adaptor and where the external SRAM is being used, only the first 64 bytes are used as described above. The remainder of internal SRAM is not used by eCos.

external SRAM

This SRAM is only present if the EVBA7 is fitted with a PA-EVBA7-144 adaptor. It is located at address 0x81000000 of the memory space, and is 1MByte in size. When this memory is being used for applications the virtual vector table starts at 0x81000050 and extends to 0x81000150. The remainder is available for use by ROM based applications. For RAM startup applications, memory below 0x81010000 is reserved for RedBoot and the remainder is available for the application.

on-chip peripherals

These are accessible at location 0xE0000000 onwards. Descriptions of the contents can be found in the LPC2000 User Manual.

Other Issues

The LEDs may be accessed from C with the following function:

```
#include <cyg/infra/hal_diag.h>
extern void hal_diag_led(int leds);
```

Values from 0 to 16 will be displayed on the LED bank representing the binary value with 1 being on and 0 being off, and with P0.7 being the MSB, and P0.4 the LSB.

The LEDs are also used during platform initialization and only P0.4 should be illuminated if booting has been successful. Other LED indications represent the stage in the initialization process that failed.

Chapter 243. Embedded Artists LPC2468 OEM Board Support

Name

eCos Support for the Embedded Artists LPC2468 OEM Board — Overview

Description

The Embedded Artists LPC2468 OEM Board is fitted with an NXP LPC2468 processor rated up to 72MHz, which contains 64KB of SRAM and 512KB of FLASH. When used in conjunction with the OEM base board, it provides access to two on-chip UARTs (one via USB, one via a 9-pin connector), a single GPIO LED, an MMC/SD card socket, and a PHY connected to the on-chip Ethernet MAC. Refer to the board documentation for full details.

Two variants of the LPC2468 OEM board are supported. The LPC2468-16 board provides a 16 bit data bus to external RAM, works with all versions of the base board, and supports UART 1. The LPC2468-32 board provides a 32 bit data bus to external RAM, works only with v1.4 and later versions of the base board, and does not allow UART 1 to be used.

For typical eCos development, a RedBoot image is programmed into the LPC2468 on-chip flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using either UART or via the ethernet.

This documentation describes platform-specific elements of the LPC2468 OEM Board support within eCos. Documentation on the NXP LPC2xxx variants is available separately, and should be read in conjunction with this documentation. The LPC2xxx documentation covers various topics including HAL support common to LPC2xxx variants, and on-chip device support. This document complements the LPC2xxx documentation.

Supported Hardware

The LPC2468 OEM Board has 512Kbyte of on-chip Flash memory. In a typical setup, RedBoot will load and run from this internal flash. An initial image must be programmed into this flash using either the FlashMagic utility, or via a JTAG debugger. Following this, it may be reprogrammed using flash drivers in RedBoot.

The first 64 bytes of on-chip SRAM are mapped by the HAL startup code using the LPC2468 memory mapping control to location 0x00000000 for speed of interrupt vector processing. The rest of SRAM is available for use by the application. 4MB of external NOR flash is available at 0x80000000; the topmost 64K of this is used by RedBoot for configuration data, the rest is available for application use and can be managed by RedBoot's flash file system. 32 MB of SDRAM is available at 0x81000000; the first 1MByte of this is reserved for use by RedBoot, the rest is available for the code and data of loaded applications.

The NXP LPC2xxx variant HAL includes support for the on-chip serial devices which is documented in the variant HAL. The interrupt-driven serial driver supports the line status and modem control (including hardware handshaking) lines on UART1 only.

The LPC2468 OEM Board port includes support for the on-chip watchdog, RTC (wallclock), and interrupt controller (VIC). This support is documented in the LPC2xxx variant HAL.

The on-chip Ethernet MAC is supported. The LPC2468-16 and LPC2468-32 use different PHYs, and both of these are supported.

The on-chip Multimedia Card Interface (MCI) is supported to allow access to Multimedia Cards (MMC) or Secure Digital (SD) cards using the socket on the OEM board.

Tools

The LPC2468 OEM Board port is intended to work with GNU tools configured for an arm-eabi target. Thumb mode is supported. The original port was done using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.16.

Name

Setup — Preparing the LPC2468 OEM Board for eCos Development

Overview

In a typical development environment, the LPC2468 OEM Board boots from internal flash into RedBoot. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.hex`
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.srec`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This baud rate can be changed via the RedBoot **baud** command.

Initial Installation

Flash Installation

This process assumes that a Microsoft Windows machine with the Embedded Systems Academy Flash Magic utility is available.

The first step is to set up the board as described in the Embedded Artists documentation. The FlashMagic tool from http://www.flashmagictool.com must be installed to program applications or RedBoot into flash. Older versions of Windows may also require the FTDI USB driver from http://www.ftdichip.com/Drivers/VCP.htm be installed and configured as described in the Embedded Artists documentation.

Install the ISP jumpers (P2.10 and RESET) and press the reset button. The board is now running a special NXP boot loader. Start FlashMagic and set the Serial Port to the FTDI USB COM*x* device activated when the target hardware is connected to the host by a suitable USB cable. Select 38400 baud and change the device to LPC2468. Older versions of FlashMagic also require the Interface “None (ISP)” and 12MHz Oscillator Frequency - these settings are available under preferences in newer versions and are set correctly by default.

Test communication with the board by using the “ISP->Read Device Signature” menu entry. If communication is not successful, check that the correct USB cable is used and connected, the ISP jumpers are installed and the correct COM port is being used.

Check “Erase blocks used by Hex File” under “Erase” OR in recent versions of FlashMagic select “Sectors used by File” next to “Erase”. In the “File” section, select the `redboot_ROM.hex` file. Under “Options”, all boxes should be clear except “Verify after programming”. Now press the “Start” button. The utility should show the progress of the flash erase and write operations.

When the process completes, the utility should be closed. Verify the programming has been successful by starting a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Remove the ISP jumpers. Reset the board and RedBoot should start. The output should be similar to the following:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.2.8/255.0.0.0, Gateway: 10.0.0.3
Default server: 0.0.0.0, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [ROM]
```

```
eCosCentric certified release, version 4.5.9 - built 10:17:51, Apr 26 2021

Copyright (C) 2000-2009 Free Software Foundation, Inc.
Copyright (C) 2003-2021 eCosCentric Limited
The RedBoot bootloader is a component of the eCos real-time operating system.
Want to know more? Visit www.ecoscentric.com for everything eCos & RedBoot related.
This is free software, covered by the eCosPro Non-Commercial Public License
and eCos Public License. You are welcome to change it and/or distribute copies
of it under certain conditions. Under the license terms, RedBoot's source code
and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: Embedded Artists LPC2468 OEM Board (ARM7TDMI)
RAM: 0xa0000000-0xa2000000 [0xa000aa18-0xa1fed000 available]
FLASH: 0x00000000-0x0007dfff, 8 x 0x1000 blocks, 14 x 0x8000 blocks, 6 x 0x1000 blocks
FLASH: 0x80000000-0x803fffff, 64 x 0x10000 blocks
RedBoot>
```

It is now necessary to initialize the flash file system and the flash configuration. This can be done with the following commands:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x803f0000-0x803fffff: .
... Program from 0xa1ff0000-0xa2000000 to 0x803f0000: .
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 10.0.1.2
Console baud rate: 38400
DNS server IP address: 10.0.0.1
Network hardware address [MAC] for eth0: 0x0E:0x00:0x00:0xEA:0x18:0xF0
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Default network device: lpc2xxx
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x803f0000-0x803fffff: .
... Program from 0xa1ff0000-0xa2000000 to 0x803f0000: .
RedBoot>
```

Replace the IP addresses in the above with those for your own network. The above also accepts the default for the MAC address, if more than one LPC2468 is to be used on the same network then different MAC addresses should be used; Embedded Artists boards are supplied with a sticker showing an assigned MAC address, and this should be used by preference.

It is it ever necessary to reinstall RedBoot, the above directions can be repeated. Alternatively, a new RedBoot may be installed from RedBoot itself. It is not possible to do this directly, since RedBoot is executing from the flash that needs to be erased and reprogrammed. Instead it is necessary to run a RAM version of RedBoot, use that to download the new ROM RedBoot to RAM, and then program that to flash.

The following shows an example session to do this. It assumes that `redboot_RAM.srec` and `redboot_ROM.bin` are available via TFTP on the server set up in **fconfig**.

```
RedBoot> load redboot_RAM.srec
Using default protocol (TFTP)
Entry point: 0xa0100040, address range: 0xa0100000-0xa011bab4
RedBoot> go
+Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.2.8/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.2, DNS server IP: 10.0.0.1

Rebuilding RedBoot

Should it prove necessary to rebuild the RedBoot binary, this is done most conveniently at the command line. Assuming your `PATH` and `ECOS_REPOSITORY` environment variables have been set correctly, the steps needed to rebuild RedBoot for the LPC2468-32 are:

```
$ mkdir redboot_ealpc2468_rom
$ cd redboot_ealpc2468_rom
$ ecosconfig new ea_lpc2468_32 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/lpc2xxx/ea_lpc2468/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.hex`.

Substitute 16 for 32 in the above to build RedBoot for the LPC2468-16 module.

Name

Configuration — Platform-specific Configuration Options

Overview

The ea_lpc2468 platform HAL package is loaded automatically when eCos is configured for an `ea_lpc2468_32` or `ea_lpc2468_16` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The ea_lpc2468 platform HAL package supports two separate startup types:

RAM This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0x0 in internal on-chip Flash and boots from that location. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into internal flash at location 0x0. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, or as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port UART0 will be claimed for HAL diagnostics.

Flash Driver

The LPC2468 OEM board contains an SST 39VF3201 NOR flash device. The `CYGPKG_DEVS_FLASH_SST_39VFXXX_V2` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the Embedded Artists LPC2468 OEM board.

Ethernet Driver

The LPC2468 contains an ethernet MAC device. The `CYGPKG_DEVS_ETH_ARM_LPC2XXX` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the LPC2468 OEM board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The PLL multipliers and dividers may be configured to allow a core clock

(CCLK) speed of up to 72MHz. However, the platform HAL currently sets the clock to 48MHz, duplicating the configuration in the supplied example code as a consequence of CPU errata affecting various revisions of the LPC2468. Setting the CPU revision with the `CYGHWR_HAL_ARM_LPC2XXX_EA_LPC2468_CPU_REVISION` configuration option can be used to provide default clock settings appropriate to the CPU revision in use. If the CPU revision cannot be guaranteed it should be left as "Initial". The description of the clock-related CDL options may be found in the LPC2xxx variant HAL documentation.

I²C Bus Configuration

The on-chip I²C devices are supported by a driver in the variant HAL package. Each bus for this driver needs to be configured in the platform HAL with the following options:

`CYGPKG_HAL_ARM_LPC2XXX_I2CX`

> This is the master component, enabling this activates all the other configuration options and causes the driver to create the data structures to access this bus.

`CYGPKG_HAL_ARM_LPC2XXX_I2CX_CLOCK`

> Bus clock speed in Hz. Usually frequencies of either 100kHz or 400kHz are chosen, the latter sometimes known as fast mode.

`CYGPKG_HAL_ARM_LPC2XXX_I2CX_SDA`

> This option describes the pin used for SDA on this bus. This takes the form of an invocation of the macro __LPC2XXX_PINSEL_FUNC. Parameters are the port number, pin within that port, and the alternate select function for the pin. See the LPC2468 user manual for details of which pins may be used by each bus.

`CYGPKG_HAL_ARM_LPC2XXX_I2CX_SCL`

> This option describes the pin used for SCL on this bus. Like SDA this takes the form of a call to __LPC2XXX_PINSEL_FUNC.

Note that "I2CX" is a placeholder for a given bus instance: "I2C0", "I2C1" or "I2C2". By default the platform HAL only enables I²C bus 0 in order to access the PCA9532 LED controller on the base board.

SPI Bus Configuration

The on-chip SSP SPI devices (not the Legacy SPI device) are supported by the NXPSSP driver package, `CYGPKG_DEVS_SPI_ARM_NXPSSP`. This needs some configuration in the platform HAL:

`CYGPKG_HAL_ARM_LPC2XXX_SPI`

> This is the master component, enabling this activates all the other configuration options. It also causes `ea_lpc2468_spi.c` to be compiled, which contains descriptions of the devices on the SPI buses.

`CYGPKG_HAL_ARM_LPC2XXX_SPIX`

> This is the master component for each bus. Enabling this activates the other configuration options for this bus, and causes the driver to support this bus.

`CYGPKG_HAL_ARM_LPC2XXX_SPIX_SCLK`

> This option describes the pin used for SCLK on SPIX. It takes the form of an invocation of __LPC2XXX_PINSEL_FUNC. The parameters are the port number, pin within that port, and the alternate select function for the pin. See the LPC2468 user manual for details."

`CYGPKG_HAL_ARM_LPC2XXX_SPIX_MISO`

> This option describes the pin used for MISO on SPIX. Like SCLK it takes the form of a call to __LPC2XXX_PINSEL_FUNC.

CYGPKG_HAL_ARM_LPC2XXX_SPIX_MOSI

This option describes the pin used for MOSI on SPIX. Like SCLK it takes the form of a call to __LPC2XXX_PINSEL_FUNC.

CYGPKG_HAL_ARM_LPC2XXX_SPIX_CS_PINS

This defines the pins to be uses as chip selects for this bus. It is a comma separated list of GPIO pin names, the first for device 0, the second for device 1, and so on. Pin names are defined in the var_io.h header in the LPC2xxx variant HAL.

Note that "SPIX" is a placeholder for a given bus instance: "SPI0" or "SPI1". By default the platform HAL only enables SPI0, for testing only.

MCI peripheral configuration

The on-chip Multimedia Card Interface (MCI) is supported to allow access to Multimedia Cards (MMC) or Secure Digital (SD) cards using the socket on the OEM board. This support is provided in conjunction with the generic MMC/SD driver package (CYGPKG_DEVS_DISK_MMC), the Primecell MCI driver package (CYGPKG_DEVS_MMCSD_ARM_PRIMECELL_MCI) and the LPC2xxx variant HAL in order to provide some elements of the DMA support. Documentation and configuration options within those packages should also be consulted. Note that the miniSD socket on the CPU board is not supported.

In order to configure the hardware for access to the socket, Jumper J47 on the base board must be set with pins 2-3 connected (P0.22 selected for MCIDAT0), and Jumper J27 must be set with MCIPWR active low.

The following CDL configuration options are used to control the behaviour of the MMC/SD card support:

MMC/SD card support (CYGPKG_HAL_ARM_LPC2XXX_EA_LPC2468_MCI)

This option allows the MMC/SD card support as a whole to be enabled or disabled, although the generic disk device driver package (CYGPKG_IO_DISK) must be loaded in order to enable the MMC/SD support.

Use on-chip USB memory for DMA (CYGSEM_HAL_ARM_LPC2XXX_EA_LPC2468_MCI_USE_USB_MEM_FOR_DMA

The LPC2468 cannot always keep up with the data transfer requirements, especially at slower CPU clock speeds. This is because the DMA controller runs at the speed of the CPU clock (CCLK) along with the fact that some LPC2468 have errata which decreases their achievable CPU clock frequency.

Using on-chip memory dedicated to USB helps reduce or remove these problems, depending on CPU frequency. Clearly this option must be disabled if the on-chip USB peripheral is to be used. It is also desirable to disable this option if the CPU frequency is high enough, in order to remove an extra copy on every data transfer, thus improving performance. The USB memory used is 512 bytes at the start of the USB memory space (0x7FD00000).

If this option is disabled and the DMA is not able to proceed quickly enough, this will be visible in the form of I/O errors. In that case, if it is not possible to enable this option it is recommended to adjust the CYGDAT_HAL_ARM_LPC2XXX_EA_LPC2468_MCI_BUS_SPEED_LIMIT configuration option.

Lock AHB bus during DMA transfer (CYGSEM_HAL_ARM_LPC2XXX_EA_LPC2468_MCI_DMA_LOCKS_AHB)

The AMBA Hardware Bus (AHB) is used to connect AMBA peripherals within the LPC2468, including the ARM core, DMA controller and memory controllers. When this option is enabled, the AHB is locked for the duration of MCI DMA transfer bursts. If another AMBA host needs to make a transfer it may be delayed as a result, which may not be desirable.

Disabling this option allows the AHB arbiter to permit other AHB hosts to perform transfers. Of course this may mean the MCI DMA transfers can in turn themselves get delayed, risking data overruns or underruns in MCI transfers, resulting in I/O errors during block reads or writes. This is particularly likely on processors running at slower clock speeds where there may already be difficulties with the DMA servicing data transfers quickly enough.

MMC/SD bus frequency limit (CYGNUM_HAL_ARM_LPC2XXX_EA_LPC2468_MCI_BUS_SPEED_LIMIT)

> The LPC2468 cannot always keep up with the data transfer requirements, especially at slower CPU clock speeds. This is because the DMA controller runs at the speed of the CPU clock (CCLK) along with the fact that some LPC2468 have errata which decreases their achievable CPU clock frequency. The adjacent options to use on-chip USB memory and to lock the AHB bus can help prevent this, but sometimes they are insufficient to prevent data overruns or underruns resulting in I/O errors during block reads or writes. In which case the only remaining recourse is to reduce the required data transfer rate between the MCI and the card.
>
> This option can be used to impose an upper limit on the MMC/SD bus frequency. The value used in this option is measured in Hertz, and the use of 4-bit mode with SD cards is not a factor - this option provides the bus frequency, so a 4-bit bus will transfer four times the amount of data as a 1-bit bus in the same time period.
>
> Note that this option provides a limit, and does not mean the card bus will operate at that frequency. The frequency is also governed by what the card will support, and the resolution of the clock used to derive the MMC/SD clock signal, and how it can be divided down.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

However there are two flags that are used if Thumb mode is to be supported:

-mthumb	The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used.
-mthumb-interwork	This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used.

Onboard NAND

The HAL port includes a low-level driver to access the on-board Samsung K9F1G08U08 NAND flash memory chip. To enable the driver, activate the CDL option CYGHWR_HAL_ARM_LPC2XXX_EA_LPC2468_NAND and ensure that the CYGPKG_DEVS_NAND_SAMSUNG_K9 package is present in your eCos configuration. The driver is capable of operating with or without the NAND_RDY line connected.

CYGHWR_HAL_ARM_LPC2XXX_EA_LPC2468_USE_NAND_RDY

> The EA OEM Base Board provides a jumper which connects the ready line of the NAND chip (NAND_RDY) to pin P2.12 on the CPU. Setting this option indicates to the driver that that jumper, or similar layout with the same effect, is in place. This provides an improvement in efficiency, but must not be set if the jumper is not so connected.

CYGHWR_HAL_ARM_LPC2XXX_EA_LPC2468_NAND_RDY_USE_INTERRUPT

> *(Only active if CYGHWR_HAL_ARM_LPC2XXX_EA_LPC2468_USE_NAND_RDY is set.)* If set, pin P2.12 (see above) is set up as an interrupt (EINT2). Setting this causes the thread invoking the driver to sleep when waiting for a program or erase operation to complete, as opposed to entering a polling loop. This potentially represents an efficiency gain if you have at least one other thread which can carry on performing useful work while the NAND chip works.
>
> If this option is not set, the driver polls the ready line.
>
> When this option is set, the driver automatically detects whether the eCos kernel scheduler is running; if it is not, interrupt mode cannot operate, and the driver falls back to polling the ready line.
>
> Interrupt mode imposes its own overheads on the driver thread. Benchmarking chip program and erase operations alone will necessarily appear to show a slow-down in interrupt mode when the scheduler is running. This option can only improve

efficiency on a holistic basis, and only then in the case where there are other threads which can continue to work while the driver is waiting for the NAND operation to complete.

Partitioning the NAND chip

The NAND chip must be partitioned before it can become available to applications.

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_DEVS_NAND_EA_LPC2468_PARTITION_MANUAL_CONFIG`); if you choose to use this, the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script sets up a single partition (number 0) encompassing the entire device.

It is possible to configure the partitions in some other way, should it be appropriate for your setup. To do so you will have to add appropriate code to `ea_lpc2468_nand.c`.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the LPC2468 OEM Board hardware, and should be read in conjunction with that specification. The LPC2468 platform HAL package complements the ARM architectural HAL and the LPC2xxx variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor to do most of this.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including PLL (for the clocks); Memory Mapping control registers to map SRAM to 0x0; the memory controller for access to external FLASH and SDRAM; and the Memory Acceleration Module (MAM). The details of the early hardware startup may be found in the header `cyg/hal/hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

on-chip Flash
: This is located at address 0x0 of the memory space, although after hardware initialization, the start of internal SRAM is mapped over locations 0x0 to 0x40. This region ends at 0x80000. The MAM is enabled to accelerate memory reads from this area. A driver is available for using this flash via the eCos flash API.

external Flash
: This is located at address 0x80000000 of the memory space. It is not used by default by eCos, although if RedBoot is asked to manage the Flash, it reserves flash addresses 0x803F0000 thru 0x803FEFFF. If RedBoot stores its configuration data in Flash, then addresses 0x803FF000 thru 0x803FFFFF are reserved by RedBoot.

internal SRAM
: This is located at address 0x40000000 of the memory space, ending at location 0x4000FFFF. The first 64 bytes are mapped to location 0x0000000.

external SDRAM
: This is located at address 0xa0000000 of the memory space, ending at location 0xa2000000. For RAM startup, available SRAM starts at location 0xa1100000, with the bottom 1Mbyte reserved for use by RedBoot.

on-chip peripherals
: These are accessible via location 0xE0000000 onwards. Descriptions of the contents can be found in the LPC2468 User Manual.

Chapter 244. Embedded Artists QuickStart Board Support

Name

eCos Support for the Embedded Artists QuickStart Boards — Overview

Introduction

This platform HAL is designed to support the QuickStart board series from Embedded Artists, fitted with an NXP LPC2xxx microcontroller, and optionally connected to an Embedded Artists QuickStart Prototype Board.

The support for the QuickStart board series provided by this HAL has been initially developed for the Embedded Artists (henceforth 'EA') LPC2148 USB QuickStart Board. This HAL documentation therefore presently corresponds to that particular board instance, and future supported variants will cause this documentation to be updated accordingly.

Description

The Embedded Artists QuickStart Board is fitted with an NXP LPC2xxx processor rated at up to 60MHz, which contains up to 64KB of SRAM and up to 512KB of FLASH, depending on choice of LPC2xxx variant. The board itself has a single 9-pin RS-232 serial interface connected to the LPC2xxx on-chip UART 0, an I²C EEPROM, and a USB device interface. Refer to EA's QuickStart board documentation for full details.

Further peripheral support is available if the board is mounted on to the EA QuickStart Prototype Board, including push buttons, LEDs, JTAG, MMC/SD card socket, buzzer, 7-segment LED, and a further 9-pin RS-232 serial interface connected to the LPC2xxx on-chip UART 1.

The typical mode of operation for eCos development usually depends on the amount of memory available. On LPC2xxx variants with 64Kbytes or more of SRAM, a GDB stub ROM image is programmed into the LPC2xxx on-chip flash memory, and the board will boot this image from reset. While RedBoot may also be used, its larger RAM footprint requirements usually make it unsuitable. Both RedBoot and the GDB stub ROM provide GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART 0.

On LPC2xxx variants with less than 64KBytes SRAM, such as the 32KBytes on the LPC2148, it is typically expected that stand-alone applications will be programmed directly to on-chip Flash, either using a hardware JTAG/ICE unit via the QuickStart Prototype Board, or by serial using the on-chip In-System Programming (ISP) mechanism included with NXP LPC2xxx microcontrollers and a suitable host application running on a PC.

This documentation describes platform-specific elements of the EA QuickStart Board support within eCos. Documentation on the NXP LPC2xxx variants is available separately, and should be read in conjunction with this documentation. The LPC2xxx documentation covers various topics including HAL support common to LPC2xxx variants, and on-chip device support. This document complements the LPC2xxx documentation.

Supported Hardware

The NXP LPC2xxx microcontrollers on the EA QuickStart Boards have up to 512Kbytes of on-chip Flash memory. In a typical setup, the GDB stub ROM or the user application will load and run from this internal flash. For initial programming of the internal Flash, external support is required, such as the NXP LPC2000 Flash Utility, the Flash Magic tool, or a hardware JTAG/ICE unit. The latter may be used with its own in-built LPC2xxx flash programming support if it exists, or the eCosPro® **ecoflash** utility. 28Kbytes of internal flash memory should be reserved for the GDB Stub ROM, the remainder being free for the application's use. Note that the LPC2xxx primary boot loader and IAP code reside in boot blocks located at the end of on-chip Flash. To determine the number and size of blocks reserved for their use, consult the specific LPC2xxx variant's datasheet.

The first 64 bytes of on-chip SRAM are mapped by the HAL startup code using the LPC2xxx memory mapping control to location 0x00000000. When loading applications using the GDB stub ROM, SRAM from location 0x40000040 to 0x40001000 is reserved for its use. The rest of SRAM is generally available for use by the application. Programs booted from ROM, or loaded directly into SRAM via JTAG may use all SRAM. In all cases, if using the eCos LPC2xxx Flash driver, the last 32 bytes (or more if a separate program buffer is used) become reserved due to the requirements of the IAP code.

The NXP LPC2xxx variant HAL includes support for the two LPC2xxx on-chip serial devices and is documented in the variant HAL. Although the interrupt-driven serial driver supports the line status and modem control lines on UART 1 (UART 0 not having such support), the QuickStart boards do not connect these pins, and so that functionality is unavailable.

The EA QuickStart port includes support for the on-chip watchdog, RTC (wallclock), interrupt controller (VIC) and on-chip Flash. This support is documented in the LPC2xxx variant HAL.

Tools

The QuickStart Board port is intended to work with GNU tools configured for an arm-eabi target. Thumb mode is supported. The original port was created using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.16.

Name

Setup — Preparing the EA QuickStart Board for eCos Development

Overview

In a typical development environment, the EA QuickStart Board boots from internal flash into either the GDB stub ROM monitor or directly into the user application. In the case of microcontrollers with less than 64Kbytes of SRAM, the latter is recommended. eCos applications to be loaded and run from the GDB stub ROM monitor may be configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable ROM image into Flash memory, either the GDB stub ROM or application images.

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and rebuilding the application, or if applicable, GDB stub ROM. A "straight through" 9-pin RS232 serial cable, with Male<->Female connectors is required. Using a "null modem" serial cable will not work.

Initial Installation

Board setup

Jumper settings must be checked and potentially changed on the board to ensure correct operation. This section describes jumper settings that are known to require attention. In general, any board-specific documentation from Embedded Artists takes precedence over the documentation here, as this may reflect hardware which has been modified since the time of writing of this documentation. Most QuickStart boards are very similar to each other, the only change of note being of course the choice of LPC2xxx microcontroller fitted. But if your board does not fit the description here (which has initially been based on the LPC2148 USB QuickStart) then you should consult the board documentation.

Firstly, there are two jumpers located close to the serial connector. In general, these jumpers should only be closed (i.e. jumper fitted and connecting the two pins) when wishing to reprogram the on-chip Flash via ISP. Otherwise they should remain open (jumper not connecting the two pins) so that any unplugging of the serial connector, movement of the serial connector, or use of flow control signals from the host PC, do not cause a spurious reset or interrupt (on the EINT1 line) of the board.

If the board is being powered directly by USB, then a jumper next to the USB connector should be closed. Otherwise it *must* be open. This also means the jumper must be open if the QuickStart board is mounted on the Prototype Board, and power is being provided by either the DC power connector or USB connector on the Prototype Board.

Note that if the Prototype Board is fitted, but the QuickStart board is being powered by its USB connector as opposed to the Prototype board's USB connector (thus meaning that the above jumper would be closed), then pin P0.23 is used as a USB power indication on LPC214x boards. This prevents its use as an SPI chip select line for the 7-segment LED on the Prototype Board.

If mounting the QuickStart LPC2xxx board on the QuickStart Prototype Board, then consult the EA documentation for the correct jumper settings and socket location appropriate to the fitted LPC2xxx model. This includes settings for the JTAG connector. In the case of the LPC213x/LPC214x, the jumper labelled "JTAG" must be closed, and the jumper labelled "DBGSEL" must be open.

It may also be useful to be aware that although eCos configures the PWM pin for the buzzer, it does not directly support it, and so it is probably useful to open the jumper labelled "P0.7" to disable the buzzer.

The jumpers adjacent to the LEDs may remain in their default state of closed, in order to get insight into system operation, and to allow use of the user-configurable LEDs, as described later.

Flash Installation

This process assumes that a Microsoft Windows machine with the Flash Magic utility installed is available. Flash Magic is a tool for programming flash based microcontrollers from NXP using a protocol via the RS232 serial port to communicate with the In-System Programming (ISP) firmware on the LPC2xxx. The Flash Magic utility is sponsored by NXP and available from this website.

The first step is to connect the RS232 cable between the serial port of the QuickStart board and the host PC. Do not use the serial port on the Prototype board. Now close the two jumpers adjacent to the serial port on the QuickStart board. These allow the software on the PC to reset the LPC2xxx and enter the ISP firmware. Finally apply the power.

Start the Flash Magic utility on the host PC, and a window will be displayed allowing various parameters to be configured in a series of steps. For step 1, firstly choose the appropriate COM port that is being used on your PC and set the Baud Rate to 38400 baud. Next select the appropriate LPC2xxx device in use such as LPC2148. The "Interface" should be set to "None (ISP)". And finally for step 1 choose the appropriate Oscillator Frequency for the QuickStart board in use. This may be found in the board documentation, and is usually visibly readable on the surface of the oscillator on the board (in a metal package). For example for the LPC2148 USB QuickStart, the oscillator reads 12.000 indicating 12MHz.

For step 2, it is usually adequate to leave the option "Erase blocks used by hex file" checked, and ignore the other settings. For step 3, you must select the program image to be downloaded, in Intel HEX format. To program the pre-built GDB stub ROM image, locate the file `gdb_module.hex` in the `loaders` subdirectory of your release. To generate an Intel HEX format version of an application you have built yourself run the following command at a shell prompt:

```
 $ arm-eabi-objcopy -O ihex app.elf app.hex
```

This converts the application image in ELF format (as output by the linker), to Intel HEX format in the file `app.hex`. Note that the arm-eabi tools must be on your path at this point. If they are not, run the command below before you run the above **arm-eabi-objcopy** command:

```
 $ . /opt/ecos/ecosenv.sh
```

In step 4, it is recommended to set the option "Verify after programming". Finally it is possible to click on "Start" to program the image into the on-chip Flash.

Tip

If there is a problem communicating with the board, such as a report of a failure to autobaud, then this may imply that the Flash Magic tool was not able to control the serial lines properly. This can happen with some USB-Serial converters. For Prototype Board users, to workaround this issue, power the board off and remove (i.e. open) the two jumpers next to the serial port. Then simultaneously press the buttons marked 'Reset' and 'P0.14' on the prototype board (the latter corresponds to interrupt EINT1), then release the Reset button, and finally release the 'P0.14' button. This is an alternative mechanism of forcing the ISP firmware to be entered. Once this has been successfully performed, the programming operation may be retried from the Flash Magic utility.

When the process completes, remove (i.e. open) the two jumpers next to the serial port. If a GDB stub ROM image has been programmed, verify the programming has been successful by starting a terminal emulation application such as HyperTerminal on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Reset the board and the stubrom should start. For boards programmed with GDB stubs the output should be similar to the following:

```
+$T050f:ec070000;0d:28080040;#52
```

This is the stubrom attempting to communicate with GDB and indicates that it is functioning correctly.

Rebuilding the GDB Stub ROM

Should it prove necessary to rebuild the GDB Stub ROM binary, this is done most conveniently at the command line. Your `PATH` and `ECOS_REPOSITORY` environment variables must first be set correctly, The following steps given an example of how to rebuild the stubs for a QuickStart board with LPC2148:

```
$ mkdir stub_rom
$ cd stub_rom
$ ecosconfig new ea_quickstart_lpc2148 stubs
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the files `gdb_module.img` (ELF format), `gdb_module.srec` (Motorola S-Record format), `gdb_module.bin` (raw binary format), and `gdb_module.hex` (Intel HEX format).

Name

Configuration — Platform-specific Configuration Options

Overview

The EA QuickStart platform HAL package is loaded automatically when eCos is configured for a target which uses it. The target names include the LPC2xxx model in use. At this time the only target supported is the `ea_quickstart_lpc2148` target. It should never be necessary to load this platform HAL package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The EA QuickStart platform HAL package supports three separate startup types:

ROM This startup type can be used for finished applications which will be programmed into internal flash at location 0x0. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. On targets with less than 64Kbytes of SRAM, this is the startup type normally used.

RAM This is the startup type which is normally used during application development on targets with 64Kbytes of SRAM or greater. The board has the GDB stubrom or RedBoot programmed into flash at location 0x0 in internal on-chip Flash and boots from that location. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the ROM monitor. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the ROM monitor, including diagnostic output. Larger applications may not fit into the available SRAM, in which case ROM startup may be required.

JTAG This is an alternative development startup type. The application is loaded into RAM via a JTAG device and is run and debugged from there. The application will be self-contained with no dependencies on services provided by other software. It is expected that hardware setup will have been performed via the JTAG device prior to loading. Some sample configuration and initialisation scripts for a number of JTAG debugging solutions may be found in the `misc` subdirectory of the platform HAL package within the component repository.

The ROM Monitor and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB Stubrom or RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, or as a testing step before switching to ROM startup. Virtual vector support is usually only required for RAM startup applications or ROM monitors. The CDL option `CYGFUN_HAL_LPC2XXX_VIRTUAL_VECTOR_SUPPORT` within the LPC2xxx variant HAL allows manual control of this facility.

If the application does not rely on a ROM monitor for diagnostic services then by default serial port UART0 will be claimed for HAL diagnostics. If using the Prototype Board, it becomes possible to use UART1 as well, and in order to allow its selection as a potential debug or diagnostic channel, the number of communications channels can be increased from 1 to 2 with the option `CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS`. To specify which serial port is used for diagnostics, the configuration option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` may be set accordingly, and its baud rate configured with `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD`.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The PLL multiplier may be configured to allow a core clock (CCLK) speed of up to 60MHz. The description of the clock-related CDL options may be found in the LPC2xxx variant HAL documentation. Note there are frequency constraints on the Current Controlled Oscillator (CCO) within the LPC2xxx, and the datasheet should be consulted to ensure the required specifications are not exceeded.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

However there are two flags that are used if Thumb mode is to be supported:

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. To build eCos in Thumb mode, enable the `CYGHWR_THUMB` configuration option in the ARM architecture HAL.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. For example, allowing a Thumb application to be used with eCos built in normal ARM mode. Without this option, some memory can be saved. This option should be used if -mthumb is used. eCos may be built with Thumb interworking support by enabling the `CYGBLD_ARM_ENABLE_THUMB_INTERWORK` CDL option in the ARM architecture HAL. Use of the LPC2xxx Flash driver requires Thumb interworking support to be enabled as the calls into the IAP firmware are must be made allowing a switch to Thumb mode.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the EA QuickStart board hardware, and should be read in conjunction with that specification. The QuickStart Board platform HAL package complements the ARM architectural HAL and the LPC2xxx variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. This includes the PINSEL functions and LED bank. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including PLL (for the clocks), Memory Mapping control registers to map SRAM to 0x0, and Memory Acceleration Module (MAM). The details of the early hardware startup may be found in the header `cyg/hal/hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

on-chip Flash
: This is located at address 0x0 of the memory space, although after hardware initialization, the start of internal SRAM is mapped over locations 0x0 to 0x40. The size of this region depends on the LPC2xxx microcontroller variant in use. In the case of the LPC2148, the region is of size 512Kbytes, ending at 0x80000. However the last few blocks of Flash are reserved for use as bootblocks for the ISP/IAP firmware, resulting in a usable Flash size of 500Kbytes, ending at 0x7d000. The MAM is enabled to accelerate memory reads from this area.

internal SRAM
: This is located at address 0x40000000 of the memory space, and is 16, 32 or 64k in size, depending on the chip fitted. The first 64 bytes are mapped to location 0x0000000. If using GDB stubs ROM, or another ROM monitor, the virtual vector table starts at 0x40000050 and extends to 0x40000150. The remainder of SRAM is available for use by applications. For RAM startup applications, SRAM below 0x40001000 is reserved for the GDB stubrom and the remainder is available for the application. An exception is if the on-chip Flash driver is to be used. In that case, the top 32 bytes of SRAM are used by it. This is automatically handled in the port's memory layout files if the flash driver is present in the configuration.

on-chip peripherals
: These are accessible at location 0xE0000000 onwards. Descriptions of the contents can be found in the LPC2xxx User Manual for the appropriate microcontroller variant.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 244.1. ea_quickstart Real-time characterization

```
            Startup, main stack : stack used   420 size  3920
             Startup :  Interrupt stack used   148 size  4096
             Startup : Idlethread stack used    88 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated
```

```
Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   15.31 microseconds (9 raw clock ticks)

Testing parameters:

```

LED use

LEDs are available on the Prototype board. Most of these are attached to lines associated with peripherals present on the Prototype board, or the QuickStart board itself. However 9 LEDS are available for application use from C. The following C function may be used:

```
#include <cyg/infra/hal_diag.h>
extern void hal_diag_led(int leds);
```

Values from 0 to 511 will be displayed on the LED bank representing the binary value with 1 being on and 0 being off. The LEDs used are connected to P0.10-P0.13 and P0.17-P0.21, and with P0.21 being the MSB, and P0.10 the LSB.

The LEDs are also used during platform initialization and only P0.10 should be illuminated if booting has been successful. Other LED indications represent the stage in the initialization process that failed.

Other Issues

The following pin assignments are configured by default for LPC2148 at board initialisation time:

PINSEL0:
P0.0/P0.1 for UART0
P0.2/P0.3 for I²C
P0.4/P0.5/P0.6 for SPI
P0.7 as PWM2 for buzzer on Prototype board
P0.8/P0.9 for UART1 (which is available on prototype board)
P0.10-P0.13 as GPIO-controlled LEDs
P0.14 EINT1 (available as button on prototype board)
P0.15 EINT2 (available as button on prototype board)

PINSEL1:
P0.16 EINT0 (available as button on prototype board)
P0.17-P0.21 as GPIO-controlled LEDs
P0.22 as GPIO output for SPI_SEL_MMC on prototype board
P0.23 as GPIO output for SPI_SEL_LED on prototype board
P0.29 as GPIO input for MMC/SD card detect on prototype board
P0.30 as EINT3 (available as button on prototype board)
(rather than GPIO input for SD write protect on prototype board)
All other pins set as GPIO inputs

PINSEL2:
P1.26-P1.31 for JTAG
All other pins set as inputs

Chapter 245. IAR KickStart Card Support

Name

eCos Support for the IAR KickStart Cards — Overview

Introduction

This platform HAL is designed to support the KickStart Card series from IAR, fitted with an NXP LPC2xxx microcontroller.

The support for the KickStart board series provided by this HAL has been initially developed for the IAR LPC2106 KickStart Card. This HAL documentation therefore presently corresponds to that particular board instance, and future supported variants will cause this documentation to be updated accordingly.

Description

The IAR KickStart Board is fitted with an NXP LPC2xxx processor rated at up to 60MHz, which contains up to 64KB of SRAM and up to 512KB of FLASH, depending on choice of LPC2xxx variant. The board itself has two 9-pin RS-232 serial interfaces connected to the LPC2xxx on-chip UART 0 and UART 1, push buttons connected to interrupt lines, LEDs, a JTAG debug port, anda prototyping area. Refer to IAR's KickStart board documentation for full details.

The typical mode of operation for eCos development usually depends on the amount of memory available. On LPC2xxx variants with 64Kbytes or more of SRAM, a GDB stub ROM image is programmed into the LPC2xxx on-chip flash memory, and the board will boot this image from reset. While RedBoot may also be used, its larger RAM footprint requirements usually make it unsuitable. Both RedBoot and the GDB stub ROM provide GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART 0.

On LPC2xxx variants with less than 64KBytes SRAM, it is typically expected that standalone applications will be programmed directly to on-chip Flash, either using a hardware JTAG/ICE unit, or by serial using the on-chip In-System Programming (ISP) mechanism included with NXP LPC2xxx microcontrollers and a suitable host application running on a PC.

This documentation describes platform-specific elements of the IAR KickStart Board support within eCos. Documentation on the NXP LPC2xxx variants is available separately, and should be read in conjunction with this documentation. The LPC2xxx documentation covers various topics including HAL support common to LPC2xxx variants, and on-chip device support. This document complements the LPC2xxx documentation.

Supported Hardware

The NXP LPC2xxx microcontrollers on the IAR KickStart Boards have up to 512Kbytes of on-chip Flash memory. In a typical setup, the GDB stub ROM or the user application will load and run from this internal flash. For initial programming of the internal Flash, external support is required, such as the NXP LPC2000 Flash Utility, the Flash Magic tool, or a hardware JTAG/ICE unit. The latter may be used with its own in-built LPC2xxx flash programming support if it exists, or the eCosPro® **ecoflash** utility. 28Kbytes of internal flash memory should be reserved for the GDB Stub ROM, the remainder being free for the application's use. Note that the LPC2xxx primary boot loader and IAP code reside in boot blocks located at the end of on-chip Flash. To determine the number and size of blocks reserved for their use, consult the specific LPC2xxx variant's datasheet.

The first 64 bytes of on-chip SRAM are mapped by the HAL startup code using the LPC2xxx memory mapping control to location 0x00000000. When loading applications using the GDB stub ROM, SRAM from location 0x40000040 to 0x40001000 is reserved for its use. The rest of SRAM is generally available for use by the application. Programs booted from ROM, or loaded directly into SRAM via JTAG may use all SRAM. In all cases, if using the eCos LPC2xxx Flash driver, the last 32 bytes (or more if a separate program buffer is used) become reserved due to the requirements of the IAP code.

The NXP LPC2xxx variant HAL includes support for the two LPC2xxx on-chip serial devices and is documented in the variant HAL. Although the interrupt-driven serial driver supports the line status and modem control lines on UART 1 (UART 0 not having such support), the KickStart boards do not connect these pins, and so that functionality is unavailable.

The IAR KickStart port includes support for the on-chip watchdog, RTC (wallclock), interrupt controller (VIC) and on-chip Flash. This support is documented in the LPC2xxx variant HAL.

Tools

The KickStart Board port is intended to work with GNU tools configured for an arm-eabi target. Thumb mode is supported. The original port was created using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.16.

Name

Setup — Preparing the IAR KickStart Board for eCos Development

Overview

In a typical development environment, the IAR KickStart Board boots from internal flash into either the GDB stub ROM monitor or directly into the user application. In the case of microcontrollers with less than 64Kbytes of SRAM, the latter is recommended. eCos applications to be loaded and run from the GDB stub ROM monitor may be configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable ROM image into Flash memory, either the GDB stub ROM or application images.

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and rebuilding the application, or if applicable, GDB stub ROM. A "straight through" 9-pin RS232 serial cable, with Male<->Female connectors is required. Using a "null modem" serial cable will not work.

Initial Installation

Board setup

Jumper settings must be checked and potentially changed on the board to ensure correct operation. This section describes jumper settings that are known to require attention. In general, any board-specific documentation from IAR takes precedence over the documentation here, as this may reflect hardware which has been modified since the time of writing of this documentation. Many KickStart boards are similar to each other, the only change of note being of course the choice of LPC2xxx microcontroller fitted. But if your board does not fit the description here (which has initially been based on the LPC2106 KickStart) then you should consult the board documentation.

Firstly, there are two jumpers located close to the serial connectors, labelled JP3 and JP4 on the LPC2106 KickStart. These can both be closed (i.e. jumper fitted and connecting the two pins) in order to permit use of both serial ports.

There are two jumpers labelled EN_SW_ISP and EN_SW_RST close to the push buttons, also labelled JP7 and JP8 respectively on the LPC2106 KickStart. In general, these jumpers should only be closed when wishing to reprogram the on-chip Flash via ISP. Otherwise they should remain open (jumper not connecting the two pins) so that any unplugging of the serial connector, movement of the serial connector, or use of flow control signals from the host PC, do not cause a spurious reset or interrupt (on the EINT1 line) of the board.

The jumpers controlling the LEDs (labelled LED Jumper Block on the LPC2106 KickStart) may remain in their default state of being connected to P0.0-P0.15. This is assumed by code which allows use of the user-configurable LEDs, as described later.

All other jumpers can remain in their factory-supplied default state.

Flash Installation

This process assumes that a Microsoft Windows machine with the Flash Magic utility installed is available. Flash Magic is a tool for programming flash based microcontrollers from NXP using a protocol via the RS232 serial port to communicate with the In-System Programming (ISP) firmware on the LPC2xxx. The Flash Magic utility is sponsored by NXP and available from this website.

The first step is to connect the RS232 cable between UART0 of the KickStart board and the host PC. Do not use UART1. Now close the two jumpers mentioned earlier labelled EN_SW_ISP and EN_SW_RST. These allow the software on the PC to reset the LPC2xxx and enter the ISP firmware. Finally apply the power.

Start the Flash Magic utility on the host PC, and a window will be displayed allowing various parameters to be configured in a series of steps. For step 1, firstly choose the appropriate COM port that is being used on your PC and set the Baud Rate to 38400 baud.

Next select the appropriate LPC2xxx device in use such as LPC2106. The "Interface" should be set to "None (ISP)". And finally for step 1 choose the appropriate Oscillator Frequency for the KickStart board in use. This may be found in the board documentation, and is usually visibly readable on the surface of the oscillator on the board (in a metal package). For example for the LPC2106 KickStart, the oscillator reads T14.7456 indicating 14.7456MHz.

For step 2, it is usually adequate to leave the option "Erase blocks used by hex file" checked, and ignore the other settings. For step 3, you must select the program image to be downloaded, in Intel HEX format. To program the pre-built GDB stub ROM image, locate the file `gdb_module.hex` in the `loaders` subdirectory of your release. To generate an Intel HEX format version of an application you have built yourself run the following command at a shell prompt:

```
$ arm-eabi-objcopy -O ihex app.elf app.hex
```

This converts the application image in ELF format (as output by the linker), to Intel HEX format in the file `app.hex`. Note that the arm-eabi tools must be on your path at this point. If they are not, run the command below before you run the above **arm-eabi-objcopy** command:

```
$ . /opt/ecos/ecosenv.sh
```

In step 4, it is recommended to set the option "Verify after programming". Finally it is possible to click on "Start" to program the image into the on-chip Flash.

Tip

If there is a problem communicating with the board, such as a report of a failure to autobaud, then this may imply that the Flash Magic tool was not able to control the serial lines properly. This can happen with some USB-Serial converters. To workaround this issue, power the board off and remove (i.e. open) the EN_SW_ISP and EN_SW_RST jumpers. Then simultaneously press the buttons marked 'Reset' and 'ISP/INT1' then release the Reset button, and finally release the 'ISP/INT1' button. This is an alternative mechanism of forcing the ISP firmware to be entered. Once this has been successfully performed, the programming operation may be retried from the Flash Magic utility.

When the process completes, remove (i.e. open) the two jumpers next to the serial port. If a GDB stub ROM image has been programmed, verify the programming has been successful by starting a terminal emulation application such as HyperTerminal on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Reset the board and the stubrom should start. For boards programmed with GDB stubs the output should be similar to the following:

```
+$T050f:ec070000;0d:28080040;#52
```

This is the stubrom attempting to communicate with GDB and indicates that it is functioning correctly.

Rebuilding the GDB Stub ROM

Should it prove necessary to rebuild the GDB Stub ROM binary, this is done most conveniently at the command line. Your `PATH` and `ECOS_REPOSITORY` environment variables must first be set correctly, The following steps given an example of how to rebuild the stubs for a KickStart board with LPC2106:

```
$ mkdir stub_rom
$ cd stub_rom
$ ecosconfig new iar_kickstart_lpc2106 stubs
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the files `gdb_module.img` (ELF format), `gdb_module.srec` (Motorola S-Record format), `gdb_module.bin` (raw binary format), and `gdb_module.hex` (Intel HEX format).

Name

Configuration — Platform-specific Configuration Options

Overview

The IAR KickStart platform HAL package is loaded automatically when eCos is configured for a target which uses it. The target names include the LPC2xxx model in use. At this time the only target supported is the `iar_kickstart_lpc2106` target. It should never be necessary to load this platform HAL package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The IAR KickStart platform HAL package supports three separate startup types:

ROM
: This startup type can be used for finished applications which will be programmed into internal flash at location 0x0. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. On targets with less than 64Kbytes of SRAM, this is the startup type normally used.

RAM
: This is the startup type which is normally used during application development on targets with 64Kbytes of SRAM or greater. The board has the GDB stubrom or RedBoot programmed into flash at location 0x0 in internal on-chip Flash and boots from that location. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the ROM monitor. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the ROM monitor, including diagnostic output. Larger applications may not fit into the available SRAM, in which case ROM startup may be required.

JTAG
: This is an alternative development startup type. The application is loaded into RAM via a JTAG device and is run and debugged from there. The application will be self-contained with no dependencies on services provided by other software. It is expected that hardware setup will have been performed via the JTAG device prior to loading. Some sample configuration and initialisation scripts for a number of JTAG debugging solutions may be found in the `misc` subdirectory of the platform HAL package within the component repository.

The ROM Monitor and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB Stubrom or RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, or as a testing step before switching to ROM startup. Virtual vector support is usually only required for RAM startup applications or ROM monitors. The CDL option `CYGFUN_HAL_LPC2XXX_VIRTUAL_VECTOR_SUPPORT` within the LPC2xxx variant HAL allows manual control of this facility.

If the application does not rely on a ROM monitor for diagnostic services then by default serial port UART0 will be claimed for HAL diagnostics. If using the Prototype Board, it becomes possible to use UART1 as well, and in order to allow its selection as a potential debug or diagnostic channel, the number of communications channels can be increased from 1 to 2 with the option `CYGNUM_HAL_VIRTUAL_VECTOR_COMM_CHANNELS`. To specify which serial port is used for diagnostics, the configuration option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` may be set accordingly, and its baud rate configured with `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD`.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The PLL multiplier may be configured to allow a core clock (CCLK) speed of up to 60MHz. The description of the clock-related CDL options may be found in the LPC2xxx variant HAL documentation. Note there are frequency constraints on the Current Controlled Oscillator (CCO) within the LPC2xxx, and the datasheet should be consulted to ensure the required specifications are not exceeded.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

However there are two flags that are used if Thumb mode is to be supported:

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. To build eCos in Thumb mode, enable the `CYGHWR_THUMB` configuration option in the ARM architecture HAL.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. For example, allowing a Thumb application to be used with eCos built in normal ARM mode. Without this option, some memory can be saved. This option should be used if -mthumb is used. eCos may be built with Thumb interworking support by enabling the `CYGBLD_ARM_ENABLE_THUMB_INTERWORK` CDL option in the ARM architecture HAL. Use of the LPC2xxx Flash driver requires Thumb interworking support to be enabled as the calls into the IAP firmware are must be made allowing a switch to Thumb mode.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the IAR KickStart board hardware, and should be read in conjunction with that specification. The KickStart Board platform HAL package complements the ARM architectural HAL and the LPC2xxx variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. This includes the PINSEL functions and LED bank. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including PLL (for the clocks), Memory Mapping control registers to map SRAM to 0x0, and Memory Acceleration Module (MAM). The details of the early hardware startup may be found in the header `cyg/hal/hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

on-chip Flash

This is located at address 0x0 of the memory space, although after hardware initialization, the start of internal SRAM is mapped over locations 0x0 to 0x40. The size of this region depends on the LPC2xxx microcontroller variant in use. In the case of the LPC2106, the region is of size 128Kbytes, ending at 0x20000. However the last few blocks of Flash are reserved for use as bootblocks for the ISP/IAP firmware, resulting in a usable Flash size of 120Kbytes, ending at 0x1e000. The MAM is enabled to accelerate memory reads from this area.

internal SRAM

This is located at address 0x40000000 of the memory space, and is 16, 32 or 64k in size, depending on the chip fitted. The first 64 bytes are mapped to location 0x0000000. If using GDB stubs ROM, or another ROM monitor, the virtual vector table starts at 0x40000050 and extends to 0x40000150. The remainder of SRAM is available for use by applications. For RAM startup applications, SRAM below 0x40001000 is reserved for the GDB stubrom and the remainder is available for the application. An exception is if the on-chip Flash driver is to be used. In that case, the top 32 bytes of SRAM are used by it. This is automatically handled in the port's memory layout files if the flash driver is present in the configuration.

on-chip peripherals

These are accessible at location 0xE0000000 onwards. Descriptions of the contents can be found in the LPC2xxx User Manual for the appropriate microcontroller variant.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 245.1. iar_kickstart Real-time characterization

```
            Startup, main stack : stack used   420 size  3920
             Startup :  Interrupt stack used   148 size  4096
             Startup : Idlethread stack used    80 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated
```

```
Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   14.94 microseconds (8 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   2
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32

```

LED use

LEDs are available on the KickStart boards although most of these are attached to lines associated with peripherals. However 4 LEDS are available for application use from C. The following C function may be used:

```
#include <cyg/infra/hal_diag.h>
extern void hal_diag_led(int leds);
```

Values from 0 to 15 will be displayed on the LED bank representing the binary value with 1 being on and 0 being off. The LEDs used are connected to P0.10-P0.13 P0.13 being the MSB, and P0.10 the LSB.

The LEDs are also used during platform initialization and only P0.10 should be illuminated if booting has been successful. Other LED indications represent the stage in the initialization process that failed.

Other Issues

The following pin assignments are configured by default for LPC2106 at board initialisation time:

PINSEL0:
    P0.0/P0.1 for UART0
    P0.2/P0.3 for I2C
    P0.4/P0.5/P0.6/P0.7 for SPI
    P0.8/P0.9 for UART1
    P0.10-P0.13 as GPIO-controlled LEDs
    P0.14 EINT1
    P0.15 EINT2

    PINSEL1:
    P0.16 EINT0
    P0.17-P0.21 as GPIO, although in practice these are used for JTAG
    if a JTAG unit is connected.
    P0.22-P0.31 as GPIO inputs

Chapter 246. Keil MCB2387 Board Support

Name

eCos Support for the Keil MCB2387 Board — Overview

Description

The Keil MCB2387 Board is fitted with an NXP LPC2387 processor rated up to 72MHz, which contains 64KB of SRAM and 512KB of FLASH. It provides access to two on-chip UARTs, an MMC/SD card socket, and a PHY connected to the on-chip Ethernet MAC. Refer to the board documentation for full details.

For typical eCos development, a GDB StubROM image is programmed into the LPC2387 on-chip flash memory, and the board will boot this image from reset. This provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART 0.

This documentation describes platform-specific elements of the MCB2387 Board support within eCos. Documentation on the NXP LPC2xxx variants is available separately, and should be read in conjunction with this documentation. The LPC2xxx documentation covers various topics including HAL support common to LPC2xxx variants, and on-chip device support. This document complements the LPC2xxx documentation.

Supported Hardware

The MCB2387 board has 512Kbyte of on-chip Flash memory. In a typical setup, the stubrom will run from this internal flash. An image must be programmed into this flash using either the FlashMagic utility, or via a JTAG debugger.

The first 64 bytes of on-chip SRAM are mapped by the HAL startup code using the LPC2387 memory mapping control to location 0x00000000 for speed of interrupt vector processing. The rest of SRAM is available for use by the application.

The NXP LPC2xxx variant HAL includes support for the on-chip serial devices which is documented in the variant HAL. While the interrupt-driven serial driver supports the line status and modem control features of the UART devices, none of these lines are made available on the COM0 or COM1 connectors.

The MCB2387 board port includes support for the on-chip watchdog, RTC (wallclock), and interrupt controller (VIC). This support is documented in the LPC2xxx variant HAL.

The on-chip Ethernet MAC is supported.

The on-chip Multimedia Card Interface (MCI) is supported to allow access to Multimedia Cards (MMC) or Secure Digital (SD) cards using the socket on the OEM board.

Drivers for I²C and SPI are present. However, since there are no on-board devices connected to these busses, they have only been tested using external devices attached to the board for the purpose.

Tools

The MCB2387 board port is intended to work with GNU tools configured for an arm-eabi target. Thumb mode is supported. The original port was done using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.16.

Name

Setup — Preparing the MCB2387 Board for eCos Development

Overview

In a typical development environment, the MCB2387 board boots from internal flash into the GDB stubrom. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable image into flash memory.

Initial Installation

Flash Installation

This process assumes that a Microsoft Windows machine with the Embedded Systems Academy Flash Magic utility is available. Install Flash Magic from http://www.flashmagictool.com. Connect a 9-pin serial cable from a COM port on the PC to the COM0 connector on the MCB2387 Board. Power the board via a USB cable.

Set the ISP jumpers (J9(RST) and J10(ISP) on, J13(ETM) off) and press the reset button. The board is now running a special NXP boot loader. Start Flash Magic and set the Communications section to select the COM port used above, 38400 baud, device LPC2387, Interface “None (ISP)” and 12MHz Oscillator Frequency. Test communication with the board by using the “ISP->Read Device Signature” menu entry. If communication is not successful, check that the serial cable is connected, the ISP jumpers are installed and the correct COM port is being used.

Check “Erase blocks used by Hex File” under “Erase”. In the “Hex File” section, select the `stubrom.hex` file. Under “Options”, all boxes should be clear except “Verify after programming”. Now press the “Start” button. The utility should show the progress of the upload.

When the process completes, the utility should be closed. Reset the ISP jumpers (J9(RST) and J10(ISP) off, J13(ETM) on). Verify the programming has been successful by starting a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Reset the board and the stubrom should start. The output should be similar to the following:

```
+$T050f:98070000;0d:48070040;#fc
```

This is the stubrom reporting it's state using the GDB remote protocol.

Rebuilding the Stubrom

Should it prove necessary to rebuild the Stubrom binary, this is done most conveniently at the command line. Assuming your `PATH` and `ECOS_REPOSITORY` environment variables have been set correctly, the steps needed to rebuild RedBoot for the MCB2387 are:

```
$ mkdir stub_mcb2387_rom
$ cd stub_mcb2387_rom
$ ecosconfig new mcb2387 stubs
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `stubrom.hex`.

Name

Configuration — Platform-specific Configuration Options

Overview

The mcb2387 platform HAL package is loaded automatically when eCos is configured for an `mcb2387` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The mcb2387 platform HAL package supports three separate startup types:

JTAG
: This is the startup type which is normally used during JTAG based application development. arm-eabi-gdb is then used to connect to the JTAG device and load a JTAG startup application into memory and debug it. It is assumed that the basic hardware has already been initialized via the JTAG device's initialization script. Otherwise the application is entirly self contained and should contain drivers for all hardware used.

RAM
: This is the startup type which is normally used during stubrom based application development. The board has the stubrom programmed into flash at location 0x0 in internal on-chip Flash and boots from that location. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the basic hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the stubrom, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into internal flash at location 0x0. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the stubrom.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, or as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port UART0 will be claimed for HAL diagnostics.

Flash Driver

The `CYGPKG_DEVS_FLASH_LPC2XXX` package contains all the code necessary to support the on-chip flash.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The PLL multipliers and dividers may be configured to allow a core clock (CCLK) speed of up to 72MHz. However, the platform HAL currently sets the clock to 48MHz, duplicating the configuration in the supplied example code as a consequence of CPU errata affecting various revisions of the LPC2387. Setting the CPU revision with the `CYGHWR_HAL_ARM_LPC2XXX_MCB2387_CPU_REVISION` configuration option can be used to provide default clock settings appropriate to the CPU revision in use. If the CPU revision cannot be guaranteed it should be left as "Initial". The description of the clock-related CDL options may be found in the LPC2xxx variant HAL documentation.

I²C Bus Configuration

The on-chip I²C devices are supported by a driver in the variant HAL package. Each bus for this driver needs to be configured in the platform HAL with the following options:

`CYGPKG_HAL_ARM_LPC2XXX_I2CX`

> This is the master component, enabling this activates all the other configuration options and causes the driver to create the data structures to access this bus.

`CYGPKG_HAL_ARM_LPC2XXX_I2CX_CLOCK`

> Bus clock speed in Hz. Usually frequencies of either 100kHz or 400kHz are chosen, the latter sometimes known as fast mode.

`CYGPKG_HAL_ARM_LPC2XXX_I2CX_SDA`

> This option describes the pin used for SDA on this bus. This takes the form of an invocation of the macro __LPC2XXX_PINSEL_FUNC. Parameters are the port number, pin within that port, and the alternate select function for the pin. See the LPC2387 user manual for details of which pins may be used by each bus.

`CYGPKG_HAL_ARM_LPC2XXX_I2CX_SCL`

> This option describes the pin used for SCL on this bus. Like SDA this takes the form of a call to __LPC2XXX_PINSEL_FUNC.

Note that "I2CX" is a placeholder for a given bus instance: "I2C0", "I2C1" or "I2C2". By default the platform HAL does not enable any I²C buses since there are no on-board devices.

SPI Bus Configuration

The on-chip SSP SPI devices (not the Legacy SPI device) are supported by the NXPSSP driver package, `CYGPKG_DEVS_SPI_ARM_NXPSSP`. This needs some configuration in the platform HAL:

`CYGPKG_HAL_ARM_LPC2XXX_SPI`

> This is the master component, enabling this activates all the other configuration options. It also causes `mcb2387_spi.c` to be compiled, which contains descriptions of the devices on the SPI buses.

`CYGPKG_HAL_ARM_LPC2XXX_SPIX`

> This is the master component for each bus. Enabling this activates the other configuration options for this bus, and causes the driver to support this bus.

`CYGPKG_HAL_ARM_LPC2XXX_SPIX_SCLK`

> This option describes the pin used for SCLK on SPIX. It takes the form of an invocation of __LPC2XXX_PINSEL_FUNC. The parameters are the port number, pin within that port, and the alternate select function for the pin. See the LPC2387 user manual for details."

`CYGPKG_HAL_ARM_LPC2XXX_SPIX_MISO`

> This option describes the pin used for MISO on SPIX. Like SCLK it takes the form of a call to __LPC2XXX_PINSEL_FUNC.

`CYGPKG_HAL_ARM_LPC2XXX_SPIX_MOSI`

> This option describes the pin used for MOSI on SPIX. Like SCLK it takes the form of a call to __LPC2XXX_PINSEL_FUNC.

CYGPKG_HAL_ARM_LPC2XXX_SPIX_CS_PINS

> This defines the pins to be uses as chip selects for this bus. It is a comma separated list of GPIO pin names, the first for device 0, the second for device 1, and so on. Pin names are defined in the `var_io.h` header in the LPC2xxx variant HAL.

Note that "SPIX" is a placeholder for a given bus instance: "SPI0" or "SPI1". By default the platform HAL does not enable any SPI busses since there are on on-chip devices.

MCI peripheral configuration

The on-chip Multimedia Card Interface (MCI) is supported to allow access to Multimedia Cards (MMC) or Secure Digital (SD) cards using the socket on the board. This support is provided in conjunction with the generic MMC/SD driver package (`CYGPKG_DEVS_DISK_MMC`), the Primecell MCI driver package (`CYGPKG_DEVS_MMCSD_ARM_PRIMECELL_MCI`) and the LPC2xxx variant HAL in order to provide some elements of the DMA support. Documentation and configuration options within those packages should also be consulted.

The following CDL configuration options are used to control the behaviour of the MMC/SD card support:

MMC/SD card support (`CYGPKG_HAL_ARM_LPC2XXX_MCB2387_MCI`)

> This option allows the MMC/SD card support as a whole to be enabled or disabled, although the generic disk device driver package (`CYGPKG_IO_DISK`) must be loaded in order to enable the MMC/SD support.

Use on-chip USB memory for DMA (`CYGSEM_HAL_ARM_LPC2XXX_MCB2387_MCI_USE_USB_MEM_FOR_DMA`

> The LPC2387 cannot always keep up with the data transfer requirements, especially at slower CPU clock speeds. This is because the DMA controller runs at the speed of the CPU clock (CCLK) along with the fact that some LPC2387 have errata which decreases their achievable CPU clock frequency.
>
> Using on-chip memory dedicated to USB helps reduce or remove these problems, depending on CPU frequency. Clearly this option must be disabled if the on-chip USB peripheral is to be used. It is also desirable to disable this option if the CPU frequency is high enough, in order to remove an extra copy on every data transfer, thus improving performance. The USB memory used is 512 bytes at the start of the USB memory space (0x7FD00000).
>
> If this option is disabled and the DMA is not able to proceed quickly enough, this will be visible in the form of I/O errors. In that case, if it is not possible to enable this option it is recommended to adjust the `CYGDAT_HAL_ARM_LPC2XXX_MCB2387_MCI_BUS_SPEED_LIMIT` configuration option.

Lock AHB bus during DMA transfer (`CYGSEM_HAL_ARM_LPC2XXX_MCB2387_MCI_DMA_LOCKS_AHB`)

> The AMBA Hardware Bus (AHB) is used to connect AMBA peripherals within the LPC2387, including the ARM core, DMA controller and memory controllers. When this option is enabled, the AHB is locked for the duration of MCI DMA transfer bursts. If another AMBA host needs to make a transfer it may be delayed as a result, which may not be desirable.
>
> Disabling this option allows the AHB arbiter to permit other AHB hosts to perform transfers. Of course this may mean the MCI DMA transfers can in turn themselves get delayed, risking data overruns or underruns in MCI transfers, resulting in I/O errors during block reads or writes. This is particularly likely on processors running at slower clock speeds where there may already be difficulties with the DMA servicing data transfers quickly enough.

MMC/SD bus frequency limit (`CYGNUM_HAL_ARM_LPC2XXX_MCB2387_MCI_BUS_SPEED_LIMIT`)

> The LPC2387 cannot always keep up with the data transfer requirements, especially at slower CPU clock speeds. This is because the DMA controller runs at the speed of the CPU clock (CCLK) along with the fact that some LPC2387 have errata which decreases their achievable CPU clock frequency. The adjacent options to use on-chip USB memory and to lock the AHB bus can help prevent this, but sometimes they are insufficient to prevent data overruns or underruns resulting in I/O errors

during block reads or writes. In which case the only remaining recourse is to reduce the required data transfer rate between the MCI and the card.

This option can be used to impose an upper limit on the MMC/SD bus frequency. The value used in this option is measured in Hertz, and the use of 4-bit mode with SD cards is not a factor - this option provides the bus frequency, so a 4-bit bus will transfer four times the amount of data as a 1-bit bus in the same time period.

Note that this option provides a limit, and does not mean the card bus will operate at that frequency. The frequency is also governed by what the card will support, and the resolution of the clock used to derive the MMC/SD clock signal, and how it can be divided down.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

However there are two flags that are used if Thumb mode is to be supported:

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the MCB2387 board hardware, and should be read in conjunction with that specification. The LPC2387 platform HAL package complements the ARM architectural HAL and the LPC2xxx variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor to do most of this and for JTAG startup, where some initialization will be done by the JTAG device.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including PLL (for the clocks); Memory Mapping control registers to map SRAM to 0x0 and the Memory Acceleration Module (MAM). The details of the early hardware startup may be found in the header `cyg/hal/hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

on-chip Flash

This is located at address 0x0 of the memory space, although after hardware initialization, the start of internal SRAM is mapped over locations 0x0 to 0x40. This region ends at 0x80000. The MAM is enabled to accelerate memory reads from this area. A driver is available for using this flash via the eCos flash API.

internal SRAM

This is located at address 0x40000000 of the memory space, ending at location 0x4000FFFF. The first 64 bytes are mapped to location 0x0000000.

on-chip peripherals

These are accessible via location 0xE0000000 onwards. Descriptions of the contents can be found in the LPC2387 User Manual.

Chapter 247. Phytec phyCORE LPC2294 Board Support

Name

eCos Support for the Phytec phyCORE LPC2294 Board — Overview

Description

The Phytec phyCORE LPC2294 Board is fitted with a Philips LPC2294 processor rated to 60MHz, which contains up to 64KB of SRAM and up to 256KB of FLASH. When used in conjunction with the phyCORE HD200 development board, it provides two 9-pin RS-232 serial interfaces connected to the LPC2294 on-chip UARTs, a single LED, two CAN interfaces and an SMSC LAN91C111 ethernet interface. Refer to the board documentation for full details.

For typical eCos development, a RedBoot image is programmed into the LPC2294 on-chip flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART 0 or via the ethernet.

This documentation describes platform-specific elements of the phyCORE LPC2294 Board support within eCos. Documentation on the Philips LPC2xxx variants is available separately, and should be read in conjunction with this documentation. The LPC2xxx documentation covers various topics including HAL support common to LPC2xxx variants, and on-chip device support. This document complements the LPC2xxx documentation.

Supported Hardware

The phyCORE LPC2294 Board has 128Kbyte of on-chip Flash memory. In a typical setup, RedBoot will load and run from this internal flash. An initial image must be programmed into this flash using either the FlashMagic utility, or via a JTAG debugger. Following this, it may be reprogrammed using flash drivers in RedBoot.

The first 64 bytes of on-chip SRAM are mapped by the HAL startup code using the LPC2294 memory mapping control to location 0x00000000 for speed of interrupt vector processing. The rest of SRAM is available for use by the application. One MByte of SRAM is available at 0x81000000; the first 64KBytes of this is reserved for use by RedBoot, the rest is available for the code and data of loaded applications.

The Philips LPC2xxx variant HAL includes support for the two on-chip serial devices and is documented in the variant HAL. The interrupt-driven serial driver supports the line status and modem control (including hardware handshaking) lines on UART1 only. These handshaking lines are not accessible at the DB9 connector (P1B).

The phyCORE LPC2294 Board port includes support for the on-chip watchdog, RTC (wallclock), and interrupt controller (VIC). This support is documented in the LPC2xxx variant HAL.

The SMSC LAN91C111 ethernet MAC is supported. However, due to PCB tracking problems, it is only capable of running at 10MBit/s and the driver forces the device to only operate at that speed.

Tools

The phyCORE LPC2294 Board port is intended to work with GNU tools configured for an arm-eabi target. Thumb mode is supported. The original port was done using arm-elf-gcc version 3.3.3, arm-elf-gdb version 6.1, and binutils version 2.14.

Name

Setup — Preparing the phyCORE LPC2294 Board for eCos Development

Overview

In a typical development environment, the phyCORE LPC2294 Board boots from internal flash into RedBoot. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable stubrom image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.hex`
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.srec`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and rebuilding the stubrom.

Initial Installation

Flash Installation

This process assumes that a Microsoft Windows machine with the Embedded Systems Academy Flash Magic utility is available.

Install Flash Magic from http://www.flashmagictool.com.

Connect the RS232 cable supplied with the phyCORE LPC2294 between port 0 of the phyCORE LPC2294 and the host PC. Apply power to the board and with the Boot button (S_1) held down, press and release the reset button (S_2). The board is now running a special NXP boot loader. Start Flash Magic and set the Communications section to select the appropraite serial port, 38400 baud, device LPC2294, Interface “None (ISP)” and 12MHz Oscillator Frequency. Test communication with the board by using the “ISP->Read Device Signature” menu entry. If communication is not successful, check that the serial cable is connected correctly, that the board was booted with the Boot button (S_1) held down and that the correct communication parameters have been selected in Flash Magic.

Check “Erase blocks used by Hex File” under “Erase”. In the “Hex File” section, select the `redboot_ROM.hex` file. Under “Options”, all boxes should be clear except “Verify after programming”. Now press the “Start” button. The utility should show the progress of the upload.

When the process completes, the utility should be closed. Verify that programming has been successful by starting a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Reset the board and RedBoot should start. The output should be similar to the following:

```
+... Read from 0x801e0000-0x801fffff to 0x810e0000:
... Read from 0x801ff000-0x801fffff to 0x810df000:
... waiting for BOOTP information
Ethernet eth0: MAC address 00:50:c2:32:ad:40
IP: 10.0.0.200/255.255.255.0, Gateway: 10.0.0.3

RAM: 0x81000000-0x81100000, [0x8100b1a8-0x810dd000] available
FLASH: 0x80000000 - 0x801fffff 16 x 0x20000 blocks
RedBoot>
```

If is it ever necessary to reinstall RedBoot, the above directions can be repeated. Alternatively, a new RedBoot may be installed from RedBoot itself. It is not possible to do this directly, since RedBoot is executing from the flash that needs to be erased and reprogrammed. Instead it is necessary to run a RAM version of RedBoot, use that to download the new ROM RedBoot to RAM, and then program that to flash.

The following shows an example session to do this. It assumes that `redboot_RAM.srec` and `redboot_ROM.bin` are available via TFTP on the server set up in **fconfig**.

```
RedBoot> load redboot_RAM.srec

Rebuilding RedBoot

Should it prove necessary to rebuild the RedBoot binary, this is done most conveniently at the command line. Assuming your `PATH` and `ECOS_REPOSITORY` environment variables have been set correctly, the steps needed to rebuild RedBoot are:

```
$ mkdir redboot_phycore_rom
$ cd redboot_phycore_rom
$ ecosconfig new phycore_lpc2294 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/lpc2xxx/phycore_lpc229x/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.hex`.

Note

The PhyCORE LPC2294 board can be fitted with a wide range of flash and SRAM parts. So it may be necessary to adjust the configuration after importing the `redboot_ROM.ecm` file to match the hardware being used. The Memory Configuration section contains full details of the options available for this.

Name

Configuration — Platform-specific Configuration Options

Overview

The phycore platform HAL package is loaded automatically when eCos is configured for an `phycore_lpc2294` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The phyCORE LPC229x platform HAL package supports two separate startup types:

RAM This is the startup type which is normally used during application development. The board has RedBoot programmed into flash at location 0x0 in internal on-chip Flash and boots from that location. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by the stubrom. By default the application will use the eCos virtual vectors mechanism to obtain certain services from the stubrom, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into internal flash at location 0x0. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, or as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port UART0 will be claimed for HAL diagnostics.

Flash Driver

The phyCORE LPC2294 board contains a number of AMD flash devices. The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2` package contains all the code necessary to support these parts and the `CYGPKG_DEVS_FLASH_ARM_PHYCORE` package contains definitions that customize the driver to the phyCORE LPC2294 board.

Ethernet Driver

The phyCORE-LPC229x board contains an SMSC LAN91C111 ethernet MAC. The `CYGPKG_DEVS_ETH_SMSC_LAN91CXX` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_ARM_PHYCORE` package contains definitions that customize the driver to the phyCORE LPC2294 board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The PLL multipliers and dividers may be configured to allow a core clock (CCLK) speed of up to 60MHz. The description of the clock-related CDL options may be found in the LPC2xxx variant HAL documentation.

Memory Configuration

The PhyCORE LPC2294 board can be fitted with a wide range of flash and SRAM parts. The following options adjust the configuration of eCos and RedBoot to accommodate these variations:

`CYGHWR_HAL_ARM_LPC2XXX_PHYCORE_MEMORY_CONFIGURATION_FLASH`

> This option describes the flash devices fitted to the board. Possible values are: AM29DL800BT, AM29LV800BT, AM29LV160BT and AM29LV320BT. Of these only the AM29DL800BT and AM29LV320BT variants have been tested.

`CYGHWR_HAL_ARM_LPC2XXX_PHYCORE_MEMORY_CONFIGURATION_FLASH_COUNT`

> This option defines the number of flash devices fitted. Flash devices can only be fitted in pairs, and there is only space for up to 4, so this value can only be 2 or 4.

`CYGHWR_HAL_ARM_LPC2XXX_PHYCORE_MEMORY_CONFIGURATION_SRAM_SIZE`

> This option defines the total SRAM size. The board can be fitted with two or four SRAM devices, of 512KB, 1MB or 2MB each, giving Possible possible SRAM sizes of: 0x100000, 0x200000, 0x400000 or 0x800000.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

However there are two flags that are used if Thumb mode is to be supported:

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the phyCORE LPC2294 Board hardware, and should be read in conjunction with that specification. The phyCORE LPC229x platform HAL package complements the ARM architectural HAL and the LPC2xxx variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. This includes the PINSEL functions and LED bank. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including PLL (for the clocks); Memory Mapping control registers to map SRAM to 0x0; the memory controller for access to external FLASH, SRAM and ethernet; and the Memory Acceleration Module (MAM). The details of the early hardware startup may be found in the header `cyg/hal/hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

on-chip Flash
: This is located at address 0x0 of the memory space, although after hardware initialization, the start of internal SRAM is mapped over locations 0x0 to 0x40. This region ends at 0x40000. The MAM is enabled to accelerate memory reads from this area. A driver is available for using this flash via the eCos flash API.

external Flash
: This is located at address 0x80000000 of the memory space. It is not used by default by eCos, although if RedBoot is asked to manage the Flash, it reserves flash addresses 0x801E0000 thru 0x801FF000. If RedBoot stores its configuration data in Flash, then addresses 0x801FF000 thru 0x801FFFFF are reserved by RedBoot. RedBoot also reserves the first block of Flash at 0x80000000 thru 0x80001FFFF to ensure that it remains erased and does not therefore inhibit the execution of RedBoot from the internal Flash. External flash is 32bits wide and accessed with 7 wait states.

internal SRAM
: This is located at address 0x40000000 of the memory space, ending at location 0x40004000. The first 64 bytes are mapped to location 0x0000000.

external SRAM
: This is located at address 0x81000000 of the memory space, ending at location 0x81100000. For RAM startup, available SRAM starts at location 0x81010000, with the bottom 64Kbytes reserved for use by RedBoot.

on-chip peripherals
: These are accessible via location 0xE0000000 onwards. Descriptions of the contents can be found in the LPC2294 User Manual.

Other Issues

The LEDs may be accessed from C with the following function:

```
#include <cyg/infra/hal_diag.h>
extern void hal_diag_led(int leds);
```

Values from 0 to 16 will be displayed on the LED bank representing the binary value with 1 being on and 0 being off, and with P0.7 being the MSB, and P0.4 the LSB.

The LEDs are also used during platform initialization and only P0.4 should be illuminated if booting has been successful. Other LED indications represent the stage in the initialization process that failed.

Chapter 248. ST STR7XX variant HAL

Name

eCos Support for the ST Microelectronics STR7XX ARM microcontrollers — Overview

Description

The ST STR7XX series of ARM microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for the on-chip flash, serial and watchdog devices. In addition it provides common functionality and definitions that STR7XX based platform ports may require, as well as definitions useful to application developers.

This documentation covers the STR7XX functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the STR7XX variant HAL provides. The areas that are specific to platform HALs and not the STR7XX variant HAL include:

- memory map and related configuration and setup
- memory remapping
- Clock parameters
- GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED/LCD control

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

On-chip memory

The ST STR7XX parts include on-chip SRAM, and on-chip FLASH. The RAM consists of a single 64KiB block. The FLASH comprises a block of program memory which is either 64KiB, 128KiB or 256KiB in size depending on model, plus a 16KiB area of higher durability data memory. There is also support in some models for external SRAM and flash, which eCos may use where available.

Typically, an eCos platform HAL port will expect a GDB stub ROM monitor or RedBoot image to be programmed into either the external FLASH or the STR7XX on-chip ROM memory for development, and the board would boot this image from reset. The stub ROM/RedBoot provides GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels. The JTAG interface may also be used for development if a suitable JTAG device is available. If RedBoot is present it may also be used to manage the on-chip and external flash memory. For production purposes, applications are programmed into the external or on-chip ROM and will be self-booting.

Serial I/O

The STR7XX variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_ARM_STR7XX` which provides all support for the STR7XX on-chip serial devices. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor or RedBoot for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

The STR7XX UARTs only provide the minimal TX and RX data lines; hardware flow control using RTS/CTS is not supported. The eCos device drivers have been extended to permit the use of a pair of GPIO lines as flow control lines. It is the responsibility of the platform HAL to enable this functionality and define the GPIO lines to be used in this way.

I^{2}C Support

The I²C® driver uses the STR7XX's internal support. This is controlled within the STR7XX variant HAL. The `CYGPKG_HAL_STR7XX_I2C` CDL component controls whether the I^{2}C driver is enabled. Within that component, there are two sub-options:

- `CYGNUM_HAL_STR7XX_I2C_BUS0_CLOCK` sets the speed of the I^{2}C bus 0 clock in Hz. This is usually 100kHz, but can be set up to 400kHz (fast mode) if the devices on the bus support this speed. Other values below 400kHz can also be chosen, subject to the accuracy of the clock waveform generation parameters.
- `CYGNUM_HAL_STR7XX_I2C_BUS1_CLOCK` sets the speed of the I^{2}C bus 1 clock in Hz. This is usually 100kHz, but can be set up to 400kHz (fast mode) if the devices on the bus support this speed. Other values below 400kHz can also be chosen, subject to the accuracy of the clock waveform generation parameters.

The I^{2}C driver is accessed via the generic I^{2}C driver package `CYGPKG_IO_I2C`. Documentation for its API may be found elsewhere.

This driver only operates in interrupt mode. It does not operate in polled mode, and thus does not operate when interrupts are disabled. It cannot therefore be used in an initialization context, before the eCos kernel thread scheduler starts, and it cannot be used with RedBoot.

Watchdog

A device driver is included for the on-chip watchdog device. This driver allows the use of the standard eCos watchdog API accessible with the `CYGPKG_IO_WATCHDOG` eCos package. If the watchdog is not reset within a time period defined in the watchdog device driver CDL, then the system is automatically reset.

The watchdog device is also used to implement reset functionality, it may also be called directly by applications using the following function:

```
#include <cyg/hal/hal_diag.h>
extern void hal_str7xx_reset_cpu(void);
```

Interrupt controller

eCos manages the on-chip Enhanced Interrupt Controller (EIC). The EIC is configured to use interrupts in non-vectored mode, although the vector mechanism is used to aid interrupt source decoding. External interrupts controlled by the XTI unit are also decoded into individual vectors.

Timer 0 is used to implement the eCos system clock. Timer-based profiling support is implemented using timer 1. If the gprof package, `CYGPKG_PROFILE_GPROF`, is included in the configuration, then timer 1 is reserved for use by the profiler. Timers 2 and 3 are free for use by applications.

Other

Other on-chip devices (SPI, USB, CAN, HDLC etc.) are not touched by the STR7XX variant HAL and unless used by the platform HAL are free for use for applications.

Name

HAL Port — Implementation Details

Overview

This section covers any remaining items of note related to the STR7xx variant support, not covered in previous sections.

LEDs

If a platform port has support for the display of values on LEDs, that support is standardised to be accessible from C with the following function:

```
#include <cyg/infra/hal_diag.h>
extern void hal_diag_led(int leds);
```

Clock Control

The platform HAL must provide the input clock frequency (`CYGARC_HAL_STR7XX_INPUT_CLOCK`) in its CDL file.

STR7XX definitions

The STR7XX variant HAL port includes the header file `var_io.h` which provides useful register definitions used by eCos, that can also be freely used by applications. It includes only limited register definitions for subsystems unused by eCos.

It may be found in the `include/cyg/hal` directory relative to your configuration's install tree, or alternatively in the source repository at `hal/arm/str7xx/var/`*`VERSION`*`/include/var_io.h`. However it should be properly included by applications by using the following to allow for platform HALs to augment or override any relevant definitions:

```
#include <cyg/hal/hal_io.h>
```

Power Control

The kernel idle thread is scheduled to run when the system has no other tasks able to run. The idle thread can call a HAL supplied macro to place the chip into an appropriate power saving mode instead of just going around a busy loop. The STR7XX variant HAL defines the `HAL_IDLE_THREAD_ACTION` macro to use the STR7XX power control support to place the chip into `WFI` mode which will stop the processor clock, without disabling the on-chip peripherals. This state continues until an interrupt is received.

Further power saving can be achieved by reducing the system clock frequencies using `hal_str7xx_clocks_setup()` described above. This function only changes the clock frequencies; it may also be necessary to change the values of dividers in various peripherals to compensate. There are several routines supplied in the HAL to do this.

Calling `hal_str7xx_uart_reinit()` will cause all the UART baud rate dividers to be reset to match the current value of PCLK1. Note that there are limitations to the range of baud rates that can be set, PCLK1 must be at least 16 times the required rate. Also, the resolution of the baud rate divider may make certain baud rates less accurate at different PCLK1 frequencies.

Calling `hal_str7xx_watchdog_init(CYGNUM_DEVS_WATCHDOG_ARM_STR7XX_DESIRED_TIMEOUT_US)` will cause the watchdog to be reinitialized with a timeout based on the current value of PCLK2. The resolution of the prescaler and the size of the 16 bit counter may render certain watchdog timeouts unachievable at some clock rates.

Calling `HAL_CLOCK_INITIALIZE(CYGNUM_HAL_RTC_PERIOD)` will cause the main system timer to be reinitialized based on the current value of PCLK2.

Description

The STR7XX variant HAL provides support for managing the power consumption of the device. This consists of a collection of functions that may be used to adjust clock frequencies, system modes and other aspects of the device. These routines mainly comprise a "kit of parts" from which applications may construct their own power management policy. The reader is referred to the STR7XX hardware documentation for full details of clock and power management.

The main function is `hal_str7xx_clocks_setup(index)` which controls the frequencies of the main clocks: MCLK, which supplies the CPU and memories; PCLK1, which supplies APB1 including the I^{2}C, SPI and UARTs; and PCLK2, which supplies APB2 including IO ports, Timers, RTC etc. The single argument to this function is an index into a table of hal_str7xx_clock_params structures, which is defined by the platform HAL. Each entry in the table has the following structure:

```
typedef struct
{
    char        *name;                  // Name string
    cyg_uint8   clk2_divider;           // 1, 2
    cyg_uint8   pll1_multiplier;        // 12, 16, 20, 24
    cyg_uint8   pll1_divider;           // 1..7
    cyg_uint8   rclk_select;            // RCLK_SELECT_* below
    cyg_uint8   mclk_divider;           // 1, 2, 4, 8
    cyg_uint8   pclk1_divider;          // 1, 2, 4, 8
    cyg_uint8   pclk2_divider;          // 1, 2, 4, 8
} hal_str7xx_clock_params;

#define RCLK_SELECT_CLK2        0
#define RCLK_SELECT_CLK2_16     1
#define RCLK_SELECT_PLL1        2
#define RCLK_SELECT_AF          3

__externC cyg_uint32 hal_str7xx_clock_param_index;
```

Each entry in the table corresponds to a single configuration of the clock hardware. Some care must be taken in specifying these entries, the resulting clocks will depend on the system input clock and the various multipliers and dividers; many configurations will result in out of range or otherwise illegal clock frequencies. See the manuals for the STR7XX variant and the platform for details.

It is recommended that the *clk2_divider* field is always set to 2. This causes the ocillator input to be divided by 2 and provides a more stable input to the rest of the clock circuity. Also, some registers in the RCCU are only accessible if MCLK is equal to RCLK, so the *mclk_divider* field should always be 1. These restrictions may be relaxed in special circumstances.

The last entry in this table should be all zeros, to mark the end of the table. A typical table would appear as follows:

```
const hal_str7xx_clock_params hal_str7xx_clock_param_table[] =
{
    // name               clk/  pll1* pll1/ rclk source          mclk/ pclk1/ pclk2/
    {  "32KHz"          ,   2,     0,    0, RCLK_SELECT_AF     ,    1,     1,     1 },
    {  "500KHz"         ,   2,     0,    0, RCLK_SELECT_CLK2_16,    1,     1,     1 },
    {  "8MHz"           ,   2,     0,    0, RCLK_SELECT_CLK2   ,    1,     1,     1 },
    {  "24/6/3MHz"      ,   2,    12,    4, RCLK_SELECT_PLL1   ,    1,     4,     8 },
    {  "32/32MHz"       ,   2,    16,    4, RCLK_SELECT_PLL1   ,    1,     1,     1 },
    {  "40/10/5MHz"     ,   2,    20,    4, RCLK_SELECT_PLL1   ,    1,     4,     8 },
    {  "40/40MHz"       ,   2,    20,    4, RCLK_SELECT_PLL1   ,    1,     1,     1 },
    {  "48/12/6MHz"     ,   2,    12,    2, RCLK_SELECT_PLL1   ,    1,     4,     8 },
    {  "48/24/12MHz"    ,   2,    12,    2, RCLK_SELECT_PLL1   ,    1,     2,     4 },

    {  0                ,   0,     0,    0,                   0,    0,     0,     0 }
};

cyg_uint32 hal_str7xx_clock_param_index = 5;
```

The naming convention used above is that a single frequency implies that all 3 clocks (MCLK, PCLK1 and PCLK2) are set to the same value. Two frequencies mean that MCLK is set to the first and both PCLK1 and PCLK2 are set to the second. Three frequencies show the values for MCLK/PCLK1/PCLK2 in order.

The variable `hal_str7xx_clock_param_index` indicates the table entry of the parameter set that is currently set. This should be initialized by the platform HAL to the index of the default parameter set, which will be used during initialization. `hal_str7xx_clocks_setup()` also sets a number of other global variables with the clock rates resulting from the parameter set in use:

```
__externC cyg_uint32 hal_str7xx_pclk1;          // PCLK1 frequency in Hz
__externC cyg_uint32 hal_str7xx_pclk2;          // PCLK2 frequency in Hz
__externC cyg_uint32 hal_str7xx_mclk;           // MCLK  frequency in Hz
```

Functions to initialize baud rate generators or prescaler dividers for various devices are also present:

`hal_str7xx_uart_setbaud(uart, baud)` sets the baud rate generator of the given UART to the given baud rate, based on the current value of PCLK1. UARTs are numbered 0 to 3, corresponding to the UARTs available on the device and baud rate is given in Hz. `hal_str7xx_uart_reinit()` causes all UARTs baud rate generators to be reinitialized using the last baud rate setting and the current PCLK1 value. It is usually called after changing the system clocks.

`hal_str7xx_i2c_init(bus, clock)` initializes the clock divider of the given I^2C bus to the given value based on the current value of PCLK1. The bus numbers are either 0 or 1, and the clock rate is given in Hz. `hal_str7xx_i2c_reinit()` causes all I^2C busses clock dividers to be reinitialized using the last clock rate setting and the current PCLK1 value.

`hal_str7xx_watchdog_init(timeout)` initializes the watchdog timeout based on the current PCLK2 setting. The timeout is given in microseconds. Some care is needed in setting this value since the resolution of the prescaler and the width of the 16 bit counter mean that certain timeouts may not be achievable at different PCLK2 frequencies.

`hal_str7xx_can_init(devno, clock)` initializes the clock divider of the given CAN device to the given baud rate based on the current PCLK1 setting. This function sets the entire Bit Timing Register, including the bit segment lengths and the synchronization jump width as well as the clock divider. While this interface is designed to support multiple CAN devices, the current implementation only supports a single CAN bus. The return value from this function indicates whether the requested clock frequency can be supported: zero if it is, -1 if not. `hal_str7xx_can_reinit()` causes the bit timings for all CAN busses to be reinitialized based on the current value of PCLK1.

`hal_str7xx_adc_init( rate )` initializes the prescaler for the ADC device based on the current PCLK2 setting. The rate argument gives the sample rate for each channel in samples per second. All channels share the same sample rate and are sampled on a round-robin basis. Therefore the combined sample rate, and hence maximum interrupt rate, will be four times this frequency. `hal_str7xx_adc_reinit()` causes the rate to be reinitialized based on the current value of PCLK2.

`hal_str7xx_mode_stop()` puts the STR7XX into STOP mode. Aside from entering STOP mode, all this routine does is set the WKUP-INT bit in the XTI CTRL register so that any of the external interrupt lines may be used to restart the system from STOP. However, it does not configure or unmask these lines. Instead, they may be unmasked and configured using the standard interrupt control API (`cyg_interrupt_unmask()`, `cyg_interrupt_configure()` etc.) It is also possible to configure the RTC to wake the STR7XX from STOP mode. The value returned from this function indicates whether STOP mode was entered: `true` if it was, `false` if not. It is usually adequate to just retry in the case of failed entry.

`hal_str7xx_mode_standby()` puts the STR7XX into STANDBY mode. As with entering STOP mode, it is the responsibility of the caller to configure the external interrupt lines and RTC to bring the system out of STANDBY mode. Exit from STANDBY mode causes the STR7XX to reboot, so if this function returns, then an error has occurred during entry to STANDBY. It is usually adequate to just retry in this case.

Note

At the time of writing, it has not been possible, at least on the STR710-EVAL board, to test RTC wakeup from STANDBY mode. It is believed that this is due to a silicon bug in the version of the STR710 present on the board.

`hal_str7xx_startup_mode()` returns the reason for the last restart. It indicates whether the restart was as a result of one of the following events:

- `STARTUP_MODE_RESET`: Standard power-on reset.
- `STARTUP_MODE_WAKEUP`: External WAKEUP event.
- `STARTUP_MODE_LOW_VOLTAGE`: Low voltage detected.
- `STARTUP_MODE_RTC_ALARM`: RTC alarm.
- `STARTUP_MODE_WATCHDOG`: Watchdog expiry.
- `STARTUP_MODE_SOFTWARE`: Software reset.

`hal_str7xx_set_clock_speed(index)` is a wrapper function that reprograms all the clocks and baud rate generators. The argument is the same index into the platform HAL supplied parameter table as given to `hal_str7xx_clocks_setup()`. After calling that function it also calls `hal_str7xx_uart_reinit()`, `hal_str7xx_i2c_reinit()`, `hal_str7xx_can_reinit()`, `HAL_CLOCK_INITIALIZE()` and `hal_str7xx_watchdog_init()`. Unlike `hal_str7xx_clocks_setup()`, this function checks that the supplied index is valid, and returns `false` if it is not.

`hal_str7xx_get_clock_speed()` returns the parameter table index given to the last call to `hal_str7xx_clocks_setup()` or `hal_str7xx_set_clock_speed()`.

The HAL also contains functions to control the Real Time Clock, RTC. These are mainly oriented towards using the RTC to resume the system from STOP or STANDBY mode. Before making any other calls to the RTC routines, the application must call `hal_str7xx_rtc_init()` to initialize the device. Calling `hal_str7xx_rtc_alarm_set(secs)` sets the alarm to fire after the given number of seconds. After the alarm had fired, or to prevent it firing, call `hal_str7xx_rtc_alarm_cancel()`. Calling `hal_str7xx_rtc_counter()` returns the current value of the RTC counter, which counts seconds. Function `hal_str7xx_rtc_counter_set( secs )` sets the RTC counter to the given value. These last two function may be used by a wallclock driver to provide time and date functionality.

RedBoot Support

The STR7XX HAL installs a number of RedBoot commands to allow testing of the power management support.

speed [-l] [index]

This command reports and sets the clock speed of the STR7XX. Giving the command on its own, with no arguments, lists the available speed settings:

```
RedBoot> speed
   0        32KHz
   1       500KHz
   2         8MHz
   3    24/6/3MHz
   4   40/10/5MHz
*  5   48/12/6MHz
   6  48/24/12MHz
RedBoot>
```

The index numbers on the left are used as arguments to the **speed** command. The names on the right correspond to the clock parameter set names described before. The parameter set currently in force is indicated by an asterisk in the first column. If the `-l` option is given, then more details of the parameter sets are given, together with the current settings of MCLK, PCLK1 and PCLK2:

```
RedBoot> speed -l
MCLK: 48000000, PCLK1 12000000, PCLK2 6000000
C Ix         Name CLK/ PLL1* PLL1/    RCLK MCLK/ PCLK1/ PCLK2/
   0        32KHz   2     0     0       AF   1     1      1
   1       500KHz   2     0     0  CLK2/16   1     1      1
   2         8MHz   2     0     0     CLK2   1     1      1
   3    24/6/3MHz   2    12     4     PLL1   1     4      8
   4   40/10/5MHz   2    20     4     PLL1   1     4      8
*  5   48/12/6MHz   2    12     2     PLL1   1     4      8
   6  48/24/12MHz   2    24     2     PLL1   2     4      8
RedBoot>
```

Supplying the **speed** command with the index number of a parameter set will change the STR7XX to use that set of clock parameters:

```
RedBoot> speed 3
Set clock speed 3, please wait...
Now running at new speed
RedBoot> speed -l
MCLK: 32000000, PCLK1 32000000, PCLK2 32000000
C Ix         Name CLK/ PLL1* PLL1/    RCLK MCLK/ PCLK1/ PCLK2/
```

```
   0        32KHz   2     0     0        AF   1     1      1
   1       500KHz   2     0     0  CLK2/16   1     1      1
   2         8MHz   2     0     0     CLK2   1     1      1
   3    24/6/3MHz   2    12     4     PLL1   1     4      8
*  4     32/32MHz   2    16     4     PLL1   1     1      1
   5   40/10/5MHz   2    20     4     PLL1   1     4      8
   6     40/40MHz   2    20     4     PLL1   1     1      1
   7   48/12/6MHz   2    12     2     PLL1   1     4      8
   8  48/24/12MHz   2    12     2     PLL1   1     2      4
RedBoot>
```

Note that setting too low a speed may result in RedBoot not being able to program the serial baud rate generator to maintain the current speed.

stop

The **stop** command puts the STR7XX into STOP mode. The RTC will be programmed to wake the system up after 5 seconds. The device may also be woken up before that timeout using the WAKEUP line, if it is connected to a switch (as it is on the STR710-EVAL board).

standby

The **standby** command puts the STR7XX into STANDBY mode. The RTC will be programmed to wake the system up after 5 seconds. The device may also be woken up before that timeout using the WAKEUP line, if it is connected to a switch (as it is on the STR710-EVAL board).

Chapter 249. ST STR710-EVAL Board HAL

Name

eCos Support for the ST STR710-EVAL Board — Overview

Description

The ST STR710-EVAL Board is fitted with an STR710FZ2T6 microcontroller to provide a development environment for all STR71X microcontrollers. The board is fitted with 4MiB of external RAM and 4MiB of external FLASH memory. The board has two 9-pin RS-232 serial interfaces connected to two of the STR710 on-chip UARTs, LEDs, and LCD display, and a JTAG debug interface. Refer to the board documentation and the STR7XX documentation for full details.

For typical eCos development, a RedBoot image is programmed into the external FLASH and the switches set so that the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using either UART0 or UART1.

This documentation describes platform-specific elements of the STR710-EVAL Board support within eCos. The STR7XX documentation covers various topics including HAL support common to STR7XX variants, and on-chip device support. This document complements the STR7XX documentation.

Supported Hardware

The STR7XX has two on-chip memory regions. A RAM region of 64KiB is present at 0x20000000, which is mapped to 0x00000000 after booting. A FLASH region is present at 0x40000000 and is comprised of 64KiB, 128KiB or 256KiB of program memory plus 16KiB of higher durability data flash. The STR710FZ2T6 on the STR710-EVAL board is equipped with 256KiB.

On-board memory consists of 4MiB of SRAM mapped to 0x62000000 and 4MiB of FLASH mapped to 0x60000000. During booting the external flash is mapped to 0x00000000 but will be replaced with the internal flash for normal execution.

The STR7XX variant HAL includes support for the four on-chip serial devices which are documented in the variant HAL. Only two of these serial devices are connected to external connectors on the board, so only these are normally usable.

The STR710-EVAL board port includes support for the on-chip watchdog and interrupt controller. This support is documented in the STR7XX variant HAL.

Tools

The STR710-EVAL Board port is intended to work with GNU tools configured for an arm-eabi target. Thumb mode is supported. The original port was done using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.16.

Name

Setup — Preparing the STR710-EVAL Board for eCos Development

Overview

In a typical development environment, the STR710-EVAL board boots from external flash into RedBoot. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from external FLASH	`redboot_ROM.ecm`	`redboot_ROM.bin`
ROM_INT	RedBoot running from internal FLASH	`redboot_ROM_INT.ecm`	`redboot_ROM_INT.bin`
ROM_INT_EXTRAM	RedBoot running from internal FLASH, using external RAM for DATA, BSS and heap	`redboot_ROM_INT_EXTRAM.ecm`	`redboot_ROM_INT_EXTRAM.bin`
RAM	RedBoot running from external RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
JTAG	RedBoot running from external RAM, loaded via JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This baud rate can be changed via the configuration option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and rebuilding the stubrom.

Under normal circumstances, RedBoot runs in-place from the external Flash. The RAM version is provided to allow for updating the resident RedBoot image in Flash. The JTAG version is only used if loading RedBoot into RAM via a JTAG debugger or ICE. It is similar to the RAM version, but loads at a lower address within RAM, and so can be used to load eCos applications, as if it is the normal resident boot monitor. The ELF format image of this JTAG version of RedBoot can also be loaded and executed from GDB using the Abatron BDI2000 bdiGDB support, to allow it to be debugged. The ROM_INT version does not contain support for the flash filesystem or flash config since it uses only internal RAM, which is not large enough for the necessary data structures. The ROM_INT_EXTRAM version uses external RAM instead of internal RAM and is therefore able to contain a full implementation of the flash filesystem and configuration.

Initial Installation

Two mechanisms are described below to program RedBoot into the external Flash. Both of them require a JTAG device. In the following documentation it is assumed that the Abatron BDI2000 is being used. For a different JTAG device, equivalent operations will need to be performed.

Preparing the Abatron BDI2000 JTAG debugger

The BDI2000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.
2. Connect the Abatron BDI2000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI2000.

3. Install the Abatron BDI2000 bdiGDB support software on the host PC.

4. Locate the file `bdi2000.str710eval.cfg` within the eCos platform HAL package in the source repository. This will be in the directory packages/hal/arm/str710eval/*VERSION*/misc relative to the root of your eCos installation.

5. Place the bdi2000.str710eval.cfg file in a location on the PC accessible to the TFTP server. Later you will configure the BDI2000 to load this file via TFTP as its configuration file.

6. Install and configure the Abatron BDI2000 in line with the bdiGDB instruction manual. Configure the BDI2000 to use the `bdi2000.str710eval.cfg` configuration file at the appropriate point of this process.

Preparing the STR710-EVAL board for programming

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to the BDI2000 using a 20-pin ARM/Xscale cable from the JTAG interface connector to the Target A port on the BDI2000.

4. Locate switches SW13, SW14 and SW15 on the board, they are in a bank of 3 next to the processor. Set all these switches to the 2-3 position, this is the position away from the processor. In due course this will ensure that the board boots RedBoot from the external Flash device.

5. Power up the STR710-EVAL board.

6. Connect to the BDI2000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

   ```
   Core#0>
   ```

7. Confirm correct connection with the BDI2000 with the **reset** command as follows:

   ```
   Core#0> reset
   - TARGET: processing reset request
   - TARGET: BDI asserts TRST and RESET
   - TARGET: BDI removes TRST
   - TARGET: Bypass check 0x00000001 => 0xFFFFFFFF
   - TARGET: JTAG exists check failed
   - TARGET: Remove RESET and try again
   - TARGET: BDI waits for RESET inactive
   - TARGET: Bypass check 0x00000001 => 0x00000001
   - TARGET: JTAG exists check passed
   - Core#0: ID code is 0x3F0F0F0F
   - TARGET: All ICEBreaker access checks passed
   - TARGET: BDI removes RESET
   - TARGET: BDI waits for RESET inactive
   - TARGET: resetting target passed
   - TARGET: processing target startup ....
   - TARGET: processing target startup passed
   Core#0>
   ```

8. Locate the `redboot_ROM.bin` image within the `loaders` subdirectory of the base of the eCos installation.

9. Copy the `redboot_ROM.bin` file into a location on the host computer accessible to its TFTP server.

Method 1 - Using the BDI2000 to directly program RedBoot into Flash

As previously mentioned, there are two methods of programming a RedBoot image into the parallel NOR Flash. This method uses the built-in capabilities of the BDI2000.

This is a three stage process. The relevant Flash blocks must first be unlocked, then erased, and finally programmed. This can be accomplished with the following steps:

1. Connect to the BDI2000 telnet port as before.

2. Cut and paste the following commands into the BDI2000 telnet session. They are used to unlock the relevant Flash blocks that will contain RedBoot.

```
Core#0>unlock 0x60000000 0x2000 8
Unlocking flash at 0x60000000
Unlocking flash at 0x60002000
Unlocking flash at 0x60004000
Unlocking flash at 0x60006000
Unlocking flash at 0x60008000
Unlocking flash at 0x6000a000
Unlocking flash at 0x6000c000
Unlocking flash at 0x6000e000
Unlocking flash passed
Core#0>unlock 0x60010000 0x10000 2
Unlocking flash at 0x60010000
Unlocking flash at 0x60020000
Unlocking flash passed
```

3. Erase the 8 initial 8Kbyte sized Flash blocks, and the following 2 64Kbyte Flash blocks with the following command (the blocks to erase are defined in the .cfg file):

```
Core#0>erase
Erasing flash at 0x60000000
Erasing flash at 0x60002000
Erasing flash at 0x60004000
Erasing flash at 0x60006000Information System (FIS):
Erasing flash at 0x60008000
Erasing flash at 0x6000a000
Erasing flash at 0x6000c000
Erasing flash at 0x6000e000
Erasing flash at 0x60010000
Erasing flash at 0x60020000
Erasing flash passed
Core#0>
```

4. Program the RedBoot image into Flash with the following command, replacing *`/RBPATH`* with the location of the redboot_ROM.bin file relative to the TFTP server root directory:

```
Core#0>prog 0x60000000 /RBPATH/redboot_ROM.bin bin
Programming /RBPATH/redboot_ROM.bin , please wait ....
Programming flash passed
Core#0>
```

   This operation can take some time.

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. The RedBoot banner should be visible on the serial port. RedBoot's Flash configuration can be initialized using the same procedure as required in Method 2 below.

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Method 2 - Program RedBoot into External Flash with RAM RedBoot

With this approach, the BDI2000 is used to load a RedBoot image into RAM, which can then in turn be used to load and program a ROM RedBoot image into Flash.

There are three stages, firstly loading the RAM RedBoot image, then initializing RedBoot's Flash configuration, and finally loading and programming the ROM RedBoot.

Loading a RAM RedBoot

1. Locate the `redboot_JTAG.bin` image within the `loaders` subdirectory of the base of the eCos installation.

2. Copy the `redboot_JTAG.bin` file into a location on the host computer accessible to its TFTP server.

3. With the BDI2000 telnet interface, execute the following command, replacing */RBPATH* with the location of the redboot_JTAG.bin file relative to the TFTP server root directory:

```
Core#0>load 0x62000000 /RBPATH/redboot_JTAG.bin bin
Loading /RBPATH/redboot_JTAG.bin , please wait ....
Loading program file passed
Core#0>
```

4. Run the loaded RAM RedBoot:

```
Core#0>go 0x62000000
Core#0>
```

The terminal emulator connected to the serial debug port should now have displayed the RedBoot banner and prompt similar to the following:

```
+RedBoot(tm) bootstrap and debug environment [JTAG]
Non-certified release, version UNKNOWN - built 17:29:34, Apr 10 2006

Platform: ST STR710-EVAL Board (ARM7TDMI)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006 eCosCentric Limited

RAM: 0x62000000-0x62400000, [0x62019a20-0x623ed000] available
     0x00000000-0x00010000, [0x00000000-0x00010000] available
FLASH: 0x40000000-0x40c40000, 4 x 0x2000 blocks, 1 x 0x8000 blocks, 3 x 0x10000 blocks, 8 x 0x10000 blocks, 2 x 0x2000 blocks
FLASH: 0x60000000-0x603fffff, 8 x 0x2000 blocks, 63 x 0x10000 blocks
RedBoot>
```

Note

It is also possible to use the RAM startup version of RedBoot and the redboot_RAM.bin file instead of redboot_JTAG.bin above. If so, then the address to the **load** command must be 0x62020000, as must be the address to the **go** command.

RedBoot Flash Configuration

The following steps describe how to initialize RedBoot's Flash configuration. This must be performed when using a JTAG or RAM RedBoot to program Flash, but is also applicable to initial configuration of a ROM RedBoot loaded using Method 1.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Unlocking from 0x603f0000-0x603fffff: .
... Erase from 0x603f0000-0x603fffff: .
... Program from 0x623f0000-0x62400000 to 0x603f0000: .
... Locking from 0x603f0000-0x603fffff: .
RedBoot>
```

2. Now configure RedBoot's Flash configuration with the command:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Console baud rate: 38400
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlocking from 0x603f0000-0x603fffff: .
... Erase from 0x603f0000-0x603fffff: .
... Program from 0x623f0000-0x62400000 to 0x603f0000: .
... Locking from 0x603f0000-0x603fffff: .
RedBoot>
```

Loading and programming the ROM RedBoot

This section describes the steps required to load the ROM RedBoot via the serial line and program it into Flash.

1. Load the RedBoot ROM binary image from the serial line. Use the following command:

```
RedBoot> load -r -m y -b %{freememlo}
CRaw file loaded 0x62038c00-0x6204eacb, assumed entry at 0x62038c00
xyzModem - CRC mode, 704(SOH)/0(STX)/0(CAN) packets, 3 retries
RedBoot>
```

2. Finally install the loaded image into Flash:

```
RedBoot> fis create RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Unlocking from 0x60000000-0x6001ffff: .........
... Erase from 0x60000000-0x6001ffff: .........
... Program from 0x62038c00-0x6204eacc to 0x60000000: .........
... Locking from 0x60000000-0x6001ffff: .........
... Unlocking from 0x603f0000-0x603fffff: .
... Erase from 0x603f0000-0x603fffff: .
... Program from 0x623f0000-0x62400000 to 0x603f0000: .
... Locking from 0x603f0000-0x603fffff: .
RedBoot>
```

It is also possible to use the **fis write** command to write the image into Flash, but if so, the relevant Flash blocks must also be explicitly unlocked with the command:

```
RedBoot> fis unlock -f 0x60000000 -l 0x20000
```

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. Output similar to the following should be seen on the serial port.

```
+RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 10:22:53, Apr 10 2006

Platform: ST STR710-EVAL Board (ARM7TDMI)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006 eCosCentric Limited

RAM: 0x62000000-0x62400000, [0x62004910-0x623ed000] available
     0x00000000-0x00010000, [0x00000000-0x00010000] available
FLASH: 0x40000000-0x40c40000, 4 x 0x2000 blocks, 1 x 0x8000 blocks, 3 x 0x10000 blocks, 8 x 0x10000 blocks, 2 x 0x2000 blocks
FLASH: 0x60000000-0x603fffff, 8 x 0x2000 blocks, 63 x 0x10000 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Method 3 - Program RedBoot into Internal Flash with RAM RedBoot

This is a variant of Method 2, which puts RedBoot into the internal flash of the STR710, rather than the external M28W320CB flash device.

The first part of this is exactly the same as Method 2: load a RAM version of RedBoot as described in the Loading a RAM RedBoot section and configure is as described in the RedBoot Flash Configuration section. Now load the `redboot_ROM_INT.bin` binary image from the serial line as follows:

```
RedBoot> load -r -m y -b %{freememlo}
CRaw file loaded 0x6201a800-0x6202c733, assumed entry at 0x6201a800
xyzModem - CRC mode, 577(SOH)/0(STX)/0(CAN) packets, 4 retries
RedBoot>
```

Install the loaded image into Flash:

```
RedBoot> fis write -f 0x40000000 -b %{freememlo} -l 0x20000
* CAUTION * about to program FLASH
            at 0x40000000..0x4001ffff from 0x6201a800 - continue (y/n)? y
... Erase from 0x40000000-0x4001ffff: ......
... Program from 0x6201a800-0x6203a800 to 0x40000000: ......
RedBoot>
```

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. Output similar to the following should be seen on the serial port.

```
+
RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 18:41:12, Jun  1 2006

FLASH: 0x60000000-0x603fffff, 8 x 0x2000 blocks, 63 x 0x10000 blocks
RedBoot>
```

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot are:

```
$ mkdir redboot_str710eval_rom
$ cd redboot_str710eval_rom
$ ecosconfig new str710eval redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/str7xx/str710eval/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

The other versions of RedBoot - ROM, RAM or JTAG - may be similarly built by choosing the appropriate alternative .ecm file.

Name

Configuration — Platform-specific Configuration Options

Overview

The STR710-EVAL Board platform HAL package is loaded automatically when eCos is configured for an `str710eval` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The STR710-EVAL Board platform HAL package supports four separate startup types:

RAM

> This is the startup type which is normally used during application development. The board has RedBoot programmed into external Flash at location 0x60000000 and uses external RAM at location 0x62000000. arm-eabi-gdb is then used to load a RAM startup application into memory from 0x62020000 and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM

> This startup type can be used for finished applications which will be programmed into external ROM at location 0x60000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x20000000 region and map internal RAM to location zero. eCos startup code will perform all necessary hardware initialization.

ROM_INT

> This startup type can be used for finished applications which will be programmed into internal Flash at location 0x40000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x40000000 region and map internal RAM to location zero. eCos startup code will perform all necessary hardware initialization.
>
> This startup is enabled by setting the `CYGHWR_HAL_STR7XX_FLASH_INTERNAL` option, when `CYG_HAL_STARTUP` is set to ROM.

ROM_INT_EXTRAM

> This startup type can be used for finished applications which will be programmed into internal Flash at location 0x40000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. It will then transfer control to the 0x40000000 region and map internal RAM to location zero. eCos startup code will perform all necessary hardware initialization. The application will also use external RAM at 0x62000000 for its DATA, BSS and heap, rather than the internal SRAM.
>
> This startup is enabled by setting the `CYGHWR_HAL_STR7XX_FLASH_INTERNAL` option, when `CYG_HAL_STARTUP` is set to ROM and additionally setting `CYGHWR_HAL_ARM_STR710EVAL_EXT_RAM`.

JTAG

> This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x62000000 and entered at that address. It will then map internal RAM to location zero. eCos startup code will perform all necessary hardware initialization and the system will be in a condition suitable for loading and running RAM applications.

The Stubrom and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option CYGSEM_HAL_ROM_MONITOR should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option CYGSEM_HAL_USE_ROM_MONITOR should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port 0 will be claimed for HAL diagnostics.

Flash Drivers

The STR710-EVAL board contains a 4Mbyte ST M28W320CB parallel Flash device. The CYGPKG_DEVS_FLASH_STRATA_V2 package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the STR710-EVAL board. This driver is not active until the generic Flash support package, CYGPKG_IO_FLASH, is included in the configuration.

A driver is also present for the internal Flash. The package CYGPKG_DEVS_FLASH_STR7XX contains all the code necessary to support this memory and the platform HAL package contains definitions that customize the driver to the STR710-EVAL board. This driver is not active until the generic Flash support package, CYGPKG_IO_FLASH, is included in the configuration.

Watchdog Driver

The STR710-EVAL board use the STR7XX's internal watchdog support. The CYGPKG_DEVICES_WATCHDOG_ARM_STR7XX package contains all the code necessary to support this device. Within that package the CYGNUM_DEVS_WATCHDOG_ARM_STR7XX_DESIRED_TIMEOUT_US configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, CYGPKG_IO_WATCHDOG, is included in the configuration.

UART Serial Driver

The STR710-EVAL boards use the STR7XX's internal UART serial support. As well as the polled HAL diagnostic interface, there is also a CYGPKG_IO_SERIAL_ARM_STR7XX package which contains all the code necessary to support interrupt-driven operation with greater functionality. All four UARTs can be supported by this driver, although only UARTs 0 and 1 are actually routed to external connectors. Note that it is not recommended to enable this driver on the port used for HAL diagnostic I/O. This driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option within the generic serial driver support package CYGPKG_IO_SERIAL is enabled in the configuration.

The STR7XX UARTs only provide the minimal TX and RX data lines; hardware flow control using RTS/CTS is not supported. The eCos device drivers have been extended to permit the use of a pair of GPIO lines to be use as flow control lines. These must be defined by the platform for each UART using the following CDL options:

CYGHWR_HAL_ARM_STR7XX_UARTX_RTS

> This value encodes which PIO line will be used as the RTS line for UARTX. The value of this option is an invocation of the macro UART_PIO(), which takes three arguments: the first is the PIO port number and the second is the bit number in that port for the PIO line. The third argument gives the polarity of the line, 0 if it is active low, 1 if it is active high.

CYGHWR_HAL_ARM_STR7XX_UARTX_CTS

> This value encodes which PIO line will be used as the CTS line for UARTX. UART_PIO() takes three arguments: the first is the PIO port number and the second is the bit number in that port for the PIO line. The third argument gives the polarity of the line, 0 if it is active low, 1 if it is active high.

CYGHWR_HAL_ARM_STR7XX_UARTX_CTS_INT

> This must be the name of the interrupt vector, from var_intr.h, that corresponds to the PIO bit selected for CTS. It is essential that the PIO bit selected be capable of generating an interrupt, so only those that have an XTI interrupt vector can be used. The polarity of the CTS line will decide whether this interrupt occurs on a rising or falling edge.

I^{2}C Support

Support for the two I²C® busses is provided by the variant HAL (`CYGPKG_HAL_ARM_STR7XX`). The STR710-EVAL board carries an ST M24C08 I^{2}C serial EEPROM connected to bus 0.

The M24C08 is an 8Kibit device, 1024 bytes. This memory is addressed by using a single byte for the least significant 8 bits of the address plus 2 bits from the device's I^{2}C address. Within eCos, this EEPROM is presented as four separate I^{2}C devices at addresses 0xA8, 0xAA, 0xAC, 0xAE. These are instantiated as four I^{2}C device objects, named `cyg_i2c_str710eval_m24c08_0`, `cyg_i2c_str710eval_m24c08_1`, `cyg_i2c_str710eval_m24c08_2` and `cyg_i2c_str710eval_m24c08_3` respectively.

A test application for use with the EEPROM is provided within the `tests` subdirectory of the `CYGPKG_HAL_ARM_STR7XX_STR710EVAL` package. This test communicates with the I^{2}C EEPROM on the board to perform read and write operations using I^{2}C. Since it overwrites the contents of the EEPROM, this test is not built by default. It may be built by enabling the configuration option `CYGBLD_HAL_ARM_STR7XX_STR710EVAL_TEST_M24C08`.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The description of the clock-related options may be found in the STR7XX variant HAL documentation.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos.

The option "-mcpu=arm7tdmi" should be set for all compilations for this platform.

There are two flags that are used if Thumb mode is to be supported:

`-mthumb`

The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used.

`-mthumb-interwork`

This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including RedBoot.

Debugging of ROM applications is only possible if using hardware breakpoints. The ARM7TDMI core of the STR7XX only supports two such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI2000 notes

On the Abatron BDI2000, the `bdi2000.str710eval.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs.

The `bdi2000.str710eval.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI2000 command line interface to make the changes take effect.

On the BDI2000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the bdiGDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI2000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI2000 is powered up, the target will always run the initialization section of the `bdi2000.str710eval.cfg` file, and halt the target. This behaviour is repeated with the **reset** command.

If the board is reset when in '**reset**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a ROM RedBoot is resident in Flash, it will be run.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured JTAG applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
Core#0>load 0x62000000 test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
Core#0>go 0x620000000
```

Consult the BDI2000 documentation for information on other formats.

Configuration of JTAG applications

JTAG applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Both of these settings are made automatically if the JTAG startup type is selected.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the STR710-EVAL Board hardware, and should be read in conjunction with that specification. The STR710-EVAL Board platform HAL package complements the ARM architectural HAL and the STR7XX variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM and JTAG startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks, GPIO pins and memory mapping control to map internal RAM 0x0. The details of the early hardware startup may be found in the header `cyg/hal/hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External RAM

This is located at address 0x62000000 of the memory space, and is 4MiB long. For ROM applications, all of RAM is available for use. For RAM startup applications, RAM below 0x62020000 is reserved for RedBoot and the remainder is available for the application.

External ROM

This is located at address 0x60000000 of the memory space. If switches SW13, SW14 and SW15 are all set to 2-3 this region will be mapped to 0x00000000 at reset. This region is 4MiB in size. RedBoot is normally programmed into this memory and the rest managed by the FIS flash file system.

Internal RAM

This is located at address 0x20000000 of the memory space, and is 64KiB in size. Normally this RAM area will be mapped to location 0x00000000 after bootstrap. The CPU vector table and the eCos VSR table occupy the bottom 64 bytes. The virtual vector table starts at 0x00000050 and extends to 0x00000150. The remainder of internal RAM is available for use by applications.

Internal ROM

This is located at address 0x40000000 of the memory space. If switches SW13 and SW14 are set to 1-2 and SW15 to 2-3 this region will be mapped to 0x00000000 at reset. This region is 256KiB in size. Applications may be configured to run from this memory by setting the `CYGHWR_HAL_STR7XX_FLASH_INTERNAL` option. This memory is not managed by RedBoot's FIS system, but it can be written using the **fis write** command and erased using the **fis erase** command.

on-chip peripherals

These are accessible at locations 0xC0000000 and 0xE0000000 upwards, depending on which APB bus they are on. Descriptions of the contents can be found in the STR7XX User Manual.

Chapter 250. Atmel AT91RM9200 Processor Support

Name

eCos Support for the Atmel AT91RM9200 Processor — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Atmel AT91RM9200 processor. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, ARM9 variant HAL and the platform HAL. It provides functionality common to AT91RM9200-based board implementations.

This support is found in the eCos package located at `packages/hal/arm/arm9/at91rm9200` within the eCos source repository.

The AT91RM9200 processor HAL package is loaded automatically when eCos is configured for an AT91RM9200-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the Atmel AT91RM9200 processor within this processor HAL package include:

- AT91RM9200-specific hardware definitions
- Interrupt controller
- Timer counters
- Serial UARTs
- MultiMedia Card Interface (MCI)
- Two-Wire Interface (TWI)
- Power saving

Support for the on-chip ethernet, interrupt-driven serial, SPI, watchdog and wallclock (RTC) features of the AT91RM9200 are also present and can be found in separate packages, outside of this processor HAL.

The watchdog hardware is also used within this HAL to perform software reset.

Name

AT91RM9200 hardware definitions — Details on obtaining hardware definitions for AT91RM9200

Register definitions

The file `<cyg/hal/at91rm9200.h>` can be included from application and eCos package sources to provide definitions related to AT91RM9200 subsystems. These include register definitions for the interrupt controller, power management controller, clock generator, memory controller, external bus interface, GPIO, USART, MCI, TWI (I²C®), Ethernet, timer counter, RTC, and SPI subsystems.

Initialization helper macros

The file `<cyg/hal/at91rm9200_init.inc>` contains definitions of helper macros which may be used by AT91RM9200 platform HALs in order to initialise common AT91RM9200 subsystems without excessive duplication between the platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary.

Name

AT91RM9200 interrupt controller — Advanced Interrupt Controller definitions and usage

Interrupt controller definitions

The file `<cyg/hal/var_ints.h>` (located at `hal/arm/arm9/at91rm9200/`*`VERSION`*`/include/var_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs:

```
#define CYGNUM_HAL_INTERRUPT_FIQ     0 // Advanced Interrupt Controller (FIQ)
#define CYGNUM_HAL_INTERRUPT_SYSTEM  1 // System Peripheral (debug unit, system timer)
#define CYGNUM_HAL_INTERRUPT_PIOA    2 // Parallel IO Controller A
#define CYGNUM_HAL_INTERRUPT_PIOB    3 // Parallel IO Controller B
#define CYGNUM_HAL_INTERRUPT_PIOC    4 // Parallel IO Controller C
#define CYGNUM_HAL_INTERRUPT_PIOD    5 // Parallel IO Controller D
#define CYGNUM_HAL_INTERRUPT_US0     6 // USART 0
#define CYGNUM_HAL_INTERRUPT_US1     7 // USART 1
#define CYGNUM_HAL_INTERRUPT_US2     8 // USART 2
#define CYGNUM_HAL_INTERRUPT_US3     9 // USART 3
#define CYGNUM_HAL_INTERRUPT_MCI    10 // Multimedia Card Interface
#define CYGNUM_HAL_INTERRUPT_UDP    11 // USB Device Port
#define CYGNUM_HAL_INTERRUPT_TWI    12 // Two-Wire Interface
#define CYGNUM_HAL_INTERRUPT_SPI    13 // Serial Peripheral Interface
#define CYGNUM_HAL_INTERRUPT_SSC0   14 // Serial Synchronous Controller 0
#define CYGNUM_HAL_INTERRUPT_SSC1   15 // Serial Synchronous Controller 1
#define CYGNUM_HAL_INTERRUPT_SSC2   16 // Serial Synchronous Controller 2
#define CYGNUM_HAL_INTERRUPT_TC0    17 // Timer Counter 0
#define CYGNUM_HAL_INTERRUPT_TC1    18 // Timer Counter 1
#define CYGNUM_HAL_INTERRUPT_TC2    19 // Timer Counter 2
#define CYGNUM_HAL_INTERRUPT_TC3    20 // Timer Counter 3
#define CYGNUM_HAL_INTERRUPT_TC4    21 // Timer Counter 4
#define CYGNUM_HAL_INTERRUPT_TC5    22 // Timer Counter 5
#define CYGNUM_HAL_INTERRUPT_UHP    23 // USB Host port
#define CYGNUM_HAL_INTERRUPT_EMAC   24 // Ethernet MAC
#define CYGNUM_HAL_INTERRUPT_IRQ0   25 // Advanced Interrupt Controller (IRQ0)
#define CYGNUM_HAL_INTERRUPT_IRQ1   26 // Advanced Interrupt Controller (IRQ1)
#define CYGNUM_HAL_INTERRUPT_IRQ2   27 // Advanced Interrupt Controller (IRQ2)
#define CYGNUM_HAL_INTERRUPT_IRQ3   28 // Advanced Interrupt Controller (IRQ3)
#define CYGNUM_HAL_INTERRUPT_IRQ4   29 // Advanced Interrupt Controller (IRQ4)
#define CYGNUM_HAL_INTERRUPT_IRQ5   30 // Advanced Interrupt Controller (IRQ5)
#define CYGNUM_HAL_INTERRUPT_IRQ6   31 // Advanced Interrupt Controller (IRQ6)

// The following interrupts are derived from the SYSTEM interrupt
#define CYGNUM_HAL_INTERRUPT_DEBUG  32 // Debug unit
#define CYGNUM_HAL_INTERRUPT_PMC    33 // Power Management Controller
#define CYGNUM_HAL_INTERRUPT_RTCH   34 // Real Time Clock
#define CYGNUM_HAL_INTERRUPT_PIT    35 // System Timer Period Interval Timer
#define CYGNUM_HAL_INTERRUPT_WDOVF  36 // System Timer Watchdog Overflow
#define CYGNUM_HAL_INTERRUPT_RTTINC 37 // System Timer Real-Time Timer Increment
#define CYGNUM_HAL_INTERRUPT_ALM    38 // System Timer Alarm
```

As indicated above, further decoding is performed on the SYSTEM interrupt to identify the cause more specifically. Note that as a result, placing an interrupt handler on the SYSTEM interrupt will not work as expected. Conversely, masking a decoded derivative of the SYSTEM interrupt will not work as this would mask other SYSTEM interrupts, but masking the SYSTEM interrupt itself will work. On the other hand, unmasking a decoded SYSTEM interrupt *will* unmask the SYSTEM interrupt as a whole, thus unmasking interrupts for the other units on this shared interrupt.

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt controller functions

The source file src/at91rm9200_misc.c within this package provides most of the support functions to manipulate the interrupt controller. The hal_IRQ_handler queries the IRQ status register to determine the interrupt cause. Functions hal_interrupt_mask and hal_interrupt_unmask enable or disable interrupts within the interrupt controller.

Interrupts are configured in the hal_interrupt_configure function, where the level and up arguments are interpreted as follows:

level	up	interrupt on
0	0	Falling Edge
0	1	Rising Edge
1	0	Low Level
1	1	High Level

To fit into the eCos interrupt model, interrupts essentially must be acknowledged immediately once decoded, and as a result, the hal_interrupt_acknowledge function is empty.

The hal_interrupt_set_level is used to set the priority level of the supplied interrupt within the Advanced Interrupt Controller.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (HAL_INTERRUPT_MASK et al) or preferably the kernel or driver APIs should be used to control interrupts.

Using the Advanced Interrupt Controller for VSRs

The AT91RM9200 HAL has been designed to exploit benefits of the on-chip Advanced Interrupt Controller (AIC) on the AT91RM9200. Support has been included for exploiting its ability to provide hardware vectoring for VSR interrupt handlers.

This support is dependent on definitions that may only be provided by the platform HAL and therefore is only enabled if the platform HAL package implements the CYGINT_HAL_AT91RM9200_AIC_VSR CDL interface. The necessary definitions are available to all platform HALs which use the facilities of the at91rm9200_init.inc header file.

The interrupt decoding path has been optimised by allowing the AIC to be interrogated for the interrupt handler VSR to use. These vectored interrupts are by default still configured to point to the default ARM architecture HAL IRQ and FIQ VSRs. However applications may set their own VSRs to override this default behaviour to allow optimised interrupt handling.

The VSR vector numbers to use when overriding are defined as follows:

```
#define CYGNUM_HAL_VECTOR_FIQ     7 // FIQ
#define CYGNUM_HAL_VECTOR_SYSTEM  8 // System Peripheral (debug unit, system timer)
#define CYGNUM_HAL_VECTOR_PIOA    9 // Parallel IO Controller A
#define CYGNUM_HAL_VECTOR_PIOB   10 // Parallel IO Controller B
#define CYGNUM_HAL_VECTOR_PIOC   11 // Parallel IO Controller C
#define CYGNUM_HAL_VECTOR_PIOD   12 // Parallel IO Controller D
#define CYGNUM_HAL_VECTOR_US0    13 // USART 0
#define CYGNUM_HAL_VECTOR_US1    14 // USART 1
#define CYGNUM_HAL_VECTOR_US2    15 // USART 2
#define CYGNUM_HAL_VECTOR_US3    16 // USART 3
#define CYGNUM_HAL_VECTOR_MCI    17 // Multimedia Card Interface
#define CYGNUM_HAL_VECTOR_UDP    18 // USB Device Port
#define CYGNUM_HAL_VECTOR_TWI    19 // Two-Wire Interface
#define CYGNUM_HAL_VECTOR_SPI    20 // Serial Peripheral Interface
#define CYGNUM_HAL_VECTOR_SSC0   21 // Serial Synchronous Controller 0
#define CYGNUM_HAL_VECTOR_SSC1   22 // Serial Synchronous Controller 1
#define CYGNUM_HAL_VECTOR_SSC2   23 // Serial Synchronous Controller 2
```

```
#define CYGNUM_HAL_VECTOR_TC0    24 // Timer Counter 0
#define CYGNUM_HAL_VECTOR_TC1    25 // Timer Counter 1
#define CYGNUM_HAL_VECTOR_TC2    26 // Timer Counter 2
#define CYGNUM_HAL_VECTOR_TC3    27 // Timer Counter 3
#define CYGNUM_HAL_VECTOR_TC4    28 // Timer Counter 4
#define CYGNUM_HAL_VECTOR_TC5    29 // Timer Counter 5
#define CYGNUM_HAL_VECTOR_UHP    30 // USB Host port
#define CYGNUM_HAL_VECTOR_EMAC   31 // Ethernet MAC
#define CYGNUM_HAL_VECTOR_IRQ0   32 // Advanced Interrupt Controller (IRQ0)
#define CYGNUM_HAL_VECTOR_IRQ1   33 // Advanced Interrupt Controller (IRQ1)
#define CYGNUM_HAL_VECTOR_IRQ2   34 // Advanced Interrupt Controller (IRQ2)
#define CYGNUM_HAL_VECTOR_IRQ3   35 // Advanced Interrupt Controller (IRQ3)
#define CYGNUM_HAL_VECTOR_IRQ4   36 // Advanced Interrupt Controller (IRQ4)
#define CYGNUM_HAL_VECTOR_IRQ5   37 // Advanced Interrupt Controller (IRQ5)
#define CYGNUM_HAL_VECTOR_IRQ6   38 // Advanced Interrupt Controller (IRQ6)
```

Consult the kernel and generic HAL documentation for more information on VSRs and how to set them.

Interrupt handling within standalone applications

For non-eCos standalone applications running under RedBoot, it is possible to install an interrupt handler into the interrupt vector table manually. Memory mappings are platform-dependent and so the platform documentation should be consulted, but in general the address of the interrupt table can be determined by analyzing RedBoot's symbol table, and searching for the address of the symbol name `hal_interrupt_handlers`. Table slots correspond to the interrupt numbers above. Pointers inserted in this table should be pointers to a C/C++ function with the following prototype:

```
extern unsigned int isr( unsigned int vector, unsigned int data );
```

For non-eCos applications run from RedBoot, the return value can be ignored. The `vector` argument will also be the interrupt vector number. The `data` argument is extracted from a corresponding table named `hal_interrupt_data` which immediately follows the interrupt vector table. It is still the responsibility of the application to enable and configure the interrupt source appropriately if needed.

Name

Timer counters — Use of on-chip timer counters

Timer counter 0

The eCos kernel system clock is implemented using Timer Counter 0. By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to `CYGNUM_HAL_RTC_DENOMINATOR`, then the configuration option `CYGNUM_HAL_RTC_NUMERATOR` may also be adjusted, and again clock-related settings will automatically be recalculated.

Timer Counter 0 is also used to implement the HAL microsecond delay function, `HAL_DELAY_US`. This is used by some device drivers, and in non-kernel configurations such as with RedBoot where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Timer-based profiling support

Timer-based profiling support is implemented using timer counter 1 (TC1). If the gprof package, `CYGPKG_PROFILE_GPROF`, is included in the configuration, then TC1 is reserved for use by the profiler.

Name

Serial UARTs — Configuration and implementation details of serial UART support

Overview

Support is included in this processor HAL package for the AT91RM9200's on-chip debug unit UART and four serial USART serial devices.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 115200,8,N,1 with no flow control.

HAL diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems. This can operate on any port, according to the configuration settings.

There are several configuration options usually found within a platform HAL which affect the use of this support in the AT91RM9200 processor HAL. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, `diag_printf()`. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL` selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the `CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS` CDL option in the HAL. Baud rates for each channel are set with the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD` options.

Interrupt-driven serial driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (`CYGPKG_IO_SERIAL`). This support can be enabled on any port.

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent ctrl-c operation when debugging.

This driver is contained in the `CYGPKG_IO_SERIAL_ARM_AT91` package. That driver package should also be consulted for documentation and configuration options. The driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Note that unlike the USART devices, the serial debug port does not support modem control signals such as those used for hardware signals. In addition, USART devices for a particular platform may also not have these control signals brought out to the physical serial port.

Name

Multimedia Card Interface (MCI) driver — Using MMC/SD cards with block drivers and filesystems

Overview

The MultiMedia Card Interface (MCI) driver in the AT91RM9200 processor HAL allows use of MultiMedia Cards (MMC cards) and Secure Digital (SD) flash storage cards within eCos, exported as block devices. This makes them suitable for use as the underlying devices for filesystems such as FAT.

Configuration

This driver provides the necessary support for the generic MMC/SD bus layer within the `CYGPKG_DEVS_DISK_MMC` package to export a disk block device. The disk block device is only available if the generic disk I/O layer found in the package `CYGPKG_IO_DISK` is included in the configuration.

The block device may then be used as the device layer for a filesystem such as FAT. Example devices are "`/dev/mmc0/1`" to refer to the first partition on the card, or "`/dev/mmc0/0`" to address the whole device including potentially the partition table at the start.

The driver may be forcibly disabled within this processor HAL package with the configuration option `CYGPKG_HAL_ARM_ARM9_AT91RM9200_MCI`.

If the driver is enabled, there are only two AT91RM9200 specific options:

`CYGIMP_HAL_ARM_ARM9_AT91RM9200_MCI_INTMODE`
: This indicates that the driver should operate in interrupt-driven mode if possible. This is enabled by default if the eCos kernel is enabled. Note though that if the driver finds that global interrupts are off when running, then it will fall back to polled mode even if this option is enabled. This allows for use of the MCI driver in an initialisation context.

`CYGNUM_HAL_ARM_ARM9_AT91RM9200_MCI_POWERSAVE_DIVIDER`
: The AT91RM9200 MCI peripheral allows the MCI clock to be divided down if told to enter power saving mode. This option specifies the divider to use. The driver itself does not implement any power saving - it is up to the application to enable power saving in the MCI control register if it is required.

Usage notes

MMC/SD cards may only be used in a MMC/SD card slot, and not a dataflash slot. The driver will detect the appropriate card sizes. Hotswapping of cards is supported by the driver, and in the case of eCosPro, the FAT filesystem. Although any cards removed before explicit unmounting or a `sync()` call to flush filesystem buffers will likely result in a corrupted filesystem on the removed card.

The MMC/SD bus layer will parse partition tables, although it can be configured to allow handling of cards with no partition table.

Name

Two-Wire Interface (TWI) driver — Configuration and implementation details of TWI (I²C®) driver

Overview

The AT91RM9200 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91RM9200. This type of bus is also known as I²C®. The API for this may be found within the `CYGPKG_IO_I2C` package.

I²C®/TWI driver configuration

The I²C® driver uses the AT91RM9200's internal Two-Wire Interface (TWI) support. This is controlled within the AT91RM9200 processor HAL (`CYGPKG_HAL_AT91RM9200`). The `CYGPKG_HAL_AT91RM9200_TWI` CDL component controls whether the TWI driver is enabled. Within that component, there are two sub-options:

- `CYGNUM_HAL_AT91RM9200_TWI_CLOCK` sets the speed of the TWI bus clock in Hz. This is usually 100kHz, but can be set up to 400kHz if the devices on the bus support this speed, also known as fast mode. However other values below 400kHz can also be chosen, subject to the accuracy of the clock waveform generation parameters.

- The second option within the `CYGPKG_HAL_AT91RM9200_TWI` component is `CYGNUM_HAL_AT91RM9200_TWI_CKDIV`. This is the clock divider used when configuring the TWI_CWGR register. Consult the AT91RM9200 datasheet description of the TWI_CWGR register for the formula used to determine the clock frequency. Increasing the divider will decrease the accuracy in practice of the generated I²C bus clock compared to `CYGNUM_HAL_AT91RM9200_TWI_CLOCK`. But the divider must also be sufficiently low that the relevant factors do not overflow valid values for CHDIV/CLDIV in TWI_CWGR. Note that when the AT91RM9200 is using a 60MHz MCK, then for 100kHz operation, a value for this option of 1 is most appropriate. For 400kHz, a value for this option of 0 is most appropriate. The default value of this CDL is an appropriate value for CKDIV assuming a 60MHz MCK and a TWI clock between 29kHz and 400kHz.

  To be specific, the CLDIV/CHDIV fields of the TWI_CWGR are considered equal. The value of, for example, CLDIV, can be expressed as:

$$CLDIV = \frac{f_{MCK} - 6 f_{TWI}}{2^{CKDIV+1} \cdot f_{TWI}}$$

To use the I²C/TWI driver, the generic I²C driver package `CYGPKG_IO_I2C` must be used. Documentation for its API may be found elsewhere.

Usage notes

This driver only operates in interrupt mode. It does not operate in polled mode, and thus does not operate when interrupts are disabled. It cannot therefore be used in an initialization context, before the eCos kernel thread scheduler starts. And it cannot be used with RedBoot.

Due to the characteristics of the AT91RM9200's operation, it is not possible to provide support for repeated starts with the I²C package API. Similarly indicating a NACK when performing a receive is equivalent to also sending a STOP.

A test application for use with the Aardvark I²C/SPI Activity Board is provided within the `tests` subdirectory of the `CYGPKG_HAL_AT91RM9200` package. This test communicates with the I²C EEPROM on the board to perform read and write operations using I²C. This test is not built by default. It may be built by enabling the configuration option `CYGBLD_HAL_ARM_ARM9_AT91RM9200_TEST_TWI_AT24C02A` within the AT91RM9200 processor HAL.

Name

Power saving support — Extensions for saving power

Overview

There is support in the AT91RM9200 processor HAL for a simple power saving mechanism. This is provided by two functions:

```
#include <cyg/hal/hal_intr.h>

__externC void cyg_hal_at91rm9200_powersave_init( cyg_uint32 ip_addr );

__externC void cyg_hal_at91rm9200_powerdown( void );
```

The powersaving system is initialized by calling `cyg_hal_at91rm9200_powersave_init()`. The argument should be the IP address of this machine in network order. This can usually be fetched from the bootp data for an interface after completion of the call to `init_all_network_interfaces()`. e.g. `eth0_bootp_data.bp_ciaddr.s_addr`.

A call to `cyg_hal_at91rm9200_powerdown()` will put the machine into a low power mode. This will involve switching to a slower system clock speed, disabling all peripherals except those that are defined to cause the system to wake up and return from this function.

Configuration

The exact behaviour of the power saving system is controlled by the following configuration options:

CYGPKG_HAL_ARM_ARM9_AT91RM9200_POWERSAVE

> This option controls the overall inclusion of the power saving system.
>
> Default value: on

CYGSEM_HAL_ARM_ARM9_AT91RM9200_POWERSAVE_POLL_ETHERNET

> This option enables polling of the ethernet interface for relevant ARP packets and unicast IP packets. It is necessary for the CPU to run at a higher CPU speed for this option to work.
>
> Default value: off

CYGSEM_HAL_ARM_ARM9_AT91RM9200_POWERSAVE_IDLE

> If this option is set, the CPU will go into idle mode, which will cause it to halt until an interrupt is delivered.
>
> Default value: off

CYGVAR_HAL_ARM_ARM9_AT91RM9200_POWERSAVE_ACTIVE_DEVICES

> This option defines the devices that are to be kept running during power down mode. An interrupt from one of these devices is usually the only way of bringing the system out of idle mode. The value of this option is a bit mask with bits set for each device that is to be kept active. The bits correspond to the peripheral identifiers described in the AT91RM9200 documentation.
>
> Default value: 0x00000000

CYGSEM_HAL_ARM_ARM9_AT91RM9200_POWERSAVE_POLL_GPIO

> This option control whether the power saving system will poll GPIO pins during power saving. For this to work the CPU cannot be put into idle mode.

Default value: on

CYGVAR_HAL_ARM_ARM9_AT91RM9200_POWERSAVE_PIO_HI

This is an array of bitmasks of the bits in the PIO PDSR registers. Within the array, index 0 corresponds to PIOA, index 1 to PIOB and so on. For each set bit in these masks, if the value is seen to be 1, then the low power mode will be terminated.

Default value: 0, 0, 0, 0

CYGVAR_HAL_ARM_ARM9_AT91RM9200_POWERSAVE_PIO_LO

This is an array of bitmasks of the bits in the PIO PDSR registers. Within the array, index 0 corresponds to PIOA, index 1 to PIOB and so on. For each set bit in these masks, if the value is seen to be 0, then the low power mode will be terminated.

Default value: 0, 0, 0, 0

CYGVAR_HAL_ARM_ARM9_AT91RM9200_POWERSAVE_PIO_CHANGE

This is an array of bitmasks of the bits in the PIO PDSR registers. Within the array, index 0 corresponds to PIOA, index 1 to PIOB and so on. For each set bit in these masks, if the value is seen to change between successive polls, then the low power mode will be terminated.

Default value: 0, 0, 0, 0

CYGBLD_HAL_ARM_ARM9_AT91RM9200_TEST_POWERSAVE

This option controls whether a simple test is built to exercise power saving support. The test is not built by default as an external means is required to wake the processor up by one of the above configured mechanisms.

Default value: 0

Chapter 251. Atmel AT91RM9200 Development Kit/Evaluation Kit Board Support

Name

eCos Support for the Atmel AT91RM9200 Development Kit/Evaluation Kit — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel AT91RM9200 Development Kit and Atmel AT91RM9200 Evaluation Kit. The AT91RM9200 Evaluation Kit (EK board) contains the AT91RM9200 processor, 8Mbytes of SDRAM, 8Mbytes of parallel NOR flash memory, a Davicom DM9161A PHY, a SD/MMC/DataFlash socket, a DAC, external connections for two serial channels (one debug, one full), ethernet, USB host/device, graphics, and the various other peripherals supported by the AT91RM9200. The AT91RM9200 Development Kit (DK board) is similar but also comes with a 128Kbytes TWI (I2C) EEPROM, IrDA port, and 8Mbytes of SPI DataFlash, although only 2Mbytes of parallel NOR flash memory. eCos support for the many devices and peripherals on the boards and the AT91RM9200 is described below.

In this document, an EK board will be assumed for the purposes of examples and output.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot into this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the AT91RM9200 processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

On the EK board, the parallel NOR flash memory consists of 8 blocks of 8Kbytes each, followed by 127 blocks of 64Kbytes each. In a typical setup, the first 192 Kbytes are reserved for the use of the ROMRAM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining blocks can be used by application code. There are 125 blocks available between 0x60030000 and 0x607EFFFF.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J10 and DTE port at J14 (connected to USART channel 1) can be used by RedBoot for communication with the host. If either of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the AT91RM9200-EK or AT91RM9200-DK targets.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91RM9200` for the on-chip ethernet device. The platform HAL package is responsible for configuring this generic driver to the EK/DK hardware. This driver is also loaded automatically when configuring for the EK or DK targets.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91RM9200`. This driver is also loaded automatically when configuring for the EK or DK targets.

There is a driver for the on-chip real-time clock (RTC) at `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91`. This driver is also loaded automatically when configuring for the EK or DK targets.

The AT91RM9200 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91RM9200. This type of bus is also known as I²C®. Further documentation may be found in the AT91RM9200 processor HAL documentation.

The AT91RM9200 processor HAL contains a driver for the MultiMedia Card Interface (MCI). This driver is loaded automatically when configuring for the EK or DK targets and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation may be found in the AT91RM9200 processor HAL documentation.

There is a driver `CYGPKG_DEVS_SPI_ARM_ATMEL_AT91RM9200_KITS` to allow access to devices on the SPI bus. This driver provides information to the more general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the EK or DK targets.

Furthermore, the platform HAL package contains support for SPI dataflash cards. The HAL support integrates with the `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` package as well as the above SPI packages. That package is automatically loaded when configuring for the EK or DK targets. Dataflash media is then accessed as a Flash device, using the Flash I/O API within the `CYGPKG_IO_FLASH` package, if that package is loaded in the configuration.

In general, devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91RM9200-EK and AT91RM9200-DK support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91RM9200-EK and AT91RM9200-DK boards for eCos Development

Overview

In a typical development environment, the AT91RM9200-EK/DK boards boot from the parallel NOR Flash and run the RedBoot ROM monitor directly. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`
JTAG	RedBoot running from RAM, loaded via JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

The ample provision of RAM memory on the board allows the ROMRAM version of RedBoot to be preferential to the standard ROM version which executes directly from Flash. Alternatively, if the ROM version is to be chosen, then the RAM version is provided to allow for updating the resident RedBoot image in Flash. The JTAG version is only used if loading RedBoot into RAM via a JTAG debugger or ICE. It is similar to the RAM version, but loads at a lower address within RAM, and so can be used to in turn load eCos applications, as if it is the normal resident boot monitor. The ELF format image of this JTAG version of RedBoot can also be loaded and executed from GDB using the Abatron BDI2000 bdiGDB support, to allow it to be debugged.

Initial Installation

The on-chip boot program on the AT91RM9200 is only capable of loading programs into 12Kbytes of on-chip SRAM and is therefore quite restrictive. Consequently two mechanisms are described below to program RedBoot into Flash. Both of them require a JTAG device. In the following documentation it is assumed that the Abatron BDI2000 is being used. For a different JTAG device, equivalent operations will need to be performed.

Preparing the Abatron BDI2000 JTAG debugger

The BDI2000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.

2. Connect the Abatron BDI2000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI2000.

3. Install the Abatron BDI2000 bdiGDB support software on the host PC.

4. Locate the file `bdi2000.at91rm9200ek.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/arm9/atmel-at91rm9200-kits/`*`VERSION`*`/misc` relative to the root of your eCos installation.

5. Locate the file `reg920t.def` within the installation of the BDI2000 bdiGDB support software.

6. Place the bdi2000.at91rm9200ek.cfg in a location on the PC accessible to the TFTP server. Later you will configure the BDI2000 to load this file via TFTP as its configuration file.

7. Similarly place the file `reg920t.def` in a location accessible to the TFTP server.

8. Open `bdi2000.at91rm9200ek.cfg` in an editor such as emacs or notepad and if necessary adjust the path of the `reg920t.def` file in the `[REGS]` section to match its location relative to the TFTP server root.

9. Install and configure the Abatron BDI2000 in line with the bdiGDB instruction manual. Configure the BDI2000 to use the `bdi2000.at91rm9200ek.cfg` configuration file at the appropriate point of this process.

Preparing the AT91RM9200-EK/DK board for programming

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between the Serial Debug Port on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to your host PC's LAN with an Ethernet cable.

4. You should designate the board with a new Ethernet MAC address. The RedBoot binary image contains a default address, but each board requires its own unique address. It is advisable to mark each board with its programmed MAC address for future identification.

5. Connect the board to the BDI2000 using a 20-pin ARM/Xscale cable from the ICE interface connector to the Target A port on the BDI2000.

6. Locate jumper J15 on the board, which is by default set to `INT`. It should be reset to `EXT`. In due course this will ensure that the board boots RedBoot from the external parallel Flash device.

7. Power up the AT91RM9200-EK board. You should see the three ethernet LEDs illuminate.

8. Connect to the BDI2000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

   ```
   Core#0>
   ```

9. Confirm correct connection with the BDI2000 with the **reset halt** command as follows:

   ```
   Core#0> reset halt
   - TARGET: processing reset request
   - TARGET: BDI asserts TRST and RESET
   - TARGET: BDI removes TRST
   - TARGET: Bypass check 0x000000001 => 0x00000001
   - TARGET: JTAG exists check passed
   - Core#0: ID code is 0x05B0203F
   - TARGET: All ICEBreaker access checks passed
   - TARGET: BDI removes RESET
   - TARGET: BDI waits for RESET inactive
   - TARGET: resetting target passed
   - TARGET: processing target startup ....
   - TARGET: processing target startup passed
   Core#0>
   ```

10.Locate the `redboot_ROMRAM.bin` image within the `loaders` subdirectory of the base of the eCos installation.

11.Copy the `redboot_ROMRAM.bin` file into a location on the host computer accessible to its TFTP server.

Method 1 - Using the BDI2000 to directly program RedBoot into Flash

As previously mentioned, there are two methods of programming a RedBoot image into the parallel NOR Flash. This method uses the built-in capabilities of the BDI2000.

This is a three stage process. The relevant Flash blocks must first be unlocked, then erased, and finally programmed. This can be accomplished with the following steps:

1. Connect to the BDI2000 telnet port as before.
2. Cut and paste the following commands into the BDI2000 telnet session. They are used to unlock the relevant Flash blocks that will contain RedBoot. The BDI2000 does have an **unlock** command, however this only works with Intel StrataFLASH and is therefore not suitable.

```
mmh 0x1000aaaa 0x00aa
mmh 0x10000000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x10002000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x10004000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x10006000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x10008000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x1000a000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x1000c000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x1000e000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x10010000 0x0070
mmh 0x1000aaaa 0x00aa
mmh 0x10020000 0x0070
```

3. Erase the 8 initial 8Kbyte sized Flash blocks, and the following 2 64Kbyte Flash blocks with the following commands:

```
Core#0>erase 0x10000000 0x2000 8
Erasing flash at 0x10000000
Erasing flash at 0x10002000
Erasing flash at 0x10004000
Erasing flash at 0x10006000
Erasing flash at 0x10008000
Erasing flash at 0x1000a000
Erasing flash at 0x1000c000
Erasing flash at 0x1000e000
Erasing flash passed
Core#0>erase 0x10010000 0x10000 2
Erasing flash at 0x10010000
Erasing flash at 0x10020000
Erasing flash passed
Core#0>
```

4. Program the RedBoot image into Flash with the following command, replacing `/RBPATH` with the location of the redboot_ROMRAM.bin file relative to the TFTP server root directory:

```
Core#0>prog 0x10000000 /RBPATH/redboot_ROMRAM.bin bin
Programming /RBPATH/redboot_ROMRAM.bin , please wait ....
Programming flash passed
Core#0>
```

This operation can take some time.

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. The RedBoot banner should be visible on the serial port. RedBoot's Flash configuration can be initialized using the same procedure as required in Method 2 below.

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Method 2 - Program RedBoot into Flash with RAM RedBoot

With this approach, the BDI2000 is used to load a RAM RedBoot image, which can then in turn be used to load and program a ROMRAM RedBoot image into Flash.

There are three stages, firstly loading the RAM RedBoot image, then initializing RedBoot's Flash configuration, and finally loading and programming the ROMRAM RedBoot.

Loading a RAM RedBoot

1. Locate the `redboot_JTAG.bin` image within the `loaders` subdirectory of the base of the eCos installation.

2. Copy the `redboot_JTAG.bin` file into a location on the host computer accessible to its TFTP server.

3. With the BDI2000 telnet interface, execute the following command, replacing */RBPATH* with the location of the redboot_JTAG.bin file relative to the TFTP server root directory:

   ```
   Core#0>load 0x20008000 /RBPATH/redboot_JTAG.bin bin
   Loading /RBPATH/redboot_JTAG.bin , please wait ....
   Loading program file passed
   Core#0>
   ```

4. Run the loaded RAM RedBoot:

   ```
   Core#0>go 0x20008000
   Core#0>
   ```

The terminal emulator connected to the serial debug port should now have displayed the RedBoot banner and prompt similar to the following:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
PHY: Davicom DM9161A
AT91RM9200 ETH: Waiting for link to come up.
AT91RM9200 ETH: 100Mb/Full Duplex
... waiting for BOOTP information
Ethernet eth0: MAC address 00:23:31:37:00:1c
IP: 192.168.7.190/255.255.255.0, Gateway: 192.168.7.1
Default server: 192.168.7.11, DNS server IP: 192.168.7.11

RedBoot(tm) bootstrap and debug environment [RAM]
eCosCentric certified release, version v2_XX - built 18:51:18, Aug 25 2005

Platform: Atmel AT91RM9200-EK (ARM9)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005 eCosCentric Limited

RAM: 0x20000000-0x20800000, [0x2002f4e0-0x207ed000] available
FLASH: 0x60000000 - 0x607fffff 8 x 0x2000 blocks 127 x 0x10000 blocks
RedBoot>
```

In the above output, a local BOOTP/DHCP server was able to serve an address to the device.

Note

It is also possible to use the RAM startup version of RedBoot and the redboot_RAM.bin file instead of redboot_JTAG.bin above. If so, then the address to the **load** command must be 0x20040000, as must be the address to the **go** command.

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration. This must be performed when using a RAM RedBoot to program Flash, but is also applicable to initial configuration of a ROMRAM RedBoot loaded using Method 1.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x60030000-0x607effff: .........................................
... Unlocking from 0x607f0000-0x607fffff: .
... Erase from 0x607f0000-0x607fffff: .
... Program from 0x207f0000-0x20800000 to 0x607f0000: .
... Locking from 0x607f0000-0x607fffff: .
RedBoot>
```

2. Now configure RedBoot's Flash configuration with the command:

```
RedBoot> fconfig -i
```

Remember to substitute the appropriate MAC address for this board at the appropriate step. If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.7.11

Loading and programming the ROMRAM RedBoot

This section describes the steps required to load the ROMRAM RedBoot from the TFTP server and program it into Flash.

1. Load the RedBoot ROMRAM binary image from the TFTP server. Use the following command, replacing *`111.222.333.444`* with the TFTP server IP address (or domain name if a DNS server has been configured), and *`/RBPATH`* with the location of the `redboot_ROMRAM.bin` file relative to the TFTP server root directory:

```
RedBoot> load -r -b %{freememlo} -h 111.222.333.444 /RBPATH/redboot_ROMRAM.bin
Using default protocol (TFTP)
```

```
Raw file loaded 0x2002f800-0x2004e367, assumed entry at 0x2002f800
RedBoot>
```

2. Finally install the loaded image into Flash:

   ```
   RedBoot> fis create RedBoot
   An image named 'RedBoot' exists - continue (y/n)? y
   ... Unlocking from 0x60000000-0x6002ffff: ..........
   ... Erase from 0x60000000-0x6002ffff: ..........
   ... Program from 0x0002f800-0x0004e368 to 0x60000000: .........
   ... Locking from 0x60000000-0x6002ffff: ..........
   ... Unlocking from 0x607f0000-0x607fffff: .
   ... Erase from 0x607f0000-0x607fffff: .
   ... Program from 0x007f0000-0x00800000 to 0x607f0000: .
   ... Locking from 0x607f0000-0x607fffff: .
   RedBoot>
   ```

   It is also possible to use the **fis write** command to write the image into Flash, but if so, the relevant Flash blocks must also be explicitly unlocked with the command:

   ```
   RedBoot> fis unlock -f 0x60000000 -l 0x30000
   ```

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. Output similar to the following should be seen on the serial port. Verify the IP settings are as expected.

```
+PHY: Davicom DM9161A
AT91RM9200 ETH: Waiting for link to come up.
AT91RM9200 ETH: 100Mb/Full Duplex

RedBoot(tm) bootstrap and debug environment [ROMRAM]
eCosCentric certified release, version v2_XX - built 18:55:20, Aug 25 2005

Platform: Atmel AT91RM9200-EK (ARM9)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005 eCosCentric Limited

RAM: 0x20000000-0x20800000, [0x20030470-0x207ed000] available
FLASH: 0x60000000 - 0x607fffff 8 x 0x2000 blocks 127 x 0x10000 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROMRAM version of RedBoot for the AT91RM9200-EK are:

```
$ mkdir redboot_at91rm9200ek_romram
$ cd redboot_at91rm9200ek_romram
$ ecosconfig new at91rm9200ek redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/atmel-at91rm9200-kits/VERSION/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

The other versions of RedBoot - ROM, RAM or JTAG - may be similarly built by choosing the appropriate alternative .ecm file.

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91RM9200-EK/DK platform HAL package is loaded automatically when eCos is configured for `at91rm9200ek` or `at91rm9200dk` targets. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x10000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROM-RAM
: This startup type can be used for finished applications which will be programmed into flash at physical location 0x10000000. However, when it starts up, the application will first copy itself to RAM at virtual address 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91RM9200-EK board contains an 8Mbyte Atmel AT49BV6416 parallel Flash device. The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX_V2` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the AT91RM9200-EK board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Ethernet Driver

The AT91RM9200-EK/DK boards use the AT91RM9200's internal EMAC ethernet device attached to an external Davicom DM9161A PHY. The `CYGPKG_DEVS_ETH_ARM_AT91RM9200` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the AT91RM9200-EK/DK boards. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The AT91RM9200-EK/DK boards use the AT91RM9200's internal RTC support. The `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91` package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The AT91RM9200-EK/DK boards use the AT91RM9200's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91RM9200` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91RM9200_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

USART Serial Driver

The AT91RM9200-EK/DK boards use the AT91RM9200's internal USART serial support as described in the AT91RM9200 processor HAL documentation. Two serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/dbg`" in the interrupt-driven driver; and USART 1 which is mapped to virtual vector channel 1 and "`/dev/ser1`". Only USART 1 supports modem control signals such as those used for hardware flow control.

MCI Driver

As the AT91RM9200 MCI driver is part of the AT91RM9200 HAL, nothing is required to load it. Similarly the MMC/SD bus driver layer (`CYGPKG_DEVS_DISK_MMC`) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (`CYGPKG_IO_DISK`), along with the intended filesystem, typically, the FAT filesystem (`CYGPKG_FS_FAT`) and any of its package dependencies (including `CYGPKG_LIBC_STRING` and `CYGPKG_LINUX_COMPAT` for FAT).

Various options can be used to control specific of the AT91RM9200 MCI driver. Consult the AT91RM9200 HAL documentation for information on its configuration.

On this target, the MMC/SD socket allows detection of when cards are inserted and removed. This may be used with the removeable media support and disk insertion/removal event notification system in the disk I/O package so that the application or other eCos subsystems are informed when cards are inserted and removed. This in turn allows use of the automounter contained within the File I/O package (`CYGPKG_FILEIO`) to mount and unmount cards automatically.

Caution

Remember that the ability to unmount cards after removal does not prevent those cards containing corrupt filesystems - instead cards should be preferably unmounted before removal, or at least have the filesystem's in-memory buffers flushed to the media using the `sync()` function).

The MMC/SD socket also allows detection of the write-protect (or "lock") switch present on SD cards. "Locked" cards will be detected and mounted read-only, and attempts to write to them will fail.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM920T CPU in the AT91RM9200.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded RAM applications, or even applications resident in ROM, including RedBoot.

Debugging of ROM applications is only possible if using hardware breakpoints. The ARM920T core of the AT91RM9200 only supports two such hardware breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI2000 notes

On the Abatron BDI2000, the `bdi2000.at91rm9200ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `bdi2000.at91rm9200ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI2000 command line interface to make the changes take effect.

On the BDI2000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the bdiGDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI2000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI2000 is powered up, the target will always run the initialization section of the `bdi2000.at91rm9200ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a ROMRAM RedBoot is resident in Flash, it will be run.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
Core#0>load 0x20008000 /test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
Core#0>go 0x20008000
```

Consult the BDI2000 documentation for information on other formats.

Configuration of RAM applications

If the JTAG device has initialized the SDRAM, such as by using the `bdi2000.at91rm9200ek.cfg` configuration on the BDI2000, RAM applications can be loaded directly into SDRAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. This will also cause the `CYGBLD_HAL_ARM9_ATMEL_AT91R-`

M9200_KITS_LOAD_LOW_RAM configuration option to be enabled allowing the application to be built with a set of memory layout files that will configure the linker script to set the program load address to be within the physical SDRAM space. Secondly the CYGDBG_HAL_DIAG_TO_DEBUG_CHAN option should be disabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USART 1 can be chosen instead by setting the CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL configuration option in the platform HAL to channel 1.

Warning

If resetting the board using the JTAG device, such as by using the BDI2000 **reset** command, the Ethernet PHY fails to interface correctly with the AT91RM9200, and consequently all subsequent ethernet operations are impossible. Only a reset by pressing the reset button or due to a watchdog timeout will cause the PHY to reset correctly.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91RM9200-EK/DK hardware, and should be read in conjunction with that specification. The AT91RM9200-EK/DK platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the AT91RM9200 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM or ROMRAM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash

This is located at address 0x10000000 of the physical memory space. The HAL uses the MMU to locate it at virtual address 0x60000000 after initialization. It remains accessible at address 0x1000000 but accesses to this address range are uncached.

SDRAM

This is located at address 0x20000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x20000000, but in order to assign hardware exception vectors vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x30000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x00040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is entirely reserved for use by the ethernet interface, since there are problems using external SDRAM for ethernet buffers.

On-chip ROM

This is located at address 0x00100000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x71000000. The same memory is also accessible uncached and unbuffered at virtual location 0x71800000.

USB host port

The USB host port (UHP) registers are located at address 0x00300000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x72800000. Memory accessed at this address is uncached and unbuffered. There is no cached variant.

SPI dataflash
: SPI Dataflash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x30000000 and the extent will clearly depend on the Dataflash capacity. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers
: These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals
: eCos uses the SDRAM, parallel NOR flash, ethernet PHY, SPI dataflash and MCI facilities on the AT91RM9200-EK/DK boards. eCos does not currently make any use of any other off-chip peripherals present on these boards.

Advanced Interrupt Controller

This port has been designed to exploit benefits of the Advanced Interrupt Controller of the AT91RM9200, using the facilities of the AT91RM9200 processor HAL. Consult the documentation in that package for details.

SPI Dataflash

eCos supports SPI access to Dataflash on the AT91RM9200. Two physical slots are provided on the board, but only the upper one may be used for SPI dataflash, not the one on the underside. This is due to an AT91RM9200 errata affecting SPI chip selects.

Accesses to Dataflash are performed via the Flash API, using 0x30000000 as the nominal address of the device, although it does not truly exist in the processor address space. On driver initialisation, eCos and RedBoot can detect the presence of a card in the socket. In particular, on reset RedBoot will indicate the presence of Flash at the 0x30000000 address range in its startup banner if it has been successfully detected. Hot swapping is not possible.

Since Dataflash is not directly addressable, access from RedBoot is only possible using **fis** command operations. Flash partitions within the FIS can be created, although users should be aware that the FIS partition data is stored in the NOR flash, and not on a per-Dataflash card basis. Therefore if a second Dataflash card is inserted it will appear to have the same FIS partitions residing on the card. Care must be taken if swapping between cards with differing partition layouts.

The MCI driver cannot be enabled simultaneously with the SPI driver, as the drivers need differing pin configurations for the same pins on this board due to the shared socket.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 251.1. atmel-at91rm9200-kits Real-time characterization

```
            Startup, main stack : stack used   412 size  3920
             Startup :  Interrupt stack used   524 size  4096
             Startup : Idlethread stack used    80 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   13.02 microseconds (6 raw clock ticks)

```

Other Issues

The AT91RM9200-EK/DK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The AT91RM9200 processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 252. Cogent CSB337 Board Support

Name

eCos Support for the CSB337 Board — Overview

Description

This document covers the Cogent CSB337 single board computer based on the Atmel AT91RM9200. The CSB337 contains the AT91RM9200 processor, 32Mb of SDRAM, 8MB of flash memory, an Intel LXT971 PHY and external connections for two serial channels, ethernet and the various other peripherals supported by the AT91RM9200. The CSB337 is usually plugged into a breakout board such as a Cogent CSB300 or CSB300CF.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of 64 blocks of 128k bytes each. In a typical setup, the first flash block is used for the ROMRAM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining 60 blocks between 0x60020000 and 0x607DFFFF can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. These devices can be used by RedBoot for communication with the host. If either of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the CSB337 target.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91RM9200` for the on-chip ethernet device. A second package `CYGPKG_DEVS_ETH_ARM_CSB337` is responsible for configuring this generic driver to the CSB337 hardware. These drivers are also loaded automatically when configuring for the CSB337 target.

The on-chip TWI device is not supported. Instead there is a bit-banged I²C bus using GPIO pins PA25 and PA26, with one attached device: a DS1307 battery-backed wallclock. The bus is supported by the `CYGPKG_IO_I2C` package and some platform-specific support. The platform HAL provides a cyg_i2c_bus structure `hal_csb337_i2c_bus`, and one cyg_i2c_device structure `cyg_i2c_wallclock_ds1307`. The wallclock is used mainly by the DS1307 device driver, but it also provides 56 bytes of non-volatile storage which can be used by the application. Any unused I²C functionality will be eliminated at link-time.

`CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1307` provides support for the DS1307 clock. This will be inactive unless the generic wallclock support `CYGPKG_IO_WALLCLOCK` is loaded. Some templates load this automatically, otherwise it must be loaded explicitly. The wallclock is not normally accessed directly. Instead it provides support for the standard C library time-related routines such as `time` and `asctime`, and can be updated by an eCos-specific function `cyg_libc_time_settime`.

eCos manages the on-chip interrupt controller. Timer counter 0 is used to implement the eCos system clock and the microsecond delay function. Other on-chip devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (SPI, MCI etc.) are not touched.

Tools

The CSB337 port is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.2.1, arm-elf-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing the CSB337 board for eCos Development

Overview

In a typical development environment, the CSB337 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector.	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. RedBoot also supports ethernet communication and flash management.

Initial Installation

Flash Installation

The CSB337 boards are shipped from Cogent with a version of Micromonitor installed.

Installing RedBoot is a matter of downloading a new binary image and overwriting the existing Micromonitor ROM image. This is a two stage process, you must first download a RAM-resident version of RedBoot and then use that to download the ROM image to be programmed into the flash memory.

Connect a serial cable between the CSB337 board serial port 0 and a host computer and start a terminal emulator such as HyperTerminal. Experiments indicate that the version of the Xmodem protocol used by Micromonitor is incompatible with that used by the Linux minicom program. It does work with HyperTerminal, so at present RedBoot must be installed from a Windows host.

When Micromonitor starts up you will see something similar to this:

```
TFS Scanning //FLASH/...
EMAC: Auto-Negotiate Complete, Link = 100MBIT, Full Duplex.
MICRO MONITOR
CPU: AT91RM9200 ARM920T
Platform: Cogent CSB337 - AT91RM9200 SBC
Built: Jan_29,2004 @ 11:42:57
Monitor RAM: 0x20000000-0x2001a044
Application RAM Base: 0x20100000
MAC: 00:23:31:37:00:01
IP: 192.168.254.210
uMON>
```

Start the download by giving the following command to Micromonitor:

```
uMON>xmodem -d -a 0x20040000
```

You may get a sequence of binary characters, which indicate that Micromonitor is waiting for the download to start. Use HyperTerminal's X-Modem file transfer option to send the file `redboot_RAM.bin`.

When the transfer is finished you will see something like:

```
Rcvd 868 pkts (111104 bytes)
EMAC: Auto-Negotiate Complete, Link = 100MBIT, Full Dupex.
uMON>
```

Start RedBoot with the **call** command, which should result in RedBoot starting up.

```
uMON>call 0x20040040
+Ethernet eth0: MAC address 00:23:31:37:00:1c
IP: 10.0.0.210/255.255.255.0, Gateway: 10.0.0.1
Default server: 10.0.0.102, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [RAM]
Non-certified release, version v2_0_11a1 - built 13:21:01, Feb 12 2004

Platform: Cogent CSB337 (ARM9)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x02000000, [0x00065e40-0x01fdd000] available
FLASH: 0x60000000 - 0x60800000, 64 blocks of 0x00020000 bytes each.
RedBoot>
```

Now the ROM image can be downloaded using the following RedBoot command:

```
RedBoot> load -r -b %{FREEMEMLO} -m xmodem
```

Again, use HyperTerminal's Xmodem support to send the file `redboot_ROMRAM.bin`. This should result in something like the following output:

```
Raw file loaded 0x00030000-0x0004d15f, assumed entry at 0x00030000
xyzModem - CRC mode, 932(SOH)/0(STX)/0(CAN) packets, 3 retries
RedBoot>
```

Once the file has been uploaded, you can check that it has been transferred correctly using the **cksum** command. On the host (Linux or Cygwin) run the **cksum** program on the binary file:

```
$ cksum redboot_ROMRAM.bin
2299507324 119136 redboot_ROMRAM.bin
```

In RedBoot, run the **cksum** command on the data that has just been loaded:

```
RedBoot> cksum -b %{FREEMEMLO} -l 119136
POSIX cksum = 2299507324 119136 (0x890fb27c 0x0001d160)
```

The second number in the output of the host **cksum** program is the file size, which should be used as the argument to the `-l` option in the RedBoot **cksum** command. The first numbers in each instance are the checksums, which should be equal.

If the program has downloaded successfully, then it can be programmed into the flash using the following commands:

```
RedBoot> fis init -f
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x60020000-0x607e0000: ..................................
... Erase from 0x60800000-0x60800000:
... Unlock from 0x607e0000-0x60800000: .
... Erase from 0x607e0000-0x60800000: .
... Program from 0x01fe0000-0x02000000 at 0x607e0000: .
... Lock from 0x607e0000-0x60800000: .
RedBoot> fis create -b %{FREEMEMLO} RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x60000000-0x60020000: .
... Program from 0x00100000-0x00120000 at 0x60000000: .
... Unlock from 0x607e0000-0x60800000: .
... Erase from 0x607e0000-0x60800000: .
... Program from 0x01fe0000-0x02000000 at 0x607e0000: .
... Lock from 0x607e0000-0x60800000: .
RedBoot>
```

The CBS337 board may now be reset either by cycling the power, pressing the reset switch, or with the **reset** command. It should then display the startup screen for the ROMRAM version of RedBoot.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROMRAM version of RedBoot for the CSB337 are:

```
$ mkdir redboot_csb337_romram
$ cd redboot_csb337_romram
$ ecosconfig new csb337 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/csb337/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

To rebuild the RAM version of RedBoot:

```
$ mkdir redboot_csb337_ram
$ cd redboot_csb337_ram
$ ecosconfig new csb337 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/csb337/current/misc/redboot_RAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This is the case for both the above builds, take care not to mix the two files up, since programming the RAM RedBoot into the ROM will render the board unbootable.

Name

Configuration — Platform-specific Configuration Options

Overview

The CSB337 platform HAL package is loaded automatically when eCos is configured for a `csb337` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The CSB337 platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x10000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROM-RAM
: This startup type can be used for finished applications which will be programmed into flash at physical location 0x10000000. However, when it starts up the application will first copy itself to RAM at 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The CBS337 board contains an 8Mb Intel StrataFlash flash device. The `CYGPKG_DEVS_FLASH_STRATA` package contains all the code necessary to support these parts and the `CYGPKG_DEVS_FLASH_CSB337` package contains definitions that customize the driver to the CSB337 board.

Ethernet Driver

The CSB337 board uses the AT91RM9200's internal EMAC ethernet device attached to an external Intel LXT971 PHY. The `CYGPKG_DEVS_ETH_ARM_AT91RM9200` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_ARM_CSB337` package contains definitions that customize the driver to the CSB337 board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There is just one flag specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM920T CPU in the AT91RM9200.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the CSB337 hardware, and should be read in conjunction with that specification. The CSB337 platform HAL package complements the ARM architectural HAL and the ARM9 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM or ROMRAM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash

This is located at address 0x10000000 of the physical memory space. However, the HAL uses the MMU to relocate it to virtual address 0x60000000 after initialization.

SDRAM

This is located at address 0x20000000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x20000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x00040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is entirely reserved for use by the ethernet interface, since there are problems using external SDRAM for ethernet buffers.

On-chip Peripheral Registers

These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

Apart from the SDRAM, flash and ethernet PHY, eCos does not currently make any use of the off-chip peripherals present on the CSB337.

Other Issues

The CSB337 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 253. SSV DNP/9200 with DNP/EVA9 Board Support

Name

eCos Support for the SSV DNP/9200 with DNP/EVA9 Evaluation Board — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the DNP/9200 with DNP/EVA9 evaluation board as provided in the SSV SK23 starter kit. This kit provides the AT91RM9200 processor, 32Mbytes of SDRAM, 16Mbytes of parallel NOR flash memory, a Davicom DM9161A PHY, a SD/MMC/DataFlash socket, a DAC, external connections for two serial channels, ethernet, USB host/device and the various other peripherals supported by the AT91RM9200. eCos support for the many devices and peripherals on the boards and the AT91RM9200 is described below.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot into this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the AT91RM9200 processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The parallel NOR flash memory consists of 128 blocks of 128Kbytes each. In a typical setup, the first 256 Kbytes are reserved for the use of the ROMRAM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining blocks can be used by application code. There are 126 blocks available between 0x60030000 and 0x60FDFFFF.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The serial port at J6 COM1 (connected to USART channel 1) and DTE port at J7 COM2 (connected to USART channel 2) can be used by RedBoot for communication with the host. If either of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the DNP/9200 target.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91RM9200` for the on-chip ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the DNP/9200 target.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91RM9200`. This driver is also loaded automatically when configuring for the DNP/9200 target.

There is a driver for the on-chip real-time clock (RTC) at `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91`. This driver is also loaded automatically when configuring for the DNP/9200 target.

The AT91RM9200 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91RM9200. This type of bus is also known as I²C®. Further documentation may be found in the AT91RM9200 processor HAL documentation.

The AT91RM9200 processor HAL contains a driver for the MultiMedia Card Interface (MCI). This driver is loaded automatically when configuring for the DNP/9200 target and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation may be found in the AT91RM9200 processor HAL documentation.

There is a general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the DNP/9200 target.

In general, devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The DNP/9200 support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the DNP/9200 with DNP/EVA9 evaluation board for eCos Development

Overview

In a typical development environment, the DNP/9200 board boots from the parallel NOR Flash and run the RedBoot ROM monitor directly. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`
JTAG	RedBoot running from RAM, loaded via JTAG	`redboot_JTAG.ecm`	`redboot_JTAG.bin`
UBOOT	RedBoot running from RAM, loaded via U-Boot	`redboot_UBOOT.ecm`	`redboot_UBOOT.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

The ample provision of RAM memory on the board allows the ROMRAM version of RedBoot to be preferential to the standard ROM version which executes directly from Flash. Alternatively, if the ROM version is to be chosen, then the RAM version is provided to allow for updating the resident RedBoot image in Flash. The JTAG version is only used if loading RedBoot into RAM via a JTAG debugger or ICE. It is similar to the RAM version, but loads at a lower address within RAM, and so can be used to in turn load eCos applications, as if it is the normal resident boot monitor. The ELF format image of this JTAG version of RedBoot can also be loaded and executed from GDB using the Abatron BDI2000 bdiGDB support, to allow it to be debugged. The UBOOT version may be used to load RedBoot into RAM using the UBOOT bootloader. This is usually only used to then load a ROMRAM executable for programming into flash. Like the JTAG version it loads at a lower RAM address and can therefore be used to load RAM applications.

Initial Installation

The on-chip boot program on the AT91RM9200 is only capable of loading programs into 12Kbytes of on-chip SRAM and is therefore quite restrictive. Consequently two mechanisms are described below to program RedBoot into Flash. The first requires a JTAG device while the other makes use of the U-Boot bootloader that is shipped with the board.

Method 1 - Program RedBoot into Flash with RAM RedBoot loaded by JTAG

With this approach, the BDI2000 is used to load a RAM RedBoot image, which can then in turn be used to load and program a ROMRAM RedBoot image into Flash. In the following documentation it is assumed that the Abatron BDI2000 is being used. For a different JTAG device, equivalent operations will need to be performed.

There are three stages, firstly loading the RAM RedBoot image, then initializing RedBoot's Flash configuration, and finally loading and programming the ROMRAM RedBoot. First, however, we must set up the BDI2000 and the board.

Preparing the Abatron BDI2000 JTAG debugger

The BDI2000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.

2. Connect the Abatron BDI2000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI2000.

3. Install the Abatron BDI2000 bdiGDB support software on the host PC.

4. Locate the file `bdi2000.dnp_sk23.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/arm/arm9/dnp_sk23/`*`VERSION`*`/misc` relative to the root of your eCos installation.

5. Locate the file `reg920t.def` within the installation of the BDI2000 bdiGDB support software.

6. Place the bdi2000.dnp_sk23.cfg in a location on the PC accessible to the TFTP server. Later you will configure the BDI2000 to load this file via TFTP as its configuration file.

7. Similarly place the file `reg920t.def` in a location accessible to the TFTP server.

8. Open `bdi2000.dnp_sk23.cfg` in an editor such as emacs or notepad and if necessary adjust the path of the `reg920t.def` file in the `[REGS]` section to match its location relative to the TFTP server root.

9. Install and configure the Abatron BDI2000 in line with the bdiGDB instruction manual. Configure the BDI2000 to use the `bdi2000.dnp_sk23.cfg` configuration file at the appropriate point of this process.

Preparing the DNP/9200 with DNP/EVA9 evaluation board for programming

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a null modem DB9 serial cable between COM1 on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to your host PC's LAN with an Ethernet cable.

4. You should designate the board with a new Ethernet MAC address. The RedBoot binary image contains a default address, but each board requires its own unique address. It is advisable to mark each board with its programmed MAC address for future identification.

5. Connect the board to the BDI2000 using a 20-pin ARM/Xscale cable from the JTAG interface connector on the DNP/9200 to the Target A port on the BDI2000. Since the JTAG connector on the DNP/9200 is non-standard, this will require an adaptor cable.

6. Power up the DNP/EVA9 board. You should see the power LED and some of the ethernet LEDs illuminate.

7. Connect to the BDI2000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

   ```
   Core#0>
   ```

8. Confirm correct connection with the BDI2000 with the **reset halt** command as follows:

```
Core#0> reset halt
- TARGET: processing reset request
- TARGET: BDI asserts TRST and RESET
- TARGET: BDI removes TRST
- TARGET: Bypass check 0x00000001 => 0x00000001
- TARGET: JTAG exists check passed
- Core#0: ID code is 0x05B0203F
- TARGET: All ICEBreaker access checks passed
- TARGET: BDI removes RESET
- TARGET: BDI waits for RESET inactive
- TARGET: resetting target passed
- TARGET: processing target startup ....
- TARGET: processing target startup passed
Core#0>
```

9. Locate the `redboot_ROMRAM.bin` image within the `loaders` subdirectory of the base of the eCos installation.

10. Copy the `redboot_ROMRAM.bin` file into a location on the host computer accessible to its TFTP server.

Loading a RAM RedBoot

1. Locate the `redboot_JTAG.bin` image within the `loaders` subdirectory of the base of the eCos installation.

2. Copy the `redboot_JTAG.bin` file into a location on the host computer accessible to its TFTP server.

3. With the BDI2000 telnet interface, execute the following command, replacing *`/RBPATH`* with the location of the redboot_JTAG.bin file relative to the TFTP server root directory:

```
Core#0>load 0x20010000 /RBPATH/redboot_JTAG.bin bin
Loading /RBPATH/redboot_JTAG.bin , please wait ....
Loading program file passed
Core#0>
```

4. Run the loaded RAM RedBoot:

```
Core#0>go 0x20010040
Core#0>
```

The terminal emulator connected to the serial debug port should now have displayed the RedBoot banner and prompt similar to the following:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
PHY: Davicom DM9161A
AT91RM9200 ETH: Waiting for link to come up.
AT91RM9200 ETH: 100Mb
... waiting for BOOTP information
Ethernet eth0: MAC address 00:23:31:37:00:1c
IP: 10.0.2.9/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.2, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [RAM]
Non-certified release, version UNKNOWN - built 17:10:26, Jun  8 2006

Platform: DNP/9200 with DNP/EVA9 (ARM9)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006 eCosCentric Limited

RAM: 0x20000000-0x20800000, [0x2002f2e0-0x207dd000] available
FLASH: 0x60000000-0x60ffffff, 128 x 0x20000 blocks
RedBoot>
```

In the above output, a local BOOTP/DHCP server was able to serve an address to the device.

Note

It is also possible to use the RAM startup version of RedBoot and the redboot_RAM.bin file instead of redboot_JTAG.bin above. If so, then the address to the **load** command must be 0x20100000, as must be the address to the **go** command.

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration. This must be performed when using a RAM RedBoot to program Flash.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Unlocking from 0x60fe0000-0x60ffffff: .
... Erase from 0x60fe0000-0x60ffffff: .
... Program from 0x207e0000-0x20800000 to 0x60fe0000: .
... Locking from 0x60fe0000-0x60ffffff: .
RedBoot>
```

2. Now configure RedBoot's Flash configuration with the command:

```
RedBoot> fconfig -i
```

Remember to substitute the appropriate MAC address for this board at the appropriate step. If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.7.11
Local IP address: 192.168.7.222
Local IP address mask: 255.255.255.0
Default server IP address: 192.168.7.9
Console baud rate: 115200
DNS server IP address: 192.168.7.11
Network hardware address [MAC]: 0x00:0x23:0x31:0x37:0x00:0x4e
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Default network device: at91rm9200_eth
Update RedBoot non-volatile configuration - continue (y/n)? y
... Unlocking from 0x60fe0000-0x60ffffff: .
... Erase from 0x60fe0000-0x60ffffff: .
... Program from 0x207e0000-0x20800000 to 0x60fe0000: .
... Locking from 0x60fe0000-0x60ffffff: .
RedBoot>
```

Loading and programming the ROMRAM RedBoot

This section describes the steps required to load the ROMRAM RedBoot from the TFTP server and program it into Flash.

1. Load the RedBoot ROMRAM binary image from the TFTP server. Use the following command, replacing *`111.222.333.444`* with the TFTP server IP address (or domain name if a DNS server has been configured), and *`/RBPATH`* with the location of the `redboot_ROMRAM.bin` file relative to the TFTP server root directory:

```
RedBoot> load -r -b %{freememlo} -h 111.222.333.444 /RBPATH/redboot_ROMRAM.bin
Using default protocol (TFTP)
Raw file loaded 0x20030000-0x2004e91b, assumed entry at 0x20030000
```

```
RedBoot>
```

2. Finally install the loaded image into Flash:

   ```
   RedBoot> fis create RedBoot
   An image named 'RedBoot' exists - continue (y/n)? y
   ... Erase from 0x60000000-0x6003ffff: ..
   ... Program from 0x20030000-0x2004e91c to 0x60000000: .
   ... Locking from 0x60000000-0x6003ffff: ..
   ... Unlocking from 0x60fe0000-0x60ffffff: .
   ... Erase from 0x60fe0000-0x60ffffff: .
   ... Program from 0x21fe0000-0x22000000 to 0x60fe0000: .
   ... Locking from 0x60fe0000-0x60ffffff: .
   RedBoot>
   ```

   It is also possible to use the **fis write** command to write the image into Flash, but if so, the relevant Flash blocks must also be explicitly unlocked with the command:

   ```
   RedBoot> fis unlock -f 0x60000000 -l 0x30000
   ```

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. Output similar to the following should be seen on the serial port. Verify the IP settings are as expected.

```
+PHY: Davicom DM9161A
AT91RM9200 ETH: 100Mb
... waiting for BOOTP information
Ethernet eth0: MAC address 00:23:31:37:00:1c
IP: 10.0.2.9/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.2, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 18:10:00, Jun  8 2006

Platform: DNP/9200 with DNP/EVA9 (ARM9)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006 eCosCentric Limited

RAM: 0x20000000-0x22000000, [0x2002ff78-0x21fdd000] available
FLASH: 0x60000000-0x60ffffff, 128 x 0x20000 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Method 2 - Program RedBoot into Flash with RAM Redboot loaded by U-Boot

With this approach, the existing U-Boot bootloader is used to load a RAM RedBoot which is then used to load and program a ROMRAM RedBoot image to replace U-Boot in Flash. A JTAG debugger is not needed for this method.

There are three stages, firstly loading the RAM RedBoot image, then initializing RedBoot's Flash configuration, and finally loading and programming the ROMRAM RedBoot. The first of these stages is described here, the remaining two stages are identical to the equivalent stages in Method 1, above.

Loading a RAM RedBoot

1. First you must connect a null modem DB9 serial cable between COM1 on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. Connect the board to your host PC's LAN with an Ethernet cable.

4. You should designate the board with a new Ethernet MAC address. The RedBoot binary image contains a default address, but each board requires its own unique address. It is advisable to mark each board with its programmed MAC address for future identification.

5. Locate the `redboot_UBOOT.bin` image within the `loaders` subdirectory of the base of the eCos installation.

6. Copy the `redboot_UBOOT.bin` file into a location on the host computer accessible to its TFTP server.

7. Power up the DNP/EVA9 board. You should see the power LED and some of the ethernet LEDs illuminate.

8. After a few seconds the following output should be seen on the serial line. Hit a key to stop the auto boot:

```
U-Boot 1.1.2 (Dec 14 2005 - 13:12:14)

U-Boot code: 21F00000 -> 21F1666C  BSS: -> 21F1AC44
RAM Configuration:
Bank #0: 20000000 32 MB
Flash: 16 MB

In:    serial
Out:   serial
Err:   serial
Hit any key to stop autoboot:  0
U-Boot>
```

9. Set up the environment of U-Boot to download the RAM RedBoot. Users with access to a TFTP server should substitute their own IP address, TFTP server address and netmask in the following commands:

```
U-Boot> setenv ipaddr 10.0.2.22
U-Boot> setenv serverip 10.0.1.2
U-Boot> setenv netmask 255.0.0.0
U-Boot> setenv bootfile redboot_UBOOT.bin
```

10. Download the RAM RedBoot. Users with access to a TFTP server should use the following command:

```
U-Boot> tftpboot 0x20040000
TFTP from server 10.0.1.2; our IP address is 10.0.2.22
Filename 'redboot_UBOOT.bin'.
Load address: 0x20040000
Loading: ########################
done
Bytes transferred = 120760 (1d7b8 hex)
```

11. Users without access to a TFTP server may use Kermit to send the file `redboot_UBOOT.bin`:

```
U-Boot> loadb 0x20040000
```

12. The downloaded RedBoot image may now be executed:

```
U-Boot> go 0x20040000
.+PHY: Davicom DM9161A
AT91RM9200 ETH: 100Mb
... waiting for BOOTP information
Ethernet eth0: MAC address 00:23:31:37:00:1c
IP: 10.0.2.9/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.2, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [UBOOT]
Non-certified release, version UNKNOWN - built 18:18:48, Jun  8 2006

Platform: DNP/9200 with DNP/EVA9 (ARM9)
Copyright (C) 2000, 2001, 2002, 2003, 2004 Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006 eCosCentric Limited

RAM: 0x20000000-0x22000000, [0x20067040-0x21fdd000] available
```

```
FLASH: 0x60000000-0x60ffffff, 128 x 0x20000 blocks
RedBoot>
```

13.Now follow the directions in the previous method to initialize the flash and program the ROMRAM RedBoot.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROMRAM version of RedBoot for the DNP/9200 with DNP/EVA9 are:

```
$ mkdir redboot_dnp_sk23_romram
$ cd redboot_dnp_sk23_romram
$ ecosconfig new dnp_sk23 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/dnp_sk23/VERSION/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

The other versions of RedBoot - ROM, RAM, JTAG or UBOOT - may be similarly built by choosing the appropriate alternative .ecm file.

Name

Configuration — Platform-specific Configuration Options

Overview

The DNP/9200 with DNP/EVA9 platform HAL package is loaded automatically when eCos is configured for `dnp_sk23` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x10000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROMRAM
: This startup type can be used for finished applications which will be programmed into flash at physical location 0x10000000. However, when it starts up, the application will first copy itself to RAM at virtual address 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The DNP/9200 board contains a 16Mbyte Intel 28F128J3 parallel Flash device. The `CYGPKG_DEVS_FLASH_STRATA_V2` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Ethernet Driver

The DNP/9200 board uses the AT91RM9200's internal EMAC ethernet device attached to an external Davicom DM9161 PHY. The `CYGPKG_DEVS_ETH_ARM_AT91RM9200` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the DNP/9200 board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The DNP/9200 board uses the AT91RM9200's internal RTC support. The `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91` package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The DNP/9200 board uses the AT91RM9200's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91RM9200` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91RM9200_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

USART Serial Driver

The DNP/9200 board uses the AT91RM9200's internal USART serial support as described in the AT91RM9200 processor HAL documentation. Two serial ports are available: USART 1 which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/ser1`" in the interrupt-driven driver; and USART 2 which is mapped to virtual vector channel 1 and "`/dev/ser2`". Both UARTs support modem control signals such as those used for hardware flow control.

MCI Driver

As described in the SSV board documentation, in order to use the MMC/SD socket on the EVA9 board, the JP8 jumper block must have all jumpers in place, i.e. closed . The SPI jumper block JP9 must have all jumpers removed, i.e. open.

As the AT91RM9200 MCI driver is part of the AT91RM9200 HAL, nothing is required to load it. Similarly the MMC/SD bus driver layer (`CYGPKG_DEVS_DISK_MMC`) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (`CYGPKG_IO_DISK`), along with the intended filesystem, typically, the FAT filesystem (`CYGPKG_FS_FAT`) and any of its package dependencies (including `CYGPKG_LIBC_STRING` and `CYGPKG_LINUX_COMPAT` for FAT).

Various options can be used to control specific of the AT91RM9200 MCI driver. Consult the AT91RM9200 HAL documentation for information on its configuration.

On this target, it is not possible to detect from the MMC/SD socket whether cards have been inserted or removed. Thus the disk I/O layer's removeable media support will not detect when cards have been inserted or removed, and therefore the only way to detect if a card has been inserted is to attempt mounts.

The MMC/SD socket also does not permit detection of the write-protect (or "lock") switch present on SD cards. "Locked" cards will therefore not be detected which means that despite the switch position, it is still possible to write to them since the lock switch does not physically enforce write protection.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM920T CPU in the AT91RM9200.

`-mthumb`
The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded RAM applications, or even applications resident in ROM, including RedBoot.

Debugging of ROM applications is only possible if using hardware breakpoints. The ARM920T core of the AT91RM9200 only supports two such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI2000 notes

On the Abatron BDI2000, the `bdi2000.dnp_sk23.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `bdi2000.dnp_sk23.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI2000 command line interface to make the changes take effect.

On the BDI2000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the bdiGDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI2000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI2000 is powered up, the target will always run the initialization section of the `bdi2000.dnp_sk23.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a ROMRAM RedBoot is resident in Flash, it will be run.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
Core#0>load 0x20008000 /test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
Core#0>go 0x20008000
```

Consult the BDI2000 documentation for information on other formats.

Configuration of RAM applications

If the JTAG device has initialized the SDRAM, such as by using the `bdi2000.dnp_sk23.cfg` configuration on the BDI2000, RAM applications can be loaded directly into SDRAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. This will also cause the `CYGBLD_HAL_ARM9_ATMEL_AT91RM9200_KITS_LOAD_LOW_RAM` configuration option to be enabled allowing the application to be built with a set of memory layout files that will configure the linker script to set the program load address to be within the physical SDRAM space. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets.

Running RAM applications

Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USART 1 can be chosen instead by setting the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` configuration option in the platform HAL to channel 1.

Warning

If resetting the board using the JTAG device, such as by using the BDI2000 **reset** command, the Ethernet PHY fails to interface correctly with the AT91RM9200, and consequently all subsequent ethernet operations are impossible. Only a reset by pressing the reset button, cycling the power or due to a watchdog timeout will cause the PHY to reset correctly.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the DNP/9200 and DNP/EVA9 hardware, and should be read in conjunction with that specification. The DNP/9200 with DNP/EVA9 platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the AT91RM9200 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM or ROMRAM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash

This is located at address 0x10000000 of the physical memory space. The HAL uses the MMU to locate it at virtual address 0x60000000 after initialization. It remains accessible at address 0x1000000 but accesses to this address range are uncached.

SDRAM

This is located at address 0x20000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x20000000, but in order to assign hardware exception vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x30000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x00100000, with the bottom 1MB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is entirely reserved for use by the ethernet interface, since there are problems using external SDRAM for ethernet buffers.

On-chip ROM

This is located at address 0x00100000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x71000000. The same memory is also accessible uncached and unbuffered at virtual location 0x71800000.

USB host port

The USB host port (UHP) registers are located at address 0x00300000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x72800000. Memory accessed at this address is uncached and unbuffered. There is no cached variant.

On-chip Peripheral Registers	These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.
Off-chip Peripherals	eCos uses the SDRAM, parallel NOR flash, ethernet PHY of the DNP/9200 board. eCos does not currently make any use of any other off-chip peripherals present on this board.

Advanced Interrupt Controller

This port has been designed to exploit benefits of the Advanced Interrupt Controller of the AT91RM9200, using the facilities of the AT91RM9200 processor HAL. Consult the documentation in that package for details.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 253.1. dnp_sk23 Real-time characterization

```
            Startup, main stack : stack used   416 size  3920
             Startup :  Interrupt stack used   524 size  4096
             Startup : Idlethread stack used    92 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   13.69 microseconds (6 raw clock ticks)

Testing parameters:
   Clock samples:            32

```

Other Issues

The DNP/9200 with DNP/EVA9 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The AT91RM9200 processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 254. KwikByte KB920x Board Family Support

Name

eCos Support for the KB920x Board Family — Overview

Description

This document covers the KwikByte KB920x family of single board computers based on the Atmel AT91RM9200. The KB9200 contains the AT91RM9200 processor, 32Mb of SDRAM, 2MB of flash memory, an Intel LXT971 PHY and external connections for one serial channel, ethernet and the various other peripherals supported by the AT91RM9200. The KB9201 is similar but with an additional SPI dataflash. The KB9202 uses a different flash memory device and increases the flash memory capacity to 16MB. The KB9202B extends SDRAM to 64MB, and the KB9202C replaces the NOR flash with Dataflash.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot into this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

On the KB9200 and KB9201, the flash memory consists of 32 blocks of 64k bytes each. On the KB9202, the flash memory consists of 128 blocks of 128k bytes each. In a typical setup, the first two flash blocks are used for the ROMRAM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining blocks can be used by application code. For the KB9200/KB9201 these are 29 blocks between 0x60020000 and 0x601EFFFF; for the KB9202 these are 125 blocks between 0x60020000 and 0x60FDFFFF.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. These devices can be used by RedBoot for communication with the host. If either of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the KB9200, KB9201 or KB9202 targets.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91RM9200` for the on-chip ethernet device. A second package `CYGPKG_DEVS_ETH_ARM_KB9200` is responsible for configuring this generic driver to the KB920x hardware. These drivers are also loaded automatically when configuring for the KB9200, KB9201 or KB9202 targets.

eCos manages the on-chip interrupt controller. Timer counter 0 is used to implement the eCos system clock and the microsecond delay function. Other on-chip devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded.

Tools

The KB920x port is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.3.3, arm-elf-gdb version 6.1, and binutils version 2.14, and subsequently retested with arm-elf-gcc version 3.4.3, arm-elf-gdb version 6.3 and binutils version 2.16.

Name

Setup — Preparing the KB920x boards for eCos Development

Overview

In a typical development environment, the KB920x boards boot from serial EEPROM into the KwikByte bootloader, which then boots the RedBoot ROM monitor from flash. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector.	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`
SRAM	RedBoot running from RAM, loaded by bootloader.	`redboot_SRAM.ecm`	`redboot_SRAM.bin`
UBOOT	RedBoot running from RAM, loaded from flash by U-Boot.	`redboot_UBOOT.ecm`	`redboot_UBOOT.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Generally only the ROMRAM version of RedBoot is used. The SRAM version is suitable only for RedBoot development and should not normally be used. On the KB9202C the UBOOT version is used.

Initial Installation -- KB9201, KB9202, KB9202B

The KB920x boards are shipped from KwikByte with the EEPROM bootloader installed and a version of Linux installed in the flash. The KB9202C board has a different installation method, described in the next section.

Installing RedBoot is a matter of downloading a new binary image and overwriting the existing Linux image. This is a two stage process, you must first download the KwikByte RAM Monitor, which is then used to download a RedBoot image and program it into the flash. To achieve this you will need a copy of the `ramMonitor.bin` image and, for Linux hosts, a copy of the KwikByte **download** tool. Both of these can be found on the CD-ROM that comes with the board. Note that the prebuilt version of the **download** tool is hardcoded to use `/dev/ttyS0` for downloads.

Connect a straight-through serial cable between the KB920x board serial port and a serial port of the host computer and start a terminal emulator such as **minicom** or HyperTerminal. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit. Press the Reset button on the board and when the bootloader starts you should see something similar to this if using the KB9200 or KB9201:

```
KB9200(www.kwikbyte.com)
        Default system configuration complete

Checking for input

>
```

When you see the "Checking for input" line, hit the Return key to put the bootloader into its command interpreter, otherwise it will proceed to boot Linux.

For the KB9202 there is less output, and the delay shorter, and so you will need to press the Return key several times immediately after pressing the Reset button before the bootloader banner is displayed:

```
KB9202(www.kwikbyte.com)

Auto boot..

>
```

The next step is to install a new startup command in the command table:

```
>s 1 e 0x10000000

>w

>
```

It is now necessary to download the Kwikbyte RAM Monitor. Start the download by giving the following command to the bootloader:

```
>x 0x20002000
C
```

You may get a sequence of C characters, which indicate that the bootloader is waiting for the download to start. If using HyperTerminal, you should now send the `ramMonitor.bin` file from the KwikByte CD-ROM using the Xmodem protocol. If using **minicom**, exit **minicom** and download the RAM Monitor using the following command:

```
$ download ramMonitor.bin
```

The **download** command produces a lot of output. When the transfer is finished, restart **minicom**.

Having downloaded the RAM monitor, issue the following command to start it:

```
>e 0x20002000

Entry: RAM Monitor

>
```

It is now necessary to prepare the flash for the RedBoot image by erasing the first 128K bytes. The RedBoot ROM image can then be downloaded:

```
>f e 0x10000000 0x1001ffff
Verifying sector erase
Flash sector erase at: 0x10000000 PASS
Verifying sector erase
Flash sector erase at: 0x10010000 PASS

>x 0x20100000
C
```

If using HyperTerminal, you should now send the `redboot_ROMRAM.bin` file using the Xmodem protocol. If using **minicom**, exit **minicom** and use the **download** command to send the file `redboot_ROMRAM.bin`. When the transfer is finished, restart **minicom**.

Having downloaded the RedBoot image, use the following command to write it to flash:

```
>f p 0x10000000 0x20100000 0x20000
..
Flash program status: PASS
```

```
>
```

The KB920x board may now be reset. It should then display the following startup sequence. Run the **fis init** and **fconfig -i** commands to initialize the flash, as shown. Note that KB9202 users will see output similar but not identical to that below.

```
KB9200(www.kwikbyte.com)
        Default system configuration complete

RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Initial Installation -- KB9202C

The KB9202C is not equipped with NOR flash, only Dataflash, so the installation method described above will not work. This board boots, via a second-stage loader into U-Boot. By default U-Boot then boots a Linux image that is also stored in Dataflash. The approach described here is to cause U-Boot to boot RedBoot instead of Linux. The following directions give basic instructions for installing RedBoot, for more details of how to configure U-Boot, please refer to the U-Boot documentation.

Connect a straight-through serial cable between the KB920C board serial port and a serial port of the host computer and start a terminal emulator such as **minicom** or HyperTerminal. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit. Power the board up and you should see the KwikByte loader and U-Boot startup messages. When it gets to the "Hit any key to stop autoboot" line, type any key. There is only a 1 second timeout here, so you need to be quick, or you can type ahead during the delay after the "NAND:" line. The final output should look like this:

```
KwikByte KB9202x Copy Loader v0.9
Loading boot loader. . . done

U-Boot 1.2.0 (Sep 26 2007 - 17:32:22)

DRAM:  64 MB
NAND:  NAND device: Manufacturer ID: 0x2c, Chip ID: 0xda (Micron NAND 256MiB 3,3V 8-bit)
256 MiB
DataFlash:AT45DB642
Nb pages:   8192
Page Size:   1056
Size= 8650752 bytes
Logical address: 0xC0000000
Area 0: C0000000 to C00020FF      Copy Loader (8kB)
Area 1: C0002100 to C00041FF      Environment (8kB)
Area 2: C0004200 to C003665F      U-Boot (195kB)
Area 3: C0036660 to C0041FFF      Secondary Boot (45kB)
Area 4: C0042000 to C0461FFF      OS (4MB)
Area 5: C0462000 to C083FFFF      DF_SPARE
In:    serial
Out:   serial
Err:   serial
Hit any key to stop autoboot:  0
KB920x >
```

Now we need to set up U-Boot to download the RedBoot image and program it into the DataFlash. First it is necessary to change U-Boot's environment to allow the image to be downloaded. In this example we will be downloading via tftp, so we need to set the ethernet and IP addresses for this board:

```
KB920x >setenv ethaddr 00:D0:93:00:05:B5
KB920x >setenv ipaddr 10.0.3.1
KB920x >setenv serverip 10.0.1.2
KB920x >saveenv
KB920x >printenv
bootargs=console=ttyS0,115200 noinitrd root=/dev/mtdblock0 rootfstype=jffs2 mem=
64M
bootdelay=1
baudrate=115200
hostname=KB9202C
kernel-size=31c8d0
bootcmd=cp.b c0042000 23000000 31c8d0; bootm 23000000
ethaddr=00:D0:93:00:05:B5
ipaddr=10.0.3.1
serverip=10.0.1.2
stdin=serial
stdout=serial
stderr=serial

Environment size: 307/8444 bytes
KB920x >
```

In the above example the `ipaddr` and `serverip` variables are set to example values. They should be set to the address of this board and the address of the TFTP server in your own network. The `redboot_UBOOT.bin` should be copied to the tftp server's root directory. It may now be downloaded:

```
KB920x >tftp 0x20100000 redboot_UBOOT.bin
TFTP from server 10.0.1.2; our IP address is 10.0.3.1
Filename 'redboot_UBOOT.bin'.
Load address: 0x20100000
Loading: T ###################
done
Bytes transferred = 94236 (1701c hex)
KB920x >
```

Now program the loaded binary into flash. In the following example, the new binary is installed into dataflash at offset 0x500000. This avoids overwriting the Linux image at offset 0x42000. If the Linux image is not required, RedBoot can be programmed in its place and the addresses in the following commands adjusted to match.

```
KB920x >cp.b 0x20100000 0xc0500000 0x20000
Copy to DataFlash... done
KB920x >
```

Finally, change the default boot command to load and execute RedBoot rather than Linux. Make sure to include the backslash before the semicolon.

```
KB920x >setenv bootcmd cp.b 0xc0500000 0x20100000 0x20000\; go 0x20100000
KB920x >saveenv
Saving Environment to dataflash...
```

Press the reset button on the board and the full boot sequence should be seen:

```
KwikByte KB9202x Copy Loader v0.9
Loading boot loader. . . done

U-Boot 1.2.0 (Sep 26 2007 - 17:32:22)

RedBoot>
```

If it is necessary to reinstall RedBoot, the above steps for downloading and programming the new image should be repeated.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROMRAM version of RedBoot for the KB9200 are:

```
$ mkdir redboot_kb9200_romram
$ cd redboot_kb9200_romram
$ ecosconfig new kb9200 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/kb9200/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The steps needed to rebuild the the ROMRAM version of RedBoot for the KB9202 are:

```
$ mkdir redboot_kb9202_romram
$ cd redboot_kb9202_romram
$ ecosconfig new kb9202 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/kb9200/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The steps needed to rebuild the the UBOOT version of RedBoot for the KB9202C are:

```
$ mkdir redboot_kb9202c_uboot
$ cd redboot_kb9202c_uboot
$ ecosconfig new kb9202c redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/kb9200/current/misc/redboot_UBOOT.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The KB920x platform HAL package is loaded automatically when eCos is configured for a `kb9200` or `kb9202` targets. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The KB920x platform HAL package supports four separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x10000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROM-RAM
: This startup type can be used for finished applications which will be programmed into flash at physical location 0x10000000. However, when it starts up the application will first copy itself to RAM at 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

SRAM
: This startup type is used for applications that are downloaded via the KwikByte bootloader directly to RAM. The application is loaded into SDRAM at location 0x20000000 and started by executing from that address. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform limited hardware initialization since it is assumed that the machine has been set up already by the bootloader.

  This configuration is primarily present as a result of the development process. It has some limitations with regard to functionality since the MMU is not enabled and no exception vectors are installed at location zero, hence no interrupts can be handled.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The KB9200 and KB9201 boards contain a 2Mb AMD Am29LV017D flash device. The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX` package contains all the code necessary to support this part and the `CYGPKG_DEVS_FLASH_KB9200` package contains definitions that customize the driver to the KB9200 board.

The KB9202 board contains a 16Mb Intel StrataFLASH 28F128J3 flash device. The `CYGPKG_DEVS_FLASH_STRATA_V2` package contains all the code necessary to support this part and the platform HAL contains definitions that customize the driver to the KB9202 board.

Ethernet Driver

The KB920x boards use the AT91RM9200's internal EMAC ethernet device attached to an external Intel LXT971 PHY. The `CYGPKG_DEVS_ETH_ARM_AT91RM9200` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_ARM_KB9200` package contains definitions that customize the driver to the KB920x boards.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There is just one flag specific to this port:

`-mcpu=arm9`

The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM920T CPU in the AT91RM9200.

`-mthumb`

The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used.

`-mthumb-interwork`

This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the KB920x hardware, and should be read in conjunction with that specification. The KB920x platform HAL package complements the ARM architectural HAL and the ARM9 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM or ROMRAM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash

This is located at address 0x10000000 of the physical memory space. The HAL uses the MMU to locate it at virtual address 0x60000000 after initialization. It remains accessible at address 0x1000000 but accesses to this address range are uncached.

SDRAM

This is located at address 0x20000000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x20000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x00040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is entirely reserved for use by the ethernet interface, since there are problems using external SDRAM for ethernet buffers.

On-chip Peripheral Registers

These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

Apart from the SDRAM, flash and ethernet PHY, eCos does not currently make any use of the off-chip peripherals present on the KB920x boards.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in Thumb mode, which provided better performance than ARM mode.

Example 254.1. kb9200 Real-time characterization

```
            Startup, main stack : stack used   336 size  3920
             Startup :  Interrupt stack used   492 size  4096
             Startup : Idlethread stack used    88 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took   15.40 microseconds (7 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  64
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32

Other Issues

The KB920x platform HAL does not affect the implementation of other parts of the eCos HAL specification. The ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 255. Motorola MX1ADS/A Board Support

Name

eCos Support for the MX1ADS/A Board — Overview

Description

This document covers the Motorola MX1ADS/A single board computer based on the Motorola MC9328MX1. This platform is both hardware and software compatible with the MXLADS/A, which contains a MC9328MXL; all references to the MX1ADS/A and MC9328MX1 should also be taken to refer to the MXLADS/A and MC9328MXL except where explicitly stated.

The MX1ADS/A contains the MC9328MX1 processor, 64Mb of SDRAM, 32MB of flash memory, a CS8900A ethernet MAC, connections for two serial channels and the various other peripherals supported by the MC9328MX1. The MX1ADS/A is identical to the MXLADS/A except that in addition to the devices supported by the MXLADS/A, it contains support for Bluetooth, analogue signal processing and SIM cards. However, since eCos does not use these devices, there is no difference in the support available.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of two Am29PDL127H devices in parallel, giving 256 blocks of 128k bytes each. In a typical setup, the first flash block is used for the ROMRAM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining 254 blocks between 0x10020000 and 0x11FDFFFF can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_MC9328MXL` which supports the two UART serial devices on the MC9328MX1. This is configured for the MX1ADS/A by the `CYGPKG_IO_SERIAL_ARM_MX1ADS_A` package. These devices can be used by RedBoot for communication with the host. If either of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the MX1ADS/A target.

There is an ethernet driver `CYGPKG_DEVS_ETH_CL_CS8900A` for the Cirrus Logic CS8900A ethernet device. A second package `CYGPKG_DEVS_ETH_ARM_MX1ADS_A` is responsible for configuring this generic driver to the MX1ADS/A hardware. These drivers are also loaded automatically when configuring for the MX1ADS/A target.

eCos manages the on-chip interrupt controller. General Purpose Timer 1 is used to implement the eCos system clock and the microsecond delay function. The Watchdog Timer is also supported. Other on-chip devices (Caches, GPIO, UARTs, memory and interrupt controllers) are initialized only as far as is necessary for eCos to run. Other devices (SPI, I^{2}C, RTC etc.) are not touched.

Tools

The MX1ADS/A port is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.3.3, arm-elf-gdb version 6.1, and binutils version 2.14.

Name

Setup — Preparing the MX1ADS/A board for eCos Development

Overview

In a typical development environment, the MX1ADS/A board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
SRAM	RedBoot running from RAM, but loaded via the JTAG interface	`redboot_SRAM.ecm`	`redboot_SRAM.bin`
RAM	RedBoot running from RAM, usually loaded by another version of RedBoot	`redboot_RAM.ecm`	`redboot_RAM.bin`
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. RedBoot also supports ethernet communication and flash management.

Initial Installation

Installing RedBoot is a matter of downloading a new binary image and overwriting the existing Boot monitor ROM image.

There are two possible mechanisms for doing this, both via the JTAG interface. The first uses the ability of some JTAG debuggers to write directly to FLASH. The second merely uses the JTAG debugger to load a version of RedBoot and to then use that to program the FLASH.

Direct FLASH Programming

The following instructions describe how to install RedBoot by programming the FLASH directly from the JTAG debugger. At present this has only been tried using an Abatron BDI2000 debugger and these instruction apply to that device. However, it should be possible to adapt these instructions to any other device.

The BDI2000 configuration file needs to be set up to initialize the SDRAM and to tell it what type of FLASH device is present. The resulting config file is shown below:

```

FILE    regMX1.def
```

The BDI2000 needs to be rebooted to cause it to reload this configuration file. Once this is done connect to the BDI2000 via its telnet port and issue a reset command:

```
Core#0>reset
- TARGET: processing reset request
- TARGET: BDI asserts TRST and RESET
- TARGET: BDI removes TRST
- TARGET: Bypass check 0x000000001 => 0x00000001
- TARGET: JTAG exists check passed
- Core#0: ID code is 0x1092001D
- TARGET: All ICEBreaker access checks passed
- TARGET: BDI removes RESET
- TARGET: BDI waits for RESET inactive
- TARGET: resetting target passed
- TARGET: processing target startup ....
- TARGET: processing target startup passed
Core#0>
```

Now ensure that the FLASH is erased. The following command uses the `ERASE` entries in the configuration file to erase the first 9 blocks in the FLASH.

```
Core#0>erase
```

```
Erasing flash at 0x10000000
Erasing flash at 0x10004000
Erasing flash at 0x10008000
Erasing flash at 0x1000c000
Erasing flash at 0x10010000
Erasing flash at 0x10014000
Erasing flash at 0x10018000
Erasing flash at 0x1001c000
Erasing flash at 0x10020000
Erasing flash passed
Core#0>
```

Copy `redboot_ROMRAM.bin` to the root directory of the same TFTP server used to fetch the configuration file and execute the following command:

```
Core#0>prog 0x10000000 redboot_ROMRAM.bin bin
Programming redboot_ROMRAM.bin , please wait ....
Programming flash passed
Core#0>
```

If this completes successfully then the FLASH has been programmed. You can start RedBoot by issuing the **go** command, or by detaching the BDI2000 and cycling the power switch of the board. You should see the RedBoot startup screen:

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.0.207/255.255.255.0, Gateway: 10.0.0.3
Default server: 10.0.0.1, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 15:51:18, Jul 19 2004

Platform: Motorola MX1ADS/A (ARM9)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x02000000, [0x0002f778-0x01fdd000] available
FLASH: 0x10000000 - 0x12000000, 256 blocks of 0x00020000 bytes each.
RedBoot>
```

Download RedBoot

The following instructions describe how to install RedBoot via the JTAG interface by downloading a version of RedBoot to program the FLASH. This is a two stage process, you must first download a RAM-resident version of RedBoot and then use that to download the ROM image to be programmed into the flash memory. The following directions are necessarily somewhat general since the specifics depend on the exact JTAG device available, and the software used to drive it.

Connect the JTAG device to the JTAG connector on the MX1ADS/A board and check that the device is functioning correctly. Using 32 bit memory writes, initialize the static memory controller so that the SDRAM and flash are accessible. The following assignments should be made:

```
*(long *)0x00221000 = 0x92120200;  // Set Precharge Command
*(long *)0x08200000 = 0x00000000;  // Issue Precharge all Command
*(long *)0x00221000 = 0xa2120200;  // Set AutoRefresh Command
*(long *)0x08000000 = 0x00000000;  // Issue AutoRefresh Command
*(long *)0x08000000 = 0x00000000;
*(long *)0x08000000 = 0x00000000;
*(long *)0x08000000 = 0x00000000;
*(long *)0x08000000 = 0x00000000;
*(long *)0x08000000 = 0x00000000;
*(long *)0x08000000 = 0x00000000;
*(long *)0x08000000 = 0x00000000;
*(long *)0x00221000 = 0xb2120200;  // Set Mode Register
*(long *)0x08111800 = 0x00000000;  // Issue Mode Register Command, Burst Length = 8
*(long *)0x00221000 = 0x82124200;  // Set to Normal Mode
```

Now load the SRAM redboot binary image from the file `redboot_SRAM.bin` into SDRAM at 0x08040000. Exactly how you do this depends on the JTAG driver software. Note that it may be easier to load the ELF or SREC files, if supported, since these contain the correct load addresses.

Connect the serial port of a host machine to UART 1 on the MX1ADS/A board and start a terminal emulator (for example **HyperTerminal** on Windows, **minicom** on Linux) set up to communicate at 38400 baud, 8 bits, one stop bit, no parity. Start RedBoot by executing from location 0x08040000, which should result in RedBoot starting up and emitting this message on the serial channel:

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.0.207/255.255.255.0, Gateway: 10.0.0.3
Default server: 10.0.0.1, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [SRAM]
Non-certified release, version UNKNOWN - built 15:50:10, Jul 19 2004

Platform: Motorola MX1ADS/A (ARM9)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x08000000-0x0c000000, [0x08065ea0-0x0bfdd000] available
FLASH: 0x10000000 - 0x12000000, 256 blocks of 0x00020000 bytes each.
RedBoot>
```

Now the ROM image can be downloaded using the following RedBoot command:

```
RedBoot> load -r -b %{FREEMEMLO} -m ymodem
```

Use the terminal emulator's Ymodem support to send the file `redboot_ROMRAM.bin`. This should result in something like the following output:

```
Raw file loaded 0x08066000-0x080b900d, assumed entry at 0x08066000
xyzModem - CRC mode, 2659(SOH)/0(STX)/0(CAN) packets, 5 retries
RedBoot>
```

Once the file has been uploaded, you can check that it has been transferred correctly using the **cksum** command. On the host (Linux or Cygwin) run the **cksum** program on the binary file:

```
$ cksum redboot_ROMRAM.bin
3848755608 118224 redboot_ROMRAM.bin
```

In RedBoot, run the **cksum** command on the data that has just been loaded:

```
RedBoot> cksum -b %{FREEMEMLO} -l 118224
POSIX cksum = 3848755608 118224 (0xe5675998 0x0001cdd0)
```

The second number in the output of the host **cksum** program is the file size, which should be used as the argument to the `-l` option in the RedBoot **cksum** command. The first numbers in each instance are the checksums, which should be equal.

If the program has downloaded successfully, then it can be programmed into the flash using the following commands:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)?y
*** Initialize FLASH Image System
... Erase from 0x11fe0000-0x12000000: .
... Program from 0x0bfe0000-0x0c000000 at 0x11fe0000: .
RedBoot> fis create -b %{FREEMEMLO} RedBoot
An image named 'RedBoot' exists - continue (y/n)?y
... Erase from 0x10000000-0x10020000: .
... Program from 0x08066000-0x08086000 at 0x10000000: .
... Erase from 0x11fe0000-0x12000000: .
... Program from 0x0bfe0000-0x0c000000 at 0x11fe0000: .
RedBoot>
```

The MX1ADS/A board may now be disconnected from the JTAG device and reset by cycling the power. It should then display the startup screen for the ROMRAM version of RedBoot:

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.0.207/255.255.255.0, Gateway: 10.0.0.3
Default server: 10.0.0.1, DNS server IP: 10.0.0.1

RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 15:51:18, Jul 19 2004

Platform: Motorola MX1ADS/A (ARM9)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x02000000, [0x0002f778-0x01fdd000] available
FLASH: 0x10000000 - 0x12000000, 256 blocks of 0x00020000 bytes each.
RedBoot>
```

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROMRAM version of RedBoot for the MX1ADS/A are:

```
$ mkdir redboot_mx1ads_a_romram
$ cd redboot_mx1ads_a_romram
$ ecosconfig new mx1ads_a redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/mx1ads_a/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

To rebuild the SRAM version of RedBoot:

```
$ mkdir redboot_mx1ads_a_sram
$ cd redboot_mx1ads_a_sram
$ ecosconfig new mx1ads_a redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/mx1ads_a/current/misc/redboot_SRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This is the case for both the above builds, take care not to mix the two files up, since programming the SRAM RedBoot into the ROM will render the board unbootable.

Name

Configuration — Platform-specific Configuration Options

Overview

The MX1ADS/A platform HAL package is loaded automatically when eCos is configured for a `mx1ads_a` or `mxlads_a` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The MC9328MX1 SoC is supported by a separate HAL, `CYGPKG_HAL_ARM_ARM9_MC9328MXL`, which supports all the devices on the MC9328MX1/L that eCos uses.

Startup

The MX1ADS/A platform HAL package supports four separate startup types:

RAM

This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM

This startup type can be used for finished applications which will be programmed into flash at physical address 0x10000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROMRAM

This startup type can be used for finished applications which will be programmed into flash at physical location 0x10000000. However, when it starts up the application will first copy itself to RAM at 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

SRAM

This startup type is used for applications that are downloaded via the JTAG interface. The application is loaded into SRAM at location 0x08040000 and started by executing from that address. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. However, it is assumed that the machine has been set up from the JTAG interface as described earlier for installing RedBoot.

This configuration is primarily present to provide support for installing RedBoot in the FLASH. It has some limitations with regard to functionality since the MMU is not enabled and no exception vectors are installed at location zero, hence no interrupts can be handled.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for

a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The MX1ADS/A board contains two 16 bit AMD Am29PDL127H flash devices arranged in parallel to form a 32 bit wide interface. The `CYGPKG_DEVS_FLASH_AMD_AM29XXXXX` package contains all the code necessary to support these parts and the `CYGPKG_DEVS_FLASH_ARM_MX1ADS_A` package contains definitions that customize the driver to the MX1ADS/A board.

Ethernet Driver

The MX1ADS/A board contains a Cirrus Logic CS8900A ethernet MAC. The `CYGPKG_DEVS_ETH_CL_CS8900A` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_ARM_MX1ADS_A` package contains definitions that customize the driver to the MX1ADS/A board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There is just one flag specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM920T CPU in the MC9328MXL.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the MX1ADS/A hardware, and should be read in conjunction with that specification. The MX1ADS/A platform HAL package complements the ARM architectural HAL and the ARM9 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize the on-chip peripherals that it uses. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM or ROMRAM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

For SRAM startup, minimal initialization is performed, and it is assumed that the JTAG device has initialized the hardware as described earlier.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x08000000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x04000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x00040000, with the bottom 256kB reserved for use by RedBoot.

In the SRAM startup configuration, the SDRAM remains at its physical address of 0x08000000, since the MMU is not enabled.

Flash

This is located at address 0x10000000 of the physical memory space. It is mapped by the HAL using the MMU to the same virtual address with caching and the write buffer enabled.

On-chip Peripheral Registers

These are located at address 0x00200000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping for these at 0xA0000000 in the virtual address space.

All hardware addresses in `mc9328mxl.h` give the physical address. To use these, the macro `CYGARC_VIRTUAL_ADDRESS()` should be applied to these. This will yield the correct address depending on the startup type.

Ethernet MAC

The Cirrus Logic CS8900A is addressed by Chip Select 4, and is located at physical address 0x15000000. It is mapped uncached and unbuffered to the same virtual address when the MMU is enabled.

Other Issues

The MX1ADS/A platform HAL does not affect the implementation of other parts of the eCos HAL specification. The ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 256. Texas Instruments OMAP L1xx Processor Support

Name

Support for the TI OMAP L1xx Processor — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the TI OMAP L1xx processor family. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, ARM9 variant HAL and the platform HAL. It provides functionality common to all OMAP L1xx-based board implementations.

This support is found in the eCos package located at `packages/hal/arm/arm9/omap-l1xx` within the eCos source repository.

The OMAP L1xx processor HAL package is loaded automatically when eCos is configured for an OMAP-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the TI OMAP processor within this processor HAL package include:

- OMAP L1xx-specific hardware definitions
- Interrupt controller
- Timers
- Serial UARTs
- MultiMedia Card Interface (MMC/SD)
- I²C two wire interface
- Pin Configuration and GPIO Support
- Peripheral Power Control
- DMA Support

Support for the on-chip SPI device, SPI NOR flash, interrupt-driven serial, watchdog and wallclock (RTC) features of the OMAP L1xx are also present and can be found in separate packages, outside of this processor HAL.

Name

OMAP L1xx Hardware Definitions — Details on obtaining hardware definitions for OMAP

Register definitions

The file `<cyg/hal/omap_l1xx.h>` can be included from application and eCos package sources to provide definitions related to OMAP subsystems. These include register definitions for the interrupt controller, power management controller, PLL clocks, memory controller, external bus interface, GPIO, USART, MMC/SD, Ethernet, timers RTC, and SPI subsystems. This file will normally be included automatically if `<cyg/hal/hal_io.h>` is included, which is the preferred way of getting these definitions.

Initialization Helper Macros

The file `<cyg/hal/omap_l1xx_init.inc>` contains definitions of helper macros which may be used by OMAP L1xx platform HALs in order to initialise common subsystems without excessive duplication between the platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary. NOTE: At present, the only extant OMAP L1xx port relies on either the TI-supplied User Boot Loader, or the JTAG initialization script, to initialize the PLLs and memory controller, so these macros currently largely contain ARM9-generic setup only.

Name

OMAP L1xx Interrupt Controller — Advanced Interrupt Controller Definitions And usage

Interrupt controller definitions

The file <cyg/hal/var_ints.h> (located at hal/arm/arm9/omap/*VERSION*/include/var_ints.h in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs.

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt Controller Functions

The source file src/omap_l1xx_misc.c within this package provides most of the support functions to manipulate the interrupt controller. The hal_IRQ_handler queries the IRQ status register to determine the interrupt cause. Functions hal_interrupt_mask and hal_interrupt_unmask enable or disable interrupts within the interrupt controller.

Interrupts are configured in the hal_interrupt_configure function. Only GPIO interrupts are configurable, and at present we do not support full decoding of these, so this function is empty.

The hal_interrupt_acknowledge function acknowledges an interrupt.

The hal_interrupt_set_level is used to set the priority level of the supplied interrupt within the Advanced Interrupt Controller. This is supported by assigning each vector to one of the 30 channels that map to the IRQ vector. The FIQ vector channels are currently ignored. The level value may range from 0 to 29, with 0 being the highest priority. This range is shifted into the 2..31 range, and any attempt to set a priority value greater than 29 is clamped to 29.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (HAL_INTERRUPT_MASK et al) or preferably the kernel or driver APIs should be used to control interrupts.

Name

Timers — Use of on-chip timers

System Clock

The eCos kernel system clock is implemented using the 3:4 half of the 64-bit TimerPlus 0. By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to `CYGNUM_HAL_RTC_DENOMINATOR`, then the configuration option `CYGNUM_HAL_RTC_NUMERATOR` may also be adjusted, and again clock-related settings will automatically be recalculated.

The same Timer is also used to implement the HAL microsecond delay function, `HAL_DELAY_US`. This is used by some device drivers, and in non-kernel configurations such as with RedBoot where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Timer-based profiling support

Timer-based profiling support is implemented using the 1:2 half of TimerPlus 0. If the gprof package, `CYGPKG_PROFILE_GPROF`, is included in the configuration, then TimerPlus0 1:2 is reserved for use by the profiler.

Name

Serial UARTs — Configuration and Implementation Details of Serial UART Support

Overview

Support is included in this processor HAL package for the OMAP's on-chip debug unit UART and up to four serial USART serial devices.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 115200,8,N,1 with no flow control.

HAL Diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems. This can operate on any port, according to the configuration settings.

There are several configuration options usually found within a platform HAL which affect the use of this support in the OMAP processor HAL. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, `diag_printf()`. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL` selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the `CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS` CDL option in the HAL. Baud rates for each channel are set with the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD` options.

Interrupt-driven Serial Driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (`CYGPKG_IO_SERIAL`). This support can be enabled on any port.

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent ctrl-c operation when debugging.

The main part of this driver is contained in the generic `CYGPKG_IO_SERIAL_GENERIC_16X5X` package. The package `CYGPKG_IO_SERIAL_ARM_OMAP_L1XX` contains definitions that configure the generic driver for the OMAP L1xx. That driver package should also be consulted for documentation and configuration options. The driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Support for hardware flow control and modem control lines is present in the driver, but will only be enabled if these control signals are brought out to the physical serial port.

Name

Multimedia Card Interface (MMC/SD) Driver — Using MMC/SD cards with block drivers and filesystems

Overview

The MultiMedia Card Interface (MMC/SD) driver in the OMAP processor HAL allows use of MultiMedia Cards (MMC cards) and Secure Digital (SD) flash storage cards within eCos, exported as block devices. This makes them suitable for use as the underlying devices for filesystems such as FAT.

Configuration

This driver provides the necessary support for the generic MMC bus layer within the `CYGPKG_DEVS_DISK_MMC` package to export a disk block device. The disk block device is only available if the generic disk I/O layer found in the package `CYGPKG_IO_DISK` is included in the configuration.

The block device may then be used as the device layer for a filesystem such as FAT. Example devices are "`/dev/mmcsd0/1`" to refer to the first partition on the card, or "`/dev/mmcsd0/0`" to address the whole device including potentially the partition table at the start.

The driver may be forcibly disabled within this processor HAL package with the configuration option `CYGPKG_HAL_ARM_ARM9_OMAP_L1XX_MMC`.

If the driver is enabled, the following options are available to control it:

`CYGPKG_HAL_ARM_ARM9_OMAP_L1XX_MMC_DEVICE`
The OMAP_L1XX has two MMC/SD devices. At present the generic MMC/SD code can only handle one device. This option selects which device that is.

`CYGIMP_HAL_ARM_ARM9_OMAP_L1XX_MMC_INTMODE`
This indicates that the driver should operate in interrupt-driven mode if possible. This is enabled by default if the eCos kernel is enabled. Note though that if the driver finds that global interrupts are off when running, then it will fall back to polled mode even if this option is enabled. This allows for use of the MMC/SD driver in an initialisation context.

`CYGNUM_HAL_ARM_ARM9_OMAP_L1XX_MMC_INT_PRI`
This is the MMC/SD bus interrupt priority. It may range from 1 to 29.

Usage Notes

The driver will detect the appropriate card sizes. Hotswapping of cards is supported by the driver, and in the case of eCosPro, the FAT filesystem. Although any cards removed before explicit unmounting or a `sync()` call to flush filesystem buffers will likely result in a corrupted filesystem on the removed card.

The MMC/SD bus layer will parse partition tables, although it can be configured to allow handling of cards with no partition table.

This driver implements multi-sector I/O operations. If you are using the FAT filesystem, see the generic MMC/SD driver documentation which describes how to exploit this feature when using FAT.

Name

I2C Two Wire Interface — Using I^{2}C devices

Overview

The I^{2}C driver in the OMAP processor HAL supports the use of I^{2}C devices within eCos. Access to the driver will be via the standard I^{2}C interface subsystem.

This driver provides support for both I^{2}C busses available on the OMAP L1XX.

Configuration

The HAL contains the following configuration options for the two I^{2}C busses:

`CYGINT_HAL_ARM_ARM9_OMAP_L1XX_I2C_BUSX`

This interface controls the inclusion of support for I^{2}C bus *X*. This will normally be implemented by the platform HAL to indicate that there are I^{2}C devices attached to the given bus, or that the SCL and SDA lines are routed to an external connector.

`CYGNUM_HAL_ARM_ARM9_OMAP_L1XX_I2C_BUSX_CLOCK`

This is the I^{2}C bus *X* clock speed in Hz. Usually frequencies of either 100kHz or 400kHz are chosen, the latter sometimes known as fast mode.

`CYGNUM_HAL_ARM_ARM9_OMAP_L1XX_I2C_BUSX_INTR_PRI`

This is the I^{2}C bus *X* interrupt priority. It may range from 1 to 29; the default of 15 places it in the centre of the priority range.

Additionally the HAL contains the following configuration option which applies to both I^{2}C buses:

`CYGNUM_HAL_ARM_ARM9_OMAP_L1XX_I2C_ALIGNED_RXBUF_SIZE`

When using DMA, transferred received data buffers must be aligned to the data cache line size, and its size must be a multiple of the cache line size. If the user does not pass in a suitable buffer, a bounce buffer must be used for the entire transfer. This option provides the size of that buffer. You should set this buffer to the maximum amount of data you can receive in a single transfer. If you can guarantee that all uses of this I^{2}C driver use appropriately aligned receive buffers, then you can disable this option entirely in order to remove the buffer. It defaults to 1024 bytes per I^{2}C bus.

Usage Notes

The design of the OMAP L1XX I^{2}C device does not make it possible to start a new bus transfer without also sending a START condition on the bus. This means that divided transactions are not possible. A divided transaction would look like this:

```
    cyg_i2c_transaction_begin(&cyg_aardvark_at24c02);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 1, tx_buf1, 1, 0);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 0, tx_buf2, 2, 0);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 0, tx_buf3, 6, 1);
    cyg_i2c_transaction_end(&cyg_aardvark_at24c02);
```

In this transaction a START and one byte are sent from tx_buf1, then 2 bytes of data from tx_buf2, finishing with 6 bytes from tx_buf3 followed by a STOP. The OMAP L1XX will not allow the tx_buf2 and tx_buf3 transfers to happen without also sending a START. The only solution to this is to combine the data into a single buffer and perform a single transfer:

```
    memcpy( tx_buf, tx_buf1, 1);
    memcpy( tx_buf+1, tx_buf2, 2);
    memcpy( tx_buf+3, tx_buf3, 6);
    cyg_i2c_tx(&cyg_aardvark_at24c02, tx_buf, 9);
```

Name

Pin Configuration and GPIO Support — Use of pin configuration and GPIO

Synopsis

#include <cyg/hal/hal_io.h>

`pin = `**`CYGHWR_HAL_L1XX_PINMUX`**`(`*`reg`*`, `*`field`*`, `*`func`*`);`

`CYGHWR_HAL_L1XX_PINMUX_SET`` (`*`pin`*`);`

`pin = `**`CYGHWR_HAL_L1XX_GPIO`**`(`*`bank`*`, `*`bit`*`, `*`mode`*`);`

`CYGHWR_HAL_L1XX_GPIO_IN`` (`*`pin`*`, `*`val`*`);`

`CYGHWR_HAL_L1XX_GPIO_INTCFG`` (`*`pin`*`, `*`mode`*`);`

`CYGHWR_HAL_L1XX_GPIO_INTSTAT`` (`*`pin`*`, `*`stat`*`);`

Description

The OMAP L1XX HAL provides a number of macros to support the encoding of pin multiplexing information and GPIO pin modes into 32 bit descriptors. This is useful to drivers and other packages that need to configure and use different lines for different devices. Because there is not a simple correspondence between pin multiplexing information and GPIO bank and pin identities, these two things are treated separately.

Pin Multiplexing

A pin multiplexing descriptor is created with `CYGHWR_HAL_L1XX_PINMUX( reg, field, func )` which takes the following arguments:

`reg`
: This identifies the PINMUX register which controls this pin. This is a value between 0 and 19.

`field`
: This gives the bit offset within the PINMUX register of the field that controls this pin. Fields are 4 bits wide, so this may only be 0, 4, 8, 12, 16, 20, 24 or 28.

`func`
: This defines the function code to program into the PINMUX field. There is no consistency between functions and function codes, and the same function for a pin may be represented by different codes in different PINMUX registers. You should refer to the OMAP L1xx documentation for the correct value to be used here.

The following examples show how this macro may be used:

```
// UART0 TX line is in PINMUX3, bits 20:23, function 2 = UART0_TXD
#define CYGHWR_HAL_L1XX_UART0_TX             CYGHWR_HAL_L1XX_PINMUX( 3, 20, 2 )

// MMCSS0 clock line is in PINMUX10, bits 0:3, function 2 = MMCSD0_CLK
#define CYGHWR_HAL_OMAP_MMCSD0_CLK           CYGHWR_HAL_L1XX_PINMUX( 10,  0, 2 )
```

The macro `CYGHWR_HAL_L1XX_PINMUX_SET( pin )` sets the pin multiplexing setting according to the descriptor passed in.

GPIO Support

A GPIO descriptor is created with `CYGHWR_HAL_L1XX_GPIO( bank, bit, mode)` which takes the following arguments:

`bank` This identifies the GPIO bank to which the pin is attached. This is a value between 0 and 7.

`bit` This gives the bit offset within the bank of the GPIO pin. This is a value between 0 and 15.

`mode` This defines whether this is an input or an output pin, and may take the values `INPUT` or `OUTPUT` respectively.

Additionally, the macro `CYGHWR_HAL_L1XX_GPIO_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used.

The following examples show how this macro may be used:

```
// MMCSD0 card detect is attached to GP4[0] and is an input
#define CYGHWR_HAL_OMAP_MMCSD0_CD_GPIO                  CYGHWR_HAL_L1XX_GPIO( 4, 0, INPUT )

// MMCSD0 write protect is attached to GP4[1] and is an input
#define CYGHWR_HAL_OMAP_MMCSD0_WP_GPIO                  CYGHWR_HAL_L1XX_GPIO( 4, 1, INPUT )
```

The remaining macros all take a GPIO pin descriptor as an argument. `CYGHWR_HAL_L1XX_GPIO_SET` configures the pin according to the descriptor and must be called before any other macros. `CYGHWR_HAL_L1XX_GPIO_OUT` sets the output to the value of the least significant bit of the *`val`* argument. The *`val`* argument of `CYGHWR_HAL_L1XX_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

There is also support for GPIO interrupts. `CYGHWR_HAL_L1XX_GPIO_INTCFG( pin, mode )` configures the interrupt mode of the pin. It may be either `FALL`, `RISE` or `FALLRISE` to configure the pin to interrupt on the falling edge, rising edge or both. The second argument to `CYGHWR_HAL_L1XX_GPIO_INTSTAT( pin, stat )` must be a pointer to an int, which will be set to 1 if an interrupt has be received on the given pin, and 0 otherwise. GPIO interrupts are currently not decoded into per-pin interrupt vectors, only the shared per-bank vectors are available. If an application needs to get interrupts from more than one pin on a bank, it needs to install a shared ISR and decode the specific pins itself.

Name

Peripheral Power Control — Description

Synopsis

#include <cyg/hal/hal_io.h>

pin = **CYGHWR_HAL_L1XX_POWER**(*device*);

CYGHWR_HAL_L1XX_POWER_ENABLE (*desc*);

CYGHWR_HAL_L1XX_POWER_DISABLE (*desc*);

Description

The OMAP L1XX HAL provides a number of macros to support the management of peripheral power. The macro `CYGHWR_HAL_L1XX_POWER( device )` encodes a power control descriptor into a 32 bit value. The argument is the name of the device to be described.

The remaining functions all take a peripheral power descriptor as an argument. `CYGHWR_HAL_L1XX_POWER_ENABLE( desc )` transitions the given device to enabled state in its PSC controller. Likewise `CYGHWR_HAL_L1XX_POWER_DISABLE( desc )` transitions the device to disabled state.

Name

DMA Support — Description

Synopsis

```
typedef struct hal_edma_channel hal_edma_channel;

typedef void hal_edma_callback( hal_edma_channel *edma_chan, cyg_uint32 event, CYG_ADDRWORD data );
```

#include <cyg/hal/hal_io.h>

pin = **CYGHWR_HAL_L1XX_EDMA_CHANNEL**(*controller*, *event*);

void hal_edma_channel_init (*hal_edma_channel *edma_chan*, *cyg_uint32 channel*, *hal_edma_callback *callback*, *CYG_ADDRWORD data*);

void hal_edma_channel_delete (*hal_edma_channel *edma_chan*);

void hal_edma_channel_source (*hal_edma_channel *edma_chan*, *void *src*, *cyg_int16 bidx*, *cyg_int16 cidx*);

void hal_edma_channel_dest (*hal_edma_channel *edma_chan*, *void *dest*, *cyg_int16 bidx*, *cyg_int16 cidx*);

void hal_edma_channel_burstsize (*hal_edma_channel *edma_chan*, *cyg_uint16 aburstsize*, *cyg_uint16 bburstsize*);

void hal_edma_channel_size (*hal_edma_channel *edma_chan*, *cyg_uint32 size*);

void hal_edma_channel_start (*hal_edma_channel *edma_chan*, *cyg_uint32 opt*);

void hal_edma_channel_stop (*hal_edma_channel *edma_chan*);

void hal_edma_poll (*void*);

Description

The HAL provides support for access to the EDMA3 DMA controllers. This support is not intended to expose the full functionality of these devices and is strictly limited to supporting peripheral DMA, in particular SPI and MMC/SD.

The user is referred to the TI EDMA3 documentation for a full description of the EDMA3 devices, and to the sources of the MMC and SPI drivers for examples of the use of this API. This documentation only gives a brief description of the functions available.

Each device transfer direction is described by a controller number (0 or 1) and an event numbers (0 to 31). These values are usually defined by the peripheral being accessed. The macro `CYGHWR_HAL_L1XX_EDMA_CHANNEL( controller, event)` combines these into a descriptor that may be used to initialize the channel. A channel is controlled by a hal_edma_channel object that must be allocated by the client. To initialize a channel, `hal_edma_channel_init()` is called, passing the channel object, the descriptor and an optional callback function and user-defined value. After use the channel can be deleted with `hal_edma_channel_delete()`.

Before starting a transfer, the channel must be initialized with the source, destination and size of the transfer to be done. `hal_edma_channel_source()` and `hal_edma_channel_dest()` describe the source and destination buffers. A memory buffer is described by its address plus the increments, or indexes, to step the read or write pointer through it. The sizes of these indexes depend on the size of the transfers that the peripheral is programmed to make, and its synchronisation mode. One of the source or destination will be the peripheral itself; the address should be the address of the peripheral's input or output data register, and the indexes should be zero to prevent the pointer incrementing.

`hal_edma_channel_size()` supplies the total transfer size in bytes. `hal_edma_channel_burstsize()` describes the A and B burst sizes for AB synchronized transfers and must be called before `hal_edma_channel_size()`. If `hal_edma_channel_burstsize()` is not called then A synchronization is assumed. The values set by `hal_edma_channel_burstsize()` remain set in the channel, and another call to this function is needed to reset them.

A transfer is started by calling `hal_edma_channel_start()`. The *`opt`* argument contains bits that will be merged with the PaRAM options field. When a transfer is complete, then `hal_edma_channel_stop()` should be called. This function may also be called to abort a transfer.

If a callback was passed to `hal_edma_channel_init()` then when the transfer finishes or encounters and error, the callback will be called from DSR context. The callback will be passed a pointer to the channel object, an event code and the user-defined value that was passed to `hal_edma_channel_init()`. There are two possible event codes: `CYGHWR_HAL_L1XX_EDMA_COMPLETE` indicates that the transfer finished successfully, and `CYGHWR_HAL_L1XX_EDMA_ERROR` indicates that an error condition was encountered.

In kernel configurations the DMA system will use interrupts to detect transfer completion or errors. In non-kernel configurations it will use polling. For the polling to happen, client code must call `hal_edma_poll()` on a regular basis. On DMA completion the callback function will be called, as before.

Chapter 257. Atmel SAM9 Processor Support

Name

Support for the Atmel SAM9 Processor — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Atmel AT91SAM9XXX processor family. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, ARM9 variant HAL and the platform HAL. It provides functionality common to all SAM9-based board implementations.

This support is found in the eCos package located at `packages/hal/arm/arm9/sam9` within the eCos source repository.

The SAM9 processor HAL package is loaded automatically when eCos is configured for an SAM9-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the Atmel SAM9 processor within this processor HAL package include:

- SAM9-specific hardware definitions
- Interrupt controller
- Timer counters
- Serial UARTs
- Two-Wire Interface (TWI)
- Power saving

Support for the on-chip ethernet(AT91SAM9260 only), interrupt-driven serial, SPI, watchdog and wallclock (RTTC) features of the SAM9 are also present and can be found in separate packages, outside of this processor HAL.

Name

SAM9 hardware definitions — Details on obtaining hardware definitions for SAM9

Register definitions

The file `<cyg/hal/sam9.h>` can be included from application and eCos package sources to provide definitions related to SAM9 subsystems. These include register definitions for the interrupt controller, power management controller, clock generator, memory controller, external bus interface, GPIO, USART, MCI, TWI (I²C®), Ethernet, timer counter, RTTC, and SPI subsystems.

Initialization helper macros

The file `<cyg/hal/sam9_init.inc>` contains definitions of helper macros which may be used by SAM9 platform HALs in order to initialise common SAM9 subsystems without excessive duplication between the platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary.

Name

SAM9 interrupt controller — Advanced Interrupt Controller definitions and usage

Interrupt controller definitions

The file `<cyg/hal/var_ints.h>` (located at `hal/arm/arm9/sam9/`*`VERSION`*`/include/var_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs:

```
// The following are common to all SAM9 devices. Per-variant
// variations are supplied later.

#define CYGNUM_HAL_INTERRUPT_FIQ     0 // Advanced Interrupt Controller (FIQ)
#define CYGNUM_HAL_INTERRUPT_SYSTEM  1 // System Peripheral (debug unit, system timer)
#define CYGNUM_HAL_INTERRUPT_PIOA    2 // Parallel IO Controller A
#define CYGNUM_HAL_INTERRUPT_PIOB    3 // Parallel IO Controller B
#define CYGNUM_HAL_INTERRUPT_PIOC    4 // Parallel IO Controller C
                                       // Vector 5 variant specific
#define CYGNUM_HAL_INTERRUPT_US0     6 // USART 0
#define CYGNUM_HAL_INTERRUPT_US1     7 // USART 1
#define CYGNUM_HAL_INTERRUPT_US2     8 // USART 2
#define CYGNUM_HAL_INTERRUPT_MCI     9 // Multimedia Card Interface
#define CYGNUM_HAL_INTERRUPT_UDP    10 // USB Device Port
#define CYGNUM_HAL_INTERRUPT_TWI    11 // Two-Wire Interface
#define CYGNUM_HAL_INTERRUPT_SPI    12 // Serial Peripheral Interface 0
#define CYGNUM_HAL_INTERRUPT_SPI1   13 // Serial Peripheral Interface 1
#define CYGNUM_HAL_INTERRUPT_SSC0   14 // Serial Synchronous Controller 0
                                       // Vector 15 variant specific
                                       // Vector 16 variant specific
#define CYGNUM_HAL_INTERRUPT_TC0    17 // Timer Counter 0
#define CYGNUM_HAL_INTERRUPT_TC1    18 // Timer Counter 1
#define CYGNUM_HAL_INTERRUPT_TC2    19 // Timer Counter 2
#define CYGNUM_HAL_INTERRUPT_UHP    20 // USB Host port
                                       // Vectors 21..28 variant specific
#define CYGNUM_HAL_INTERRUPT_IRQ0   29 // Advanced Interrupt Controller (IRQ0)
#define CYGNUM_HAL_INTERRUPT_IRQ1   30 // Advanced Interrupt Controller (IRQ1)
#define CYGNUM_HAL_INTERRUPT_IRQ2   31 // Advanced Interrupt Controller (IRQ2)

// Variant specific vectors

#if defined(CYGHWR_HAL_ARM_ARM9_SAM9_SAM9260)

#define CYGNUM_HAL_INTERRUPT_ADC     5 // Analog to Digital Converter
                                       // Vector 15 unused
                                       // Vector 16 unused
#define CYGNUM_HAL_INTERRUPT_EMAC   21 // Ethernet MAC
#define CYGNUM_HAL_INTERRUPT_ISI    22 // Image Sensor Interface
#define CYGNUM_HAL_INTERRUPT_US3    23 // USART 3
#define CYGNUM_HAL_INTERRUPT_US4    24 // USART 4
#define CYGNUM_HAL_INTERRUPT_US5    25 // USART 5
#define CYGNUM_HAL_INTERRUPT_TC3    26 // Timer Counter 3
#define CYGNUM_HAL_INTERRUPT_TC4    27 // Timer Counter 4
#define CYGNUM_HAL_INTERRUPT_TC5    28 // Timer Counter 5

#elif defined(CYGHWR_HAL_ARM_ARM9_SAM9_SAM9261)

                                       // Vector 5 unused
#define CYGNUM_HAL_INTERRUPT_SSC1   15 // Serial Synchronous Controller 1
#define CYGNUM_HAL_INTERRUPT_SSC2   16 // Serial Synchronous Controller 2
#define CYGNUM_HAL_INTERRUPT_LCD    21 // LCD controller
                                       // Vectors 22..28 unused

#else
#error Unknown SAM9 variant
#endif
```

```
// The following interrupts are derived from the SYSTEM interrupt
#define CYGNUM_HAL_INTERRUPT_PITC   32 // System Timer Period Interval Timer
#define CYGNUM_HAL_INTERRUPT_DEBUG  33 // Debug unit
#define CYGNUM_HAL_INTERRUPT_WDTC   34 // Watchdog
#define CYGNUM_HAL_INTERRUPT_RTTC   35 // Real Time Clock
#define CYGNUM_HAL_INTERRUPT_PMC    36 // Power Management Controller
#define CYGNUM_HAL_INTERRUPT_RSTC   37 // Reset Controller
```

As indicated above, further decoding is performed on the SYSTEM interrupt to identify the cause more specifically. Note that as a result, placing an interrupt handler on the SYSTEM interrupt will not work as expected. Conversely, masking a decoded derivative of the SYSTEM interrupt will not work as this would mask other SYSTEM interrupts, but masking the SYSTEM interrupt itself will work. On the other hand, unmasking a decoded SYSTEM interrupt *will* unmask the SYSTEM interrupt as a whole, thus unmasking interrupts for the other units on this shared interrupt.

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt controller functions

The source file `src/sam9_misc.c` within this package provides most of the support functions to manipulate the interrupt controller. The `hal_IRQ_handler` queries the IRQ status register to determine the interrupt cause. Functions `hal_interrupt_mask` and `hal_interrupt_unmask` enable or disable interrupts within the interrupt controller.

Interrupts are configured in the `hal_interrupt_configure` function, where the `level` and `up` arguments are interpreted as follows:

level	up	interrupt on
0	0	Falling Edge
0	1	Rising Edge
1	0	Low Level
1	1	High Level

To fit into the eCos interrupt model, interrupts essentially must be acknowledged immediately once decoded, and as a result, the `hal_interrupt_acknowledge` function is empty.

The `hal_interrupt_set_level` is used to set the priority level of the supplied interrupt within the Advanced Interrupt Controller.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (`HAL_INTERRUPT_MASK` et al) or preferably the kernel or driver APIs should be used to control interrupts.

Using the Advanced Interrupt Controller for VSRs

The SAM9 HAL has been designed to exploit benefits of the on-chip Advanced Interrupt Controller (AIC) on the SAM9. Support has been included for exploiting its ability to provide hardware vectoring for VSR interrupt handlers.

This support is dependent on definitions that may only be provided by the platform HAL and therefore is only enabled if the platform HAL package implements the `CYGINT_HAL_SAM9_AIC_VSR` CDL interface. The necessary definitions are available to all platform HALs which use the facilities of the `sam9_init.inc` header file.

The interrupt decoding path has been optimised by allowing the AIC to be interrogated for the interrupt handler VSR to use. These vectored interrupts are by default still configured to point to the default ARM architecture HAL IRQ and FIQ VSRs. However applications may set their own VSRs to override this default behaviour to allow optimised interrupt handling.

The VSR vector numbers to use when overriding are defined as follows:

```
// FIQ is already defined as vector 7 in the architecture hal_intr.h
#define CYGNUM_HAL_VECTOR_SYSTEM  8 // System Peripheral (debug unit, system timer)
#define CYGNUM_HAL_VECTOR_PIOA    9 // Parallel IO Controller A
#define CYGNUM_HAL_VECTOR_PIOB   10 // Parallel IO Controller B
#define CYGNUM_HAL_VECTOR_PIOC   11 // Parallel IO Controller C
                                    // VSR 12 variant specific
#define CYGNUM_HAL_VECTOR_US0    13 // USART 0
#define CYGNUM_HAL_VECTOR_US1    14 // USART 1
#define CYGNUM_HAL_VECTOR_US2    15 // USART 2
#define CYGNUM_HAL_VECTOR_MCI    16 // Multimedia Card Interface
#define CYGNUM_HAL_VECTOR_UDP    17 // USB Device Port
#define CYGNUM_HAL_VECTOR_TWI    18 // Two-Wire Interface
#define CYGNUM_HAL_VECTOR_SPI    19 // Serial Peripheral Interface
#define CYGNUM_HAL_VECTOR_SPI1   20 // Serial Peripheral Interface
#define CYGNUM_HAL_VECTOR_SSC0   21 // Serial Synchronous Controller 0
                                    // VSR 22 variant specific
                                    // VSR 23 variant specific
#define CYGNUM_HAL_VECTOR_TC0    24 // Timer Counter 0
#define CYGNUM_HAL_VECTOR_TC1    25 // Timer Counter 1
#define CYGNUM_HAL_VECTOR_TC2    26 // Timer Counter 2
#define CYGNUM_HAL_VECTOR_UHP    27 // USB Host port
                                    // VSRs 28..35 variant specific
#define CYGNUM_HAL_VECTOR_IRQ0   36 // Advanced Interrupt Controller (IRQ0)
#define CYGNUM_HAL_VECTOR_IRQ1   37 // Advanced Interrupt Controller (IRQ1)
#define CYGNUM_HAL_VECTOR_IRQ2   38 // Advanced Interrupt Controller (IRQ2)

// Variant specific vectors

#if defined(CYGHWR_HAL_ARM_ARM9_SAM9_SAM9260)

#define CYGNUM_HAL_VECTOR_ADC    12 // Analog to Digital Converter
                                    // Vector 22 unused
                                    // Vector 23 unused

#define CYGNUM_HAL_VECTOR_TC3    33 // Timer Counter 3
#define CYGNUM_HAL_VECTOR_TC4    34 // Timer Counter 4
#define CYGNUM_HAL_VECTOR_TC5    35 // Timer Counter 5

#elif defined(CYGHWR_HAL_ARM_ARM9_SAM9_SAM9261)

                                    // Vector 12 unused
#define CYGNUM_HAL_VECTOR_SSC1   22 // Serial Synchronous Controller 1
#define CYGNUM_HAL_VECTOR_SSC2   23 // Serial Synchronous Controller 2
#define CYGNUM_HAL_VECTOR_LCD    28 // LCD controller
                                    // Vectors 29..35 unused

#else

#error Unknown SAM9 variant

#endif
```

Consult the kernel and generic HAL documentation for more information on VSRs and how to set them.

Interrupt handling withing standalone applications

For non-eCos standalone applications running under RedBoot, it is possible to install an interrupt handler into the interrupt vector table manually. Memory mappings are platform-dependent and so the platform documentation should be consulted, but in general the address of the interrupt table can be determined by analyzing RedBoot's symbol table, and searching for the address of the symbol name `hal_interrupt_handlers`. Table slots correspond to the interrupt numbers above. Pointers inserted in this table should be pointers to a C/C++ function with the following prototype:

```
extern unsigned int isr( unsigned int vector, unsigned int data );
```

For non-eCos applications run from RedBoot, the return value can be ignored. The `vector` argument will also be the interrupt vector number. The `data` argument is extracted from a corresponding table named `hal_interrupt_data` which immediately follows the interrupt vector table. It is still the responsibility of the application to enable and configure the interrupt source appropriately if needed.

Name

Timers — Use of on-chip timers

Periodic Interval Timer

The eCos kernel system clock is implemented using the Periodic Interval Timer (PIT). By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to `CYGNUM_HAL_RTC_DENOMINATOR`, then the configuration option `CYGNUM_HAL_RTC_NUMERATOR` may also be adjusted, and again clock-related settings will automatically be recalculated.

The PIT is also used to implement the HAL microsecond delay function, `HAL_DELAY_US`. This is used by some device drivers, and in non-kernel configurations such as with RedBoot where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Timer-based profiling support

Timer-based profiling support is implemented using timer counter 1 (TC1). If the gprof package, `CYGPKG_PROFILE_GPROF`, is included in the configuration, then TC1 is reserved for use by the profiler.

Name

Serial UARTs — Configuration and implementation details of serial UART support

Overview

Support is included in this processor HAL package for the SAM9's on-chip debug unit UART and up to four serial USART serial devices.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 115200,8,N,1 with no flow control.

HAL diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems. This can operate on any port, according to the configuration settings.

There are several configuration options usually found within a platform HAL which affect the use of this support in the SAM9 processor HAL. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, `diag_printf()`. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL` selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the `CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS` CDL option in the HAL. Baud rates for each channel are set with the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD` options.

Interrupt-driven serial driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (`CYGPKG_IO_SERIAL`). This support can be enabled on any port.

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent ctrl-c operation when debugging.

This driver is contained in the `CYGPKG_IO_SERIAL_ARM_AT91` package. That driver package should also be consulted for documentation and configuration options. The driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Note that unlike the USART devices, the serial debug port does not support modem control signals such as those used for hardware signals. In addition, USART devices for a particular platform may also not have these control signals brought out to the physical serial port.

Name

Two-Wire Interface (TWI) driver — Configuration and implementation details of TWI (I²C®) driver

Overview

The SAM9 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the SAM9. This type of bus is also known as I²C®. The API for this may be found within the `CYGPKG_IO_I2C` package.

I²C/TWI driver configuration

The I²C® driver uses the SAM9's internal Two-Wire Interface (TWI) support. This is controlled within the SAM9 processor HAL (`CYGPKG_HAL_SAM9`). The `CYGPKG_HAL_SAM9_TWI` CDL component controls whether the TWI driver is enabled. Within that component, there are two sub-options:

- `CYGNUM_HAL_SAM9_TWI_CLOCK` sets the speed of the TWI bus clock in Hz. This is usually 100kHz, but can be set up to 400kHz if the devices on the bus support this speed, also known as fast mode. However other values below 400kHz can also be chosen, subject to the accuracy of the clock waveform generation parameters.

- The second option within the `CYGPKG_HAL_SAM9_TWI` component is `CYGNUM_HAL_SAM9_TWI_CKDIV`. This is the clock divider used when configuring the TWI_CWGR register. Consult the SAM9 datasheet description of the TWI_CWGR register for the formula used to determine the clock frequency. Increasing the divider will decrease the accuracy in practice of the generated I²C bus clock compared to `CYGNUM_HAL_SAM9_TWI_CLOCK`. But the divider must also be sufficiently low that the relevant factors do not overflow valid values for CHDIV/CLDIV in TWI_CWGR. Note that when the SAM9 is using a 60MHz MCK, then for 100kHz operation, a value for this option of 1 is most appropriate. For 400kHz, a value for this option of 0 is most appropriate. The default value of this CDL is an appropriate value for CKDIV assuming a 60MHz MCK and a TWI clock between 29kHz and 400kHz.

  To be specific, the CLDIV/CHDIV fields of the TWI_CWGR are considered equal. The value of, for example, CLDIV, can be expressed as:

$$CLDIV = \frac{f_{MCK} - 6 f_{TWI}}{2^{CKDIV+1} \cdot f_{TWI}}$$

To use the I²C/TWI driver, the generic I²C driver package `CYGPKG_IO_I2C` must be used. Documentation for its API may be found elsewhere.

Usage notes

Due to the characteristics of the SAM9's operation, it is not possible to provide support for repeated starts with the I²C package API. Similarly indicating a NACK when performing a receive is equivalent to also sending a STOP.

A test application for use with the AT24C512 serial EEPROM fitted to the AT91SAM9260EK board is provided within the `tests` subdirectory of the `CYGPKG_HAL_SAM9` package. This test communicates with the I²C EEPROM on the board to perform read and write operations using I²C. This test is not built by default. It may be built by enabling the configuration option `CYGBLD_HAL_ARM_ARM9_SAM9_TEST_TWI_AT24C512` within the SAM9 processor HAL.

Name

Power saving support — Extensions for saving power

Overview

There is support in the SAM9 processor HAL for a simple power saving mechanism. This is provided by two functions:

```
#include <cyg/hal/hal_intr.h>

__externC void cyg_hal_sam9_powersave_init( cyg_uint32 ip_addr );

__externC void cyg_hal_sam9_powerdown( void );
```

The powersaving system is initialized by calling `cyg_hal_sam9_powersave_init()`. The argument should be the IP address of this machine in network order. This can usually be fetched from the bootp data for an interface after completion of the call to `init_all_network_interfaces()`. e.g. `eth0_bootp_data.bp_ciaddr.s_addr`.

A call to `cyg_hal_sam9_powerdown()` will put the machine into a low power mode. This will involve switching to a slower system clock speed, disabling all peripherals except those that are defined to cause the system to wake up and return from this function.

Configuration

The exact behaviour of the power saving system is controlled by the following configuration options:

CYGPKG_HAL_ARM_ARM9_SAM9_POWERSAVE

> This option controls the overall inclusion of the power saving system.
>
> Default value: on

CYGSEM_HAL_ARM_ARM9_SAM9_POWERSAVE_POLL_ETHERNET

> This option enables polling of the ethernet interface for relevant ARP packets and unicast IP packets. It is necessary for the CPU to run at a higher CPU speed for this option to work.
>
> Default value: off

CYGSEM_HAL_ARM_ARM9_SAM9_POWERSAVE_IDLE

> If this option is set, the CPU will go into idle mode, which will cause it to halt until an interrupt is delivered.
>
> Default value: off

CYGVAR_HAL_ARM_ARM9_SAM9_POWERSAVE_ACTIVE_DEVICES

> This option defines the devices that are to be kept running during power down mode. An interrupt from one of these devices is usually the only way of bringing the system out of idle mode. The value of this option is a bit mask with bits set for each device that is to be kept active. The bits correspond to the peripheral identifiers described in the SAM9 documentation.
>
> Default value: 0x00000000

CYGSEM_HAL_ARM_ARM9_SAM9_POWERSAVE_POLL_GPIO

> This option control whether the power saving system will poll GPIO pins during power saving. For this to work the CPU cannot be put into idle mode.

Default value: on

CYGVAR_HAL_ARM_ARM9_SAM9_POWERSAVE_PIO_HI

This is an array of bitmasks of the bits in the PIO PDSR registers. Within the array, index 0 corresponds to PIOA, index 1 to PIOB and so on. For each set bit in these masks, if the value is seen to be 1, then the low power mode will be terminated.

Default value: 0, 0, 0, 0

CYGVAR_HAL_ARM_ARM9_SAM9_POWERSAVE_PIO_LO

This is an array of bitmasks of the bits in the PIO PDSR registers. Within the array, index 0 corresponds to PIOA, index 1 to PIOB and so on. For each set bit in these masks, if the value is seen to be 0, then the low power mode will be terminated.

Default value: 0, 0, 0, 0

CYGVAR_HAL_ARM_ARM9_SAM9_POWERSAVE_PIO_CHANGE

This is an array of bitmasks of the bits in the PIO PDSR registers. Within the array, index 0 corresponds to PIOA, index 1 to PIOB and so on. For each set bit in these masks, if the value is seen to change between successive polls, then the low power mode will be terminated.

Default value: 0, 0, 0, 0

CYGBLD_HAL_ARM_ARM9_SAM9_TEST_POWERSAVE

This option controls whether a simple test is built to exercise power saving support. The test is not built by default as an external means is required to wake the processor up by one of the above configured mechanisms.

Default value: 0

Chapter 258. Atmel AT91SAM9260 Evaluation Kit Board Support

Name

eCos Support for the Atmel AT91SAM9260 Evaluation Kit — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel AT91SAM9260 Evaluation Kit. The AT91SAM9260 Evaluation Kit contains the AT91SAM9260 microprocessor, 64Mbytes of SDRAM, 256Mbytes of NAND flash memory, an Atmel Dataflash, an Atmel serial EEPROM, a Davicom DM9161A PHY, a SD/MMC/DataFlash socket, a DAC, external connections for three serial channels (one debug, one full modem, one flow controlled), ethernet, USB host/device, and the various other peripherals supported by the AT91SAM9260. eCos support for the many devices and peripherals on the boards and the AT91SAM9260 is described below.

For typical eCos development, a RedBoot image is programmed into the dataflash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the SAM9 processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The Dataflash consists of 8192 blocks of 1056 bytes each. In a typical setup, the first 33792 bytes are reserved for the second-level bootstrap, AT91Bootstrap. The following 164736 bytes are reserved for the use of the ROM RedBoot image (The odd size aligns the end of the RedBoot area to a 1056 block boundary). The topmost block is used to manage the flash and the next block down holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J17 and DTE port at J20 (connected to USART channel 0) and flow controlled port at J18 (connected to USART channel 1) can be used by RedBoot for communication with the host. If any of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the AT91SAM9260-EK target.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91` for the on-chip ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the AT91SAM9260-EK board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the board.

There is a driver for the on-chip real-time timer controller (RTTC) at `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC`. This driver is also loaded automatically when configuring for the target.

The SAM9 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91SAM9260. This type of bus is also known as I²C®. Further documentation may be found in the SAM9 processor HAL documentation.

There is a driver for the MultiMedia Card Interface (MCI) at `CYGPKG_DEVS_MMCSD_ATMEL_SAM_MCI`. This driver is loaded automatically when configuring for the AT91SAM9260-EK target and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation may be found within that package.

The platform HAL provides definitions to allow access to devices on the SPI bus. The HAL provides information to the more general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board.

Furthermore, the platform HAL package contains support for SPI dataflash cards. The HAL support integrates with the CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH package as well as the above SPI packages. That package is automatically loaded when configuring for the target. Dataflash media is then accessed as a Flash device, using the Flash I/O API within the CYGPKG_IO_FLASH package, if that package is loaded in the configuration.

It is also possible to configure the HAL to access MMC cards in SPI mode, instead of using the MCI interface.

In general, devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM9260-EK support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM9260-EK board for eCos Development

Overview

In a typical development environment, the AT91SAM9260-EK board boots from the DataFlash and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from Dataflash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from Dataflash by the second-level bootstrap. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The on-chip boot program on the AT91SAM9260 is only capable of loading programs from Dataflash or NAND flash into 4Kbytes of on-chip SRAM and is therefore quite restrictive. Consequently RedBoot cannot be booted directly and a second-level bootstrap must be used. Such a second-level bootstrap is supplied by Atmel in the form of AT91Bootstrap. This is therefore programmed into the start of Dataflash and is then responsible for initializing the SDRAM and loading RedBoot from Dataflash and executing it.

Caution

There is a size limit on the size of applications which the AT91Bootstrap second level bootstrap will load. Images larger than 320Kbytes will require the AT91Bootstrap application to be rebuilt with a larger `IMG_SIZE` definition in `AT91Bootstrap/board/at91sam9260ek/dataflash/at91sam9260ek.h` within the sam9260ek HAL package in the eCos source repository (`packages/hal/arm/arm9/sam9260ek/current/`).

There are basically two ways to write the second-level bootstrap and RedBoot to the Dataflash. The first is to use the Atmel-supplied SAM-BA program that interacts with the on-chip boot program. The second is to use a JTAG debugger that understands the microcontroller and can write to the dataflash (for example the Ronetix PEEDI). Since the availability of the latter cannot be guaranteed, only the first method will be described here.

Programming RedBoot into DataFlash using SAM-BA

The following gives the steps needed to program the second-level bootstrap and RedBoot into the DataFlash using SAM-BA. The user should refer to the SAM-BA documentation for full details of how to run the program.

1. Download the AT91 In-system Programmer software package from the Atmel website and install it. SAM9 series CPU's require the 2.1.x series version of SAM-BA. Atmel provide both Linux and Windows versions of SAM-BA so ensure you select the version appropriate to your host operating system. The remainder of this document describes the process according to a Windows installation. The steps for the Linux version of SAM-BA are similar and can easily be determined from the Windows process.

2. From the root directory of your eCosPro installation, copy the file `dataflash_at91sam9260ek.bin` from the sub-directory `packages/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9260ek` and the file `redboot_ROM.bin` from the sub-directory `loaders/sam9260ek` to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the DEBUG serial port of the board and a serial port on a convenient host (which need not be the PC running SAM-BA). Run a terminal emulator (Hyperterm or minicom) at 115200 baud. Connect a USB cable between the PC and the AT91SAM9260-EK board.

4. Power up or reset the board and Windows should recognize the USB device. If it does not, hold down switch BP4 while powering up or resetting the board. This will erase any previous bootloader from the dataflash. Reset the board again and it should be recognized now. Windows may ask you to install a new driver, in which case follow the instructions. If the USB device does not appear, check the USB cable.

   ### Note

   Under Linux this device may appear as `/dev/ACM0` or `/dev/ttyUSB0`. SAM-BA currently only recognises the latter so you may have to create a symbolic link from `/dev/ACM0` to `/dev/ttyUSB0`.

5. Start SAM-BA. Select "\usb\ARM0" for the communication interface, and "AT91SAM9260-EK" for the board. If the USB option does not appear, look in the Windows Device Manager for the new USB COM device. If all is well, click on "Connect".

6. In the SAM-BA main window, select the "DataFlash AT45DB/DBC" tab and in the "Scripts" dropdown menu select "Enable Dataflash (SPIO CS1)", to program the on-board Dataflash device. Click Execute and SAM-BA should emit the following in the message area:

   ```
   (AT91-ISP v1.13) 1 % DATAFLASH::Init 1
   -I- DATAFLASH::Init 1 (trace level : 4)
   -I- Loading applet isp-dataflash-at91sam9260.bin at address 0x20000000
   -I- Memory Size : 0x840000 bytes
   -I- Buffer address : 0x20002A70
   -I- Buffer size: 0x80E80 bytes
   -I- Applet initialization done
   ```

   The actual options and output of SAM-BA may vary according to the version you are using. The behaviour documented here is that of SAM-BA 2.9.

7. Now select the DataFlash tab again, "Send BootFile" from the "Scripts" menu and "Execute" it. When the file open dialog appears, select the `dataflash_at91sam9260ek.bin` file and click "Open". The following output should be seen:

   ```
   (AT91-ISP v1.13) 1 % GENERIC::SendBootFileGUI
   GENERIC::SendFile dataflash_at91sam9260ek.bin at address 0x0
   -I- File size : 0xF82 byte(s)
   -I-     Writing: 0xF82 bytes at 0x0 (buffer addr : 0x20002A70)
   -I-     0xF82 bytes written by applet
   ```

8. The second-level bootstrap has now been written to DataFlash, we must now write RedBoot.

9. In the "Send File Name" box type in the path name to the `redboot_ROM.bin` file, or use the Open Folder button and browse to it.

10. In the Address field set the value to 0x8400.

11. Click the "Send File" button. SAM-BA will put up a dialog box while it is writing the file to the DataFlash, and will output something similar to the following in the message area:

    ```
    (AT91-ISP v1.13) 1 % send_file {DataFlash AT45DB/DCB} "redboot_ROM.bin" 0x8400 0
    -I- Send File //bert/Shared/Releng/sam9260ek/redboot_ROM.bin at address 0x8400
    GENERIC::SendFile //bert/Shared/Releng/sam9260ek/redboot_ROM.bin at address 0x8400
    -I- File size : 0x243D0 byte(s)
    -I-     Writing: 0x243D0 bytes at 0x8400 (buffer addr : 0x20002A70)
    ```

```
-I-     0x243D0 bytes written by applet
```

12. Shut down SAM-BA and disconnect the USB cable. Press the reset button on the board and something similar to the following should be output on the DEBUG serial line.

```
RomBOOT
>Start AT91Bootstrap...
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
No space to add 'net_device'
AT91_ETH: Waiting for PHY to reset.
AT91_ETH: Waiting for link to come up..
Ethernet eth0: MAC address 12:34:56:78:9a:bc
No IP info for device!

RedBoot(tm) bootstrap and debug environment [ROM]
eCosCentric certified release, version v3_0_3 - built 12:50:09, Sep 24 2009

Copyright (C) 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009
Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: AT91SAM9260-EK (ARM9)
RAM: 0x20000000-0x24000000 [0x20035d08-0x23ffef80 available]
FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
RedBoot>
```

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x4083fbe0-0x4083ffff: .
... Program from 0x23fffbe0-0x24000000 to 0x4083fbe0: .
RedBoot>
```

2. Now configure RedBoot's Flash configuration with the command:

```
RedBoot> fconfig -i
```

Remember to substitute the appropriate MAC address for this board at the appropriate step. If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.7.11
Local IP address: 192.168.7.83
Local IP address mask: 255.255.255.0
Default server IP address: 192.168.7.11
Console baud rate: 115200
DNS domain name: farm.ecoscentric.com
DNS server IP address: 192.168.7.11
Network hardware address [MAC]: 0x0E:0x00:0x00:0xEA:0x18:0xF0
```

```
GDB connection port: 9000
Force console for special debug messages: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x4083f7c0-0x4083fbdf: .
... Program from 0x23fff7c0-0x23fffbe0 to 0x4083f7c0: .
RedBoot>
```

The RedBoot installation is now complete. This can be tested by powering off the board, and then powering on the board again. Output similar to the following should be seen on the DEBUG serial port. Verify the IP settings are as expected.

```
Ethernet eth0: MAC address 0e:00:00:ea:18:a2
IP: 192.168.7.83/255.255.255.0, Gateway: 192.168.7.11
Default server: 192.168.7.11
DNS server IP: 192.168.7.11, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [ROM]

Platform: AT91SAM9260-EK (ARM9)
RAM: 0x20000000-0x24000000 [0x20035d08-0x23ffef80 available]
FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the AT91SAM9260-EK are:

```
$ mkdir redboot_at91sam9260ek_rom
$ cd redboot_at91sam9260ek_rom
$ ecosconfig new at91sam9260ek redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/sam9260ek/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding AT91Bootstrap

The sources of AT91Bootstrap are found in the `AT91Bootstrap` directory of the sam9260ek package. This is a copy of the software as supplied by Atmel with some slight modifications to permit it to be built with the same tools as eCos.

To rebuild the second-level bootstrap for the AT91SAM9260-EK execute the following commands:

```
$ cd $ECOS_REPOSITORY/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9260ek/dataflash
$ make
```

This should result in the creation of a number of files, including `dataflash_at91sam9260ek.bin` which can be copied out.

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM9260-EK platform HAL package is loaded automatically when eCos is configured for the `sam9260ek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into DataFlash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is the startup type which can be used during application development via a JTAG device such as the PEEDI. arm-eabi-gdb is used to load a JTAG startup application into memory and debug it. Hardware setup is divided between the initialization section of the PEEDI configuration file and software in the loaded application.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM9260-EK board contains an 8Mbyte Atmel AT45DB DataFlash device. The `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the AT91SAM9260-EK board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Ethernet Driver

The AT91SAM9260-EK board uses the AT91SAM9260's internal EMAC ethernet device attached to an external Davicom DM9161A PHY. The `CYGPKG_DEVS_ETH_ARM_AT91` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the AT91SAM9260-EK board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The AT91SAM9260-EK board uses the AT91SAM9260's internal RTTC support. The `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC` package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

I^{2}C Driver

Warning

While the I^{2}C® driver uses the SAM9's internal Two-Wire Interface (TWI) support (see Two-Wire Interface (TWI) driver), you may experience problems using the I^{2}C device on the AT91SAM9260-EK board. This is because the Ethernet MII interface and I^{2}C bus 0 share GPIO lines PA23 and PA24. By default the Ethernet MAC uses the RMII interface and these shared lines are not, in theory, used. However, these lines are connected to the PHY and interference from the PHY has been observed, which prevents I^{2}C functioning correctly.

The solution is to unsolder resistors R121 and R122 to isolate the PHY from the I^{2}C lines.

Watchdog Driver

The AT91SAM9260-EK board uses the AT91SAM9260's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

Warning

The ATSAM926x processor will boot with watchdog support enabled, and the watchdog configuration is write-once. That is, if it is disabled, it cannot be re-enabled. Due to its nature, RedBoot disables the watchdog when it starts so any eCos applications with watchdog support enabled that are run by RedBoot will not function correctly.

USART Serial Driver

The AT91SAM9260-EK board uses the AT91SAM9260's internal USART serial support as described in the SAM9 processor HAL documentation. Three serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/dbg`" in the interrupt-driven driver; USART 0 which is mapped to virtual vector channel 1 and "`/dev/ser0`"; and USART 1 which is mapped to virtual vector channel 2 and "`/dev/ser1`". Only USART 0 supports full modem control signals but USART 1 supports RTS/CTS.

MCI Driver

As the SAM MCI driver is included in the hardware-specific configuration for this target, nothing is required to load it. Similarly the MMC/SD bus driver layer (`CYGPKG_DEVS_DISK_MMC`) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (`CYGPKG_IO_DISK`), along with the intended filesystem, typically, the FAT filesystem (`CYGPKG_FS_FAT`) and any of its package dependencies (including `CYGPKG_LIBC_STRING` and `CYGPKG_LINUX_COMPAT` for FAT).

If the generic disk I/O infrastructure is needed for some other reason, and you do not wish to also include the MCI driver, then the configuration option within this platform HAL `CYGPKG_HAL_ARM_ARM9_SAM9260EK_MMCSD` can be used to forcibly disable it.

Various options can be used to control specifics of the SAM MCI driver. Consult the SAM MCI driver documentation for information on its configuration.

On this target, it is not possible to detect from the MMC/SD socket whether cards have been inserted or removed. Thus the disk I/O layer's removeable media support will not detect when cards have been inserted or removed, and therefore the only way to detect if a card has been inserted is to attempt mounts.

The MMC/SD socket also does not permit detection of the write-protect (or "lock") switch present on SD cards. "Locked" cards will therefore not be detected which means that despite the switch position, it is still possible to write to them since the lock switch does not physically enforce write protection.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`
The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM926EJ CPU in the AT91SAM9260.

`-mthumb`
The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Onboard NAND

The HAL port includes a low-level driver to access the on-board Samsung K9F2G08U08 NAND flash memory chip. To enable the driver, activate the CDL option `CYGPKG_HAL_SAM9260EK_NAND` and ensure that the `CYGPKG_DEVS_NAND_SAMSUNG_K9` package is present in your eCos configuration.

`CYGHWR_HAL_SAM9260EK_NAND_USE_STATUS_LINE`
If set, this option configures the driver to wait for NAND operations to complete by waiting for the chip to deassert its Busy line. This is the default behaviour and is recommended, but may be disabled if you need to use the line (PIO C13) for some other purpose. (If disabled, the memory controller is configured to stall NAND accesses until they complete, which will interfere with multi-threading.)

`CYGNUM_HAL_SAM9260EK_NAND_POLL_INTERVAL`
The number of microseconds delay in the polling loops which wait for NAND operations to complete.

Partitioning the NAND chip

The NAND chip must be partitioned before it can become available to applications.

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_DEVS_NAND_SAM9260EK_PARTITION_MANUAL_CONFIG`); if you choose to use this, the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script sets up a single partition (number 0) encompassing the entire device.

It is possible to configure the partitions in some other way, should it be appropriate for your setup, for example to read a Linux-style partition table from the chip. To do so you will have to add appropriate code to `sam9260ek_nand.c`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only JTAG configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.at91sam9260ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `peedi.at91sam9260ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.at91sam9260ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a second-level bootstrap and ROM RedBoot is resident in DataFlash, it will be run.

An issue occurs when the AT91 Ethernet driver is included in your configuration. In order to work around a board hardware design issue, the CPU generates an external reset in order to reset the Ethernet PHY. However this can be interpreted by the PEEDI as an indication that the CPU itself has reset, and if the PEEDI configuration file option `CORE0_STARTUP_MODE` is set to `RESET` then the CPU will be halted at this point. To avoid this issue, the `CORE0_STARTUP_MODE` can be set to `RUN`.

Consult the PEEDI documentation for information on other features.

Running JTAG applications

Applications configured for JTAG startup can be run directly under a JTAG debugger. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USARTs 0 or 1 can be chosen instead by setting the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` configuration option in the platform HAL to channel 1 or 2.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM9260-EK hardware, and should be read in conjunction with that specification. The AT91SAM9260-EK platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the SAM9 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x20000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x20000000, but in order to assign hardware exception vectors vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x30000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x20040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is unused by eCos and is available for application use.

On-chip ROM

This is located at address 0x00100000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x71000000. The same memory is also accessible uncached and unbuffered at virtual location 0x71800000.

USB host port

The USB host port (UHP) registers are located at address 0x00300000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x72800000. Memory accessed at this address is uncached and unbuffered. There is no cached variant.

SPI dataflash

SPI Dataflash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x40000000 for the on-board flash and 0x50000000 for the dataflash slot, the extent will clearly depend on the Dataflash capacity. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers

These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

eCos uses the SDRAM, ethernet PHY, MCI, and SPI dataflash facilities on the AT91SAM9260-EK board. eCos does not currently make any use of any other off-chip peripherals present on this board.

Advanced Interrupt Controller

This port has been designed to exploit benefits of the Advanced Interrupt Controller of the AT91SAM9260, using the facilities of the SAM9 processor HAL. Consult the documentation in that package for details.

SPI Dataflash

eCos supports SPI access to Dataflash on the AT91SAM9260-EK. An on-board device and an external card slot are provided on the board. The on-chip device is typically used to contain RedBoot and flash configuration data. The external slot is available for application use.

Accesses to Dataflash are performed via the Flash API, using 0x40000000 or 0x50000000 as the nominal address of the device, although it does not truly exist in the processor address space. For the external card slot, on driver initialisation, eCos and RedBoot can detect the presence of a card in the socket. In particular, on reset RedBoot will indicate the presence of Flash at the 0x40000000 address range in its startup banner if it has been successfully detected. Hot swapping is not possible.

Since Dataflash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

The MCI driver cannot be enabled simultaneously with the SPI driver, as the drivers need differing pin configurations for the same pins on this board due to the shared socket.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 258.1. sam9260ek Real-time characterization

```
            Startup, main stack : stack used   420 size  3920
             Startup :  Interrupt stack used   528 size  4096
             Startup : Idlethread stack used    80 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    6.28 microseconds (38 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  64

```

Other Issues

The AT91SAM9260-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SAM9 processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 259. Atmel AT91SAM9261 Evaluation Kit Board Support

Name

eCos Support for the Atmel AT91SAM9261 Evaluation Kit — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel AT91SAM9261 Evaluation Kit. The AT91SAM9261 Evaluation Kit contains the AT91SAM9261 microprocessor, 64Mbytes of SDRAM, 256Mbytes of NAND flash memory, an Atmel Dataflash, a Davicom DM9000 MAC+PHY, a SD/MMC/DataFlash socket, a DAC, an LCD display, external connections for a DEBUG serial channel, ethernet, USB host/device, and the various other peripherals supported by the AT91SAM9261. eCos support for the many devices and peripherals on the boards and the AT91SAM9261 is described below.

For typical eCos development, a RedBoot image is programmed into the on-board dataflash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the SAM9 processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The on-board Dataflash consists of 8192 blocks of 1056 bytes each. In a typical setup, the first 32K bytes are reserved for the second-level bootstrap, AT91Bootstrap. The following 164736 bytes are reserved for the use of the ROM RedBoot image (The odd size aligns the end of the RedBoot area to a 1056 block boundary). The topmost block is used to manage the flash and the next block down holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J15 can be used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the AT91SAM9261EK target.

There is an ethernet driver `CYGPKG_DEVS_ETH_DAVICOM_DM9000` for the DM9000 ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the AT91SAM9261EK board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the board.

There is a driver for the on-chip real-time timer controller (RTTC) at `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC`. This driver is also loaded automatically when configuring for the target.

The SAM9 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91SAM9261. This type of bus is also known as I²C®. Further documentation may be found in the SAM9 processor HAL documentation.

There is a driver for the MultiMedia Card Interface (MCI) at `CYGPKG_DEVS_MMCSD_ATMEL_SAM_MCI`. This driver is loaded automatically when configuring for the SAM9261-EK target and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation may be found within that package.

The platform HAL provides definitions to allow access to devices on the SPI bus. The HAL provides information to the more general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board..

Furthermore, the platform HAL package contains support for SPI dataflash cards. The HAL support integrates with the `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` package as well as the above SPI packages. That package is automatically loaded when configuring for the target. Dataflash media is then accessed as a Flash device, using the Flash I/O API within the `CYGPKG_IO_FLASH` package, if that package is loaded in the configuration.

It is also possible to configure the HAL to access MMC cards in SPI mode, instead of using the MCI interface.

In general, devices (Caches, PIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM9261-EK support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM9261-EK board for eCos Development

Overview

In a typical development environment, the AT91SAM9261-EK board boots from the DataFlash and run the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from Dataflash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is an historical accident. RedBoot actually runs from SDRAM after being loaded there from Dataflash by the second-level bootstrap. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The on-chip boot program on the AT91SAM9261 is only capable of loading programs from Dataflash or NAND flash into on-chip SRAM and is therefore quite restrictive. Consequently RedBoot cannot be booted directly and a second-level bootstrap must be used. Such a second-level bootstrap is supplied by Atmel in the form of AT91Bootstrap. This is therefore programmed into the start of Dataflash and is then responsible for initializing the SDRAM and loading RedBoot from Dataflash and executing it.

Caution

There is a size limit on the size of applications which the AT91Bootstrap second level bootstrap will load. Images larger than 320Kbytes will require the AT91Bootstrap application to be rebuilt with a larger `IMG_SIZE` definition in `AT91Bootstrap/board/at91sam9261ek/dataflash/at91sam9261ek.h` within the sam9260ek HAL package in the eCos source repository (`packages/hal/arm/arm9/sam9260ek/current/`).

There are basically two ways to write the second-level bootstrap and RedBoot to the Dataflash. The first is to use the Atmel-supplied SAM-BA program that interacts with the on-chip boot program. The second is to use a JTAG debugger that understands the microcontroller and can write to the dataflash (for example the Ronetix PEEDI). Since the availability of the latter cannot be guaranteed, only the first method will be described here.

Programming RedBoot into DataFlash using SAM-BA

The following gives the steps needed to program the second-level bootstrap and RedBoot into the DataFlash using SAM-BA. The user should refer to the SAM-BA documentation for full details of how to run the program.

1. Download the AT91 In-system Programmer software package from the Atmel website. SAM9 series CPU's require the 2.1.x series version of SAM-BA. Install it on a suitable PC running Windows.

2. From the root directory of your eCosPro installation, copy the file `dataflash_at91sam9261ek.bin` from the sub-directory `packages/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9261ek` and `redboot_ROM.bin` from the sub-directory `loaders/sam9261ek` to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the DEBUG serial port of the board and a serial port on a convenient host (which need not be the PC running SAM-BA). Run a terminal emulator (Hyperterm or minicom) at 115200 baud. Connect a USB cable between the PC and the AT91SAM9261-EK board.

4. Power up or reset the board and Windows should recognize the USB device. If it does not, then move J21 to the 2-3 position and reset the board, it should be recognized now. Windows may ask you to install a new driver, in which case follow the instructions.

5. Start SAM-BA. Select "\usb\ARM0" for the communication interface, and "AT91SAM9261-EK" for the board. If the USB option does not appear, check the cable and look in the Windows Device Manager for the new USB COM device. If all is well, click on "Connect".

6. If you moved J21 to 2-3, move it back to the default 1-2 position.

7. In the SAM-BA main window, select the "DataFlash AT45DB/DBC" tab and in the "Scripts" dropdown menu select "Enable Dataflash (SPI0 CS0)", to program the on-board Dataflash device. Click Execute and SAM-BA should emit the following in the message area:

   ```
   (AT91-ISP v1.13) 1 % DATAFLASH::Init 0
   -I- DATAFLASH::Init 0 (trace level : 4)
   -I- Loading applet isp-dataflash-at91sam9261.bin at address 0x20000000
   -I- Memory Size : 0x840000 bytes
   -I- Buffer address : 0x20002A40
   -I- Buffer size: 0x80E80 bytes
   -I- Applet initialization done
   ```

8. Select "Send BootFile" from the "Scripts" menu and "Execute" it. When the file open dialog appears, select the `dataflash_at91sam9261ek.bin` file and click "Open". The following output should be seen:

   ```
   (AT91-ISP v1.13) 1 % GENERIC::SendBootFileGUI
   GENERIC::SendFile dataflash_at91sam9261ek.bin at address 0x0
   -I- File size : 0x10A2 byte(s)
   -I-     Writing: 0x10A2 bytes at 0x0 (buffer addr : 0x20002A40)
   -I-     0x10A2 bytes written by applet
   ```

9. The second-level bootstrap has now been written to DataFlash, we must now write RedBoot.

10. In the "Send File Name" box type in the path name to the `redboot_ROM.bin` file, or use the Open Folder button and browse to it.

11. In the Address field set the value to 0x8400.

12. Click the "Send File" button. SAM-BA will put up a dialog box while it is writing the file to the DataFlash, and will output something similar to the following in the message area:

    ```
    (AT91-ISP v1.13) 1 % send_file {DataFlash AT45DB/DCB} "redboot_ROM.bin" 0x8400 0
    -I- Send File //bert/Shared/Releng/sam9261ek/redboot_ROM.bin at address 0x8400
    GENERIC::SendFile //bert/Shared/Releng/sam9261ek/redboot_ROM.bin at address 0x8400
    -I- File size : 0x1F928 byte(s)
    -I-     Writing: 0x1F928 bytes at 0x8400 (buffer addr : 0x20002A40)
    -I-     0x1F928 bytes written by applet
    ```

13. Shut down SAM-BA and disconnect the USB cable. Press the reset button on the board and something similar to the following should be output on the DEBUG serial line.

    ```
    RomBOOT
    >Start AT91Bootstrap...
    +**Warning** FLASH configuration checksum error or invalid key
    Use 'fconfig -i' to [re]initialize database
    >Start AT91Bootstrap...
    No network interfaces found

    RedBoot(tm) bootstrap and debug environment [ROM]
    ```

```
eCosCentric certified release, version v3_0_3 - built 12:53:09, Sep 24 2009

Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: SAM9261-EK (ARM9)
RAM: 0x20000000-0x24000000 [0x20031230-0x23ffef80 available]
FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
RedBoot>
```

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x4083fbe0-0x4083ffff: .
... Program from 0x23fffbe0-0x24000000 to 0x4083fbe0: .
RedBoot> fis list
Name              FLASH addr  Mem addr    Length      Entry point
(reserved)        0x40000000  0x40000000  0x00008000  0x00000000
RedBoot           0x40008000  0x40008000  0x00028380  0x00000000
RedBoot config    0x4083F7C0  0x4083F7C0  0x00000420  0x00000000
FIS directory     0x4083FBE0  0x4083FBE0  0x00000420  0x00000000
RedBoot>
```

2. Now configure RedBoot's Flash configuration with the command:

```
RedBoot> fconfig -i
```

Remember to substitute the appropriate MAC address for this board at the appropriate step. If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.7.11
Local IP address: 192.168.7.222
Local IP address mask: 255.255.255.0
Default server IP address: 192.168.7.9
Console baud rate: 115200
DNS server IP address: 192.168.7.11
Network hardware address [MAC]: 0x00:0x23:0x31:0x37:0x00:0x4e
GDB connection port: 9000
Force console for special debug messages: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x4083f7c0-0x4083fbdf: .
... Program from 0x23fff7c0-0x23fffbe0 to 0x4083f7c0: .
RedBoot>
```

The RedBoot installation is now complete. This can be tested by powering off the board, and then powering on the board again. Output similar to the following should be seen on the DEBUG serial port. Verify the IP settings are as expected.

```
RomBOOT
```

```
>Start AT91Bootstrap...
+Ethernet eth0: MAC address 00:03:47:df:32:a8
IP: 192.168.7.85/255.255.255.0, Gateway: 192.168.7.11
Default server: 192.168.7.11
DNS server IP: 192.168.7.11, DNS domain name: <null%gt;

RedBoot(tm) bootstrap and debug environment [ROM]

Platform: SAM9261-EK (ARM9)
RAM: 0x20000000-0x24000000 [0x20031230-0x23ffef80 available]
FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the AT91SAM9261-EK are:

```
$ mkdir redboot_at91sam9261ek_rom
$ cd redboot_at91sam9261ek_rom
$ ecosconfig new at91sam9261ek redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/sam9261ek/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding AT91Bootstrap

The sources of AT91Bootstrap are found in the `AT91Bootstrap` directory of the sam9260ek package. This is a copy of the software as supplied by Atmel with some slight modifications to permit it to be built with the same tools as eCos.

To rebuild the second-level bootstrap for the AT91SAM9261EK execute the following commands:

```
$ cd $ECOS_REPOSITORY/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9261ek/dataflash
$ make
```

This should result in the creation of a number of files, including `dataflash_at91sam9261ek.bin` which can be copied out.

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM9261-EK platform HAL package is loaded automatically when eCos is configured for the `sam9261ek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into DataFlash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is the startup type which can be used during application development via a JTAG device such as the PEEDI. arm-eabi-gdb is used to load a JTAG startup application into memory and debug it. Hardware setup is divided between the initialization section of the PEEDI configuration file and software in the loaded application.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM9261-EK board contains an 8Mbyte Atmel AT45DB DataFlash device. The `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the AT91SAM9261-EK board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Ethernet Driver

The AT91SAM9261-EK board uses a Davicom DM9000 ethernet MAC and PHY chip for ethernet connectivity. The `CYGPKG_DEVS_ETH_DAVICOM_DM9000` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the AT91SAM9261-EK board. This driver is not active until the generic Ethernet support package, CYGPKG_IO_ETH_DRIVERS, is included in the configuration.

RTC Driver

The AT91SAM9261-EK board uses the AT91SAM9261's internal RTTC support. The CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, CYGPKG_IO_WALLCLOCK, is included in the configuration.

Watchdog Driver

The AT91SAM9261-EK board uses the AT91SAM9261's internal watchdog support. The CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC package contains all the code necessary to support this device. Within that package the CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, CYGPKG_IO_WATCHDOG, is included in the configuration.

Warning

The ATSAM926x processor will boot with watchdog support enabled, and the watchdog configuration is write-once. That is, if it is disabled, it cannot be re-enabled. Due to its nature, RedBoot disables the watchdog when it starts so any eCos applications with watchdog support enabled that are run by RedBoot will not function correctly.

USART Serial Driver

The AT91SAM9261-EK board uses the AT91SAM9261's internal USART serial support as described in the SAM9 processor HAL documentation. Just one serial port is available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "/dev/dbg" in the interrupt-driven driver. This serial port only provides basic TX and RX lines, with no modem control or flow control lines. RTS/CTS.

MCI Driver

As the SAM MCI driver is included in the hardware-specific configuration for this target, nothing is required to load it. Similarly the MMC/SD bus driver layer (CYGPKG_DEVS_DISK_MMC) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (CYGPKG_IO_DISK), along with the intended filesystem, typically, the FAT filesystem (CYGPKG_FS_FAT) and any of its package dependencies (including CYGPKG_LIBC_STRING and CYGPKG_LINUX_COMPAT for FAT).

If the generic disk I/O infrastructure is needed for some other reason, and you do not wish to also include the MCI driver, then the configuration option within this platform HAL CYGPKG_HAL_ARM_ARM9_SAM9261EK_MMCSD can be used to forcibly disable it.

Various options can be used to control specifics of the SAM MCI driver. Consult the SAM MCI driver documentation for information on its configuration.

On this target, it is not possible to detect from the MMC/SD socket whether cards have been inserted or removed. Thus the disk I/O layer's removeable media support will not detect when cards have been inserted or removed, and therefore the only way to detect if a card has been inserted is to attempt mounts.

The MMC/SD socket also does not permit detection of the write-protect (or "lock") switch present on SD cards. "Locked" cards will therefore not be detected which means that despite the switch position, it is still possible to write to them since the lock switch does not physically enforce write protection.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM926EJ CPU in the AT91SAM9261.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Onboard NAND

The HAL port includes a low-level driver to access the on-board Samsung K9F1208U08 NAND flash memory chip. To enable the driver, activate the CDL option `CYGPKG_HAL_SAM9261EK_NAND` and ensure that the `CYGPKG_DEVS_NAND_SAMSUNG_K9` package is present in your eCos configuration.

`CYGHWR_HAL_SAM9261EK_NAND_USE_STATUS_LINE`
: If set, this option configures the driver to wait for NAND operations to complete by waiting for the chip to deassert its Busy line. This is the default behaviour and is recommended, but may be disabled if you need to use the line (PIO C13) for some other purpose. (If disabled, the memory controller is configured to stall NAND accesses until they complete, which will interfere with multi-threading.)

`CYGNUM_HAL_SAM9261EK_NAND_POLL_INTERVAL`
: The number of microseconds delay in the polling loops which wait for NAND operations to complete.

Partitioning the NAND chip

The NAND chip must be partitioned before it can become available to applications.

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_DEVS_NAND_SAM9261EK_PARTITION_MANUAL_CONFIG`); if you choose to use this, the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script sets up a single partition (number 0) encompassing the entire device.

It is possible to configure the partitions in some other way, should it be appropriate for your setup, for example to read a Linux-style partition table from the chip. To do so you will have to add appropriate code to `sam9261ek_nand.c`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only JTAG configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.at91sam9261ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `peedi.at91sam9261ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.at91sam9261ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a second-level bootstrap and ROM RedBoot is resident in DataFlash, it will be run.

Consult the PEEDI documentation for information on other features.

Running JTAG applications

Applications configured for JTAG startup can be run directly under a JTAG debugger. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM9261-EK hardware, and should be read in conjunction with that specification. The AT91SAM9261-EK platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the SAM9 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x20000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x20000000, but in order to assign hardware exception vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x30000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x20040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is unused by eCos and is available for application use.

On-chip ROM

This is located at address 0x00100000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x71000000. The same memory is also accessible uncached and unbuffered at virtual location 0x71800000.

USB host port

The USB host port (UHP) registers are located at address 0x00300000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x72800000. Memory accessed at this address is uncached and unbuffered. There is no cached variant.

SPI dataflash

SPI Dataflash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x40000000 for the on-board flash and 0x50000000 for the dataflash slot, the extent will clearly depend on the Dataflash capacity. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers
: These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

DM9000 Ethernet Device
: This is located on chip select 2 of the static memory controller and is visible at physical address 0x30000000. The HAL uses the MMU to relocate this to 0x80000000 in the virtual memory space.

Off-chip Peripherals
: eCos uses the SDRAM, MCI, and SPI dataflash facilities on the AT91SAM9261-EK board. eCos does not currently make any use of any other off-chip peripherals present on this board.

Advanced Interrupt Controller

This port has been designed to exploit benefits of the Advanced Interrupt Controller of the AT91SAM9261, using the facilities of the SAM9 processor HAL. Consult the documentation in that package for details.

SPI Dataflash

eCos supports SPI access to Dataflash on the AT91SAM9261. An on-board device and an external card slot are provided on the board. The on-chip device is typically used to contain RedBoot and flash configuration data. The external slot is available for application use.

Accesses to Dataflash are performed via the Flash API, using 0x40000000 or 0x50000000 as the nominal address of the device, although it does not truly exist in the processor address space. For the external card slot, on driver initialisation, eCos and RedBoot can detect the presence of a card in the socket. In particular, on reset RedBoot will indicate the presence of Flash at the 0x40000000 address range in its startup banner if it has been successfully detected. Hot swapping is not possible.

Since Dataflash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

RedBoot or applications can also be booted from the Dataflash card socket, as well as from the on-board Dataflash device. Booting from the Dataflash card socket can be performed by switching jumper J21 from pins 1-2 closed, to pins 2-3 closed. When booting RedBoot or applications in this way, you *must* enable the SAM9261-EK platform HAL configuration option "SPI chip select #0 is socket" (`CYGHWR_HAL_ARM_ARM9_SAM9261EK_DATAFLASH_NPCS0_SOCKET`) found within the "External Atmel AT49xxxx DataFlash memory support" component. Failure to do so will not just render the Dataflash card inaccessible after booting, but is likely to cause permanent damage to the AT91SAM9261.

Once an appropriately configured "ROM" startup image has been built, it can be converted to raw binary format using **arm-eabi-objcopy**. You must then copy an AT91Bootstrap second stage boot loader binary image to the beginning (offset 0) of the card, and then the RedBoot/application image at offset 0x8000 on the card.

Programming on the card can be performed with SAM-BA, an external programmer, or with a standard build of RedBoot booted from the on-board Dataflash. An example of using an installed RedBoot loaded from on-board Dataflash to program the card would be as follows. Note the two Flash memories detected by RedBoot, as shown in the **version** output. The first is the on-board Dataflash part, the second is the Dataflash located in the card socket.

```

RedBoot>
```

After this, the board can be powered off, jumper J21 switched to pins 2-3, and the board powered up again. The application or RedBoot will then boot from the Dataflash card.

The MCI driver cannot be enabled simultaneously with the SPI driver, as the drivers need differing pin configurations for the same pins on this board due to the shared socket.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 259.1. sam9261ek Real-time characterization

```
            Startup, main stack : stack used   420 size  3920
             Startup :  Interrupt stack used   536 size  4096
             Startup : Idlethread stack used    80 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    6.37 microseconds (39 raw clock ticks)

```

Other Issues

The AT91SAM9261-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SAM9 processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 260. Atmel AT91SAM9263 Evaluation Kit Board Support

Name

eCos Support for the Atmel AT91SAM9263 Evaluation Kit — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel AT91SAM9263 Evaluation Kit. The AT91SAM9263 Evaluation Kit contains the AT91SAM9263 microprocessor, 64Mbytes of SDRAM, 4MBytes of PSRAM, 256Mbytes of NAND flash memory, an Atmel serial EEPROM, a Davicom DM9161A PHY, one SD/MMC/DataFlash socket and a SD/MMC socket, a DAC, external connections for two serial channels (one debug channel and one flow controlled), ethernet, USB host/device, and the various other peripherals supported by the AT91SAM9263. eCos support for the many devices and peripherals on the boards and the AT91SAM9263 is described below.

For typical eCos development, a RedBoot image is programmed onto a dataflash card in the SD/MMC/DataFlash socket, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the SAM9 processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

Booting is from a DataFlash card in the SD/MMC/DataFlash socket. In a typical setup, the first 32K bytes are reserved for the second-level bootstrap, AT91Bootstrap. The following 164736 bytes are reserved for the use of the ROM RedBoot image (The odd size aligns the end of the RedBoot area to a block boundary). The topmost block is used to manage the flash and the next block down holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J14 and flow controlled port at J18 (connected to USART channel 0) can be used by RedBoot for communication with the host. If any of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the AT91SAM9263EK target.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91` for the on-chip ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the AT91SAM9263EK board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the board.

There is a driver for the on-chip real-time timer controller (RTTC) at `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC`. This driver is also loaded automatically when configuring for the target.

The SAM9 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91SAM9263. This type of bus is also known as I²C®. Further documentation may be found in the SAM9 processor HAL documentation.

There is a driver for the MultiMedia Card Interface (MCI) at `CYGPKG_DEVS_MMCSD_ATMEL_SAM_MCI`. This driver is loaded automatically when configuring for the SAM9263-EK target and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation may be found within that package. The driver can be configured to use either the SD/MMC/DataFlash socket at J19 or the SD/MMC socket at J10. By default it uses J10, leaving J9 for the bootstrap Dataflash.

The platform HAL provides definitions to allow access to devices on the SPI bus. The HAL provides information to the more general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board.

Furthermore, the platform HAL package contains support for SPI dataflash cards. The HAL support integrates with the CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH package as well as the above SPI packages. That package is automatically loaded when configuring for the target. Dataflash media is then accessed as a Flash device, using the Flash I/O API within the CYGPKG_IO_FLASH package, if that package is loaded in the configuration.

It is also possible to configure the HAL to access MMC cards in SPI mode, instead of using the MCI interface.

The on-board NAND interface is supported. At the time of writing, this has been tested with the Micron MT29F2G08 part fitted to kit BOM revision 007 and later.

Note

Revision 007 of this board has a known issue with accessing the NAND flash device. Refer to section 1.5, "NAND Flash Access Issue", of the Rev.B User Guide (Atmel document no. 6341) for more details. During testing with a rev 007 board, eCosCentric found it necessary to tie the CS line as per that document in order to ensure reliable access to the device.

In general, devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM9263-EK support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM9263-EK board for eCos Development

Overview

In a typical development environment, the AT91SAM9263-EK board boots from a 4MiB DataFlash card and run the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from 4MiB Dataflash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is an historical accident. RedBoot actually runs from SDRAM after being loaded there from Dataflash by the second-level bootstrap. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The on-chip boot program on the AT91SAM9263 is only capable of loading programs from DataFlash, SD card or NAND flash into on-chip SRAM and is therefore quite restrictive. Consequently RedBoot cannot be booted directly and a second-level bootstrap must be used. Such a second-level bootstrap is supplied by Atmel in the form of AT91Bootstrap. This is therefore programmed into the start of Dataflash and is then responsible for initializing the SDRAM and loading RedBoot from Dataflash and executing it.

Caution

There is a size limit on the size of applications which the AT91Bootstrap second level bootstrap will load. Images larger than 320Kbytes will require the AT91Bootstrap application to be rebuilt with a larger `IMG_SIZE` definition in `AT91Bootstrap/board/at91sam9263ek/dataflash/at91sam9263ek.h` within the sam9260ek HAL package in the eCos source repository (`packages/hal/arm/arm9/sam9260ek/current/`).

There are basically two ways to write the second-level bootstrap and RedBoot to the Dataflash. The first is to use the Atmel-supplied SAM-BA program that interacts with the on-chip boot program. The second is to use a JTAG debugger that understands the microcontroller and can write to the dataflash (for example the Ronetix PEEDI). Since the availability of the latter cannot be guaranteed, only the first method will be described here.

Programming RedBoot into DataFlash using SAM-BA

The following gives the steps needed to program the second-level bootstrap and RedBoot into the DataFlash card using SAM-BA. The user should refer to the SAM-BA documentation for full details of how to run the program.

1. Download the AT91 In-system Programmer software package from the Atmel website. SAM9 series CPU's require the 2.1.x series version of SAM-BA. Install it on a suitable PC running Windows.
2. From the root directory of your eCosPro installation, copy the file `dataflash_at91sam9263ek.bin` from the sub-directory `packages/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9263ek` and `redboot_ROM.bin` from the sub-directory `loaders/sam9263ek` to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the DEBUG serial port of the board and a serial port on a convenient host (which need not be the PC running SAM-BA). Run a terminal emulator (Hyperterm or minicom) at 115200 baud. Connect a USB cable between the PC and the AT91SAM9263-EK board. Windows may ask you to install a new driver, in which case follow the instructions.

4. Power up the board without the DataFlash card inserted. This will force the bootstrap to enter ISP mode.

5. Start SAM-BA. Select "\usb\ARM0" for the communication interface, and "AT91SAM9263-EK" for the board. If the USB option does not appear, check the cable and look in the Windows Device Manager for the new USB COM device. If all is well, click on "Connect".

6. In the SAM-BA main window, select the "SDRAM" tab, select the "Enable SDRAM 100MHz" script from the dropdown menu and click Execute. SAM-BA should emit the following messages:

   ```
   (AT91-ISP v1.10) 34 % SDRAM::initSDRAM_100
   -I- Configure PIOD as peripheral (D16/D31)
   -I- Init MATRIX to support EBI0 CS1 for SDRAM
   -I- Init SDRAM
   -I- 1. A minimum pause of 200us is provided to precede any signal toggle
   -I- 2. A Precharge All command is issued to the SDRAM
   -I- *pSDRAM = 0;
   -I- 3. Eight Auto-refresh are provided
   -I- *pSDRAM = 0;
   -I- *pSDRAM = 0;
   -I- *pSDRAM = 0;
   -I- *pSDRAM = 0;
   -I- *pSDRAM = 0;
   -I- *pSDRAM = 0;
   -I- *pSDRAM = 0;
   -I- *pSDRAM = 0;
   -I- 4. A mode register cycle is issued to program the SDRAM parameters
   -I- *(pSDRAM+0x20) = 0;
   -I- 5. Write refresh rate into SDRAMC refresh timer COUNT register
   -I- 6. A Normal Mode Command is provided, 3 clocks after tMRD is set
   -I- *pSDRAM = 0;
   -I- End of Init_SDRAM_100
   (AT91-ISP v1.10) 34 %
   ```

7. Now insert the DataFlash card into the socket at J9. In the SAM-BA main window, select the "DataFlash AT45DB/DBC" tab and in the "Scripts" dropdown menu select "Enable Dataflash (SPI0 CS0)", to program the Dataflash card. Click Execute and SAM-BA should emit the following in the message area:

   ```
   (AT91-ISP v1.13) 1 % DATAFLASH::Init 0
   -I- DATAFLASH::Init 0 (trace level : 4)
   -I- Loading applet isp-dataflash-at91sam9263.bin at address 0x20000000
   -I- Memory Size : 0x840000 bytes
   -I- Buffer address : 0x20002A40
   -I- Buffer size: 0x80E80 bytes
   -I- Applet initialization done
   ```

   The actual options and output of SAM-BA may vary according to the version you are using. The behaviour documented here is that of SAM-BA 2.9.

8. Select "Send BootFile" from the "Scripts" menu and "Execute" it. When the file open dialog appears, select the `dataflash_at91sam9263ek.bin` file and click "Open". The following output should be seen:

   ```
   (AT91-ISP v1.13) 1 % GENERIC::SendBootFileGUI
   GENERIC::SendFile dataflash_at91sam9263ek.bin at address 0x0
   -I- File size : 0x106E byte(s)
   -I-     Writing: 0x106E bytes at 0x0 (buffer addr : 0x20002A40)
   -I-     0x106E bytes written by applet
   ```

9. The second-level bootstrap has now been written to DataFlash, we must now write RedBoot.

10. In the "Send File Name" box type in the path name to the `redboot_ROM.bin` file, or use the Open Folder button and browse to it.

11. In the Address field set the value to 0x8400.

12. Click the "Send File" button. SAM-BA will put up a dialog box while it is writing the file to the DataFlash, and will output something similar to the following in the message area:

    ```
    (AT91-ISP v1.13) 1 % send_file {DataFlash AT45DB/DCB} "redboot_ROM.bin" 0x8400 0
    -I- Send File //bert/Shared/Releng/sam9263ek/redboot_ROM.bin at address 0x8400
    GENERIC::SendFile //bert/Shared/Releng/sam9263ek/redboot_ROM.bin at address 0x8400
    -I- File size : 0x24290 byte(s)
    -I-     Writing: 0x24290 bytes at 0x8400 (buffer addr : 0x20002A40)
    -I-     0x24290 bytes written by applet
    ```

13. Shut down SAM-BA and disconnect the USB cable. Press the reset button on the board and something similar to the following should be output on the DEBUG serial line.

    ```
    RomBOOT
    >Start AT91Bootstrap...
    +**Warning** FLASH configuration checksum error or invalid key
    Use 'fconfig -i' to [re]initialize database
    No space to add 'net_device'
    AT91_ETH: Waiting for PHY to reset.
    AT91_ETH: Waiting for link to come up..
    No network interfaces found

    RedBoot(tm) bootstrap and debug environment [ROM]
    eCosCentric certified release, version v3_0_3 - built 12:56:09, Sep 24 2009

    Copyright (C) 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009
    Free Software Foundation, Inc.
    Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited
    RedBoot is free software, covered by the eCos license, derived from the
    GNU General Public License. You are welcome to change it and/or distribute
    copies of it under certain conditions. Under the license terms, RedBoot's
    source code and full license terms must have been made available to you.
    Redboot comes with ABSOLUTELY NO WARRANTY.

    Platform: AT91SAM9263-EK (ARM9)
    RAM: 0x20000000-0x24000000 [0x20035ba8-0x23fff5b0 available]
    FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
    RedBoot>
    ```

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

    ```
    RedBoot> fis init
    About to initialize [format] FLASH image system - continue (y/n)? y
    *** Initialize FLASH Image System
    ... Erase from 0x4083fbe0-0x4083ffff: .
    ... Program from 0x23fffbe0-0x24000000 to 0x4083fbe0: .
    RedBoot>
    ```

2. Now configure RedBoot's Flash configuration with the command:

    ```
    RedBoot> fconfig -i
    ```

    Remember to substitute the appropriate MAC address for this board at the appropriate step. If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.7.11
Local IP address: 192.168.7.222
Local IP address mask: 255.255.255.0
Default server IP address: 192.168.7.9
Console baud rate: 115200
DNS domain name: ecoscentric.com
DNS server IP address: 192.168.7.11
Network hardware address [MAC]: 0x00:0x23:0x31:0x37:0x00:0x4e
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x4083f7c0-0x4083fbdf: .
... Program from 0x23fff7c0-0x23fffbe0 to 0x4083f7c0: .
RedBoot>
```

The RedBoot installation is now complete. This can be tested by powering off the board, and then powering on the board again. Output similar to the following should be seen on the DEBUG serial port. Verify the IP settings are as expected.

```
RomBOOT
>Start AT91Bootstrap...
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 192.168.7.222/255.255.255.0, Gateway: 192.168.7.11
Default server: 192.168.7.11
DNS server IP: 192.168.7.11, DNS domain name: <null>

Platform: AT91SAM9263-EK (ARM9)
RAM: 0x20000000-0x24000000 [0x20035ba8-0x23fff5b0 available]
FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the AT91SAM9263-EK are:

```
$ mkdir redboot_at91sam9263ek_rom
$ cd redboot_at91sam9263ek_rom
$ ecosconfig new at91sam9263ek redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/sam9263ek/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding AT91Bootstrap

The sources of AT91Bootstrap are found in the `AT91Bootstrap` directory of the sam9260ek package. This is a copy of the software as supplied by Atmel with some slight modifications to permit it to be built with the same tools as eCos.

To rebuild the second-level bootstrap for the AT91SAM9263EK execute the following commands:

```
$ cd $ECOS_REPOSITORY/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9263ek/dataflash
$ make
```

This should result in the creation of a number of files, including `dataflash_at91sam9263ek.bin` which can be copied out.

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM9263-EK platform HAL package is loaded automatically when eCos is configured for the `sam9263ek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into DataFlash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is the startup type which can be used during application development via a JTAG device such as the PEEDI. arm-eabi-gdb is used to load a JTAG startup application into memory and debug it. Hardware setup is divided between the initialization section of the PEEDI configuration file and software in the loaded application.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The board has an SD/MMC/DataFlash socket into which a dataflash card may be inserted. The `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the AT91SAM9263-EK board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Ethernet Driver

The AT91SAM9263-EK board uses the AT91SAM9263's internal EMAC ethernet device attached to an external Davicom DM9161A PHY. The `CYGPKG_DEVS_ETH_ARM_AT91` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the AT91SAM9263-EK board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The AT91SAM9263-EK board uses the AT91SAM9263's internal RTTC support. The CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, CYGPKG_IO_WALLCLOCK, is included in the configuration.

Watchdog Driver

The AT91SAM9263-EK board uses the AT91SAM9263's internal watchdog support. The CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC package contains all the code necessary to support this device. Within that package the CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, CYGPKG_IO_WATCHDOG, is included in the configuration.

Warning

The ATSAM926x processor will boot with watchdog support enabled, and the watchdog configuration is write-once. That is, if it is disabled, it cannot be re-enabled. Due to its nature, RedBoot disables the watchdog when it starts so any eCos applications with watchdog support enabled that are run by RedBoot will not function correctly.

USART Serial Driver

The AT91SAM9263-EK board uses the AT91SAM9263's internal USART serial support as described in the SAM9 processor HAL documentation. Two serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "/dev/dbg" in the interrupt-driven driver; and USART 0 which is mapped to virtual vector channel 1 and "/dev/ser0". The debug port is two wires only. but USART 0 supports RTS/CTS.

MCI Driver

As the SAM MCI driver is included in the hardware-specific configuration for this target, nothing is required to load it. Similarly the MMC/SD bus driver layer (CYGPKG_DEVS_DISK_MMC) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (CYGPKG_IO_DISK), along with the intended filesystem, typically, the FAT filesystem (CYGPKG_FS_FAT) and any of its package dependencies (including CYGPKG_LIBC_STRING and CYGPKG_LINUX_COMPAT for FAT).

If the generic disk I/O infrastructure is needed for some other reason, and you do not wish to also include the MCI driver, then the configuration option within this platform HAL CYGPKG_HAL_ARM_ARM9_SAM9263EK_MMCSD can be used to forcibly disable it.

Various options can be used to control specifics of the SAM MCI driver. Consult the SAM MCI driver documentation for information on its configuration. The option CYGHWR_DEVS_MMCSD_ATMEL_SAM_MCI_DEVICE controls which of the two MCI interfaces will be used by the driver.

The MMC/SD socket does not permit detection of the write-protect (or "lock") switch present on SD cards. "Locked" cards will therefore not be detected which means that despite the switch position, it is still possible to write to them since the lock switch does not physically enforce write protection.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM926EJ CPU in the AT91SAM9263.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Onboard NAND

The HAL port includes a low-level driver to access the on-board Micron MT29F2G08 NAND flash memory chip found on revision B of the board. To enable the driver, add the CYGPKG_IO_NAND package to your eCos configuration.

`CYGHWR_HAL_SAM9263EK_NAND_USE_STATUS_LINE`
: If set, this option configures the driver to wait for NAND operations to complete by waiting for the chip to deassert its Busy line. This is the default behaviour and is recommended, but may be disabled if you need to use the line for some other purpose or on derived hardware. (If disabled, the driver falls back to a combination of delay loops and polling the chip's Read Status function.)

`CYGNUM_HAL_SAM9263EK_NAND_POLL_INTERVAL`
: The number of microseconds delay in the polling loops which wait for NAND operations to complete.

Partitioning the NAND chip

The NAND chip must be partitioned before it can become available to applications.

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_DEVS_NAND_SAM9263EK_PARTITION_MANUAL_CONFIG`); if you choose to use this, the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script sets up a single partition (number 0) encompassing the entire device.

It is possible to configure the partitions in some other way, should it be appropriate for your setup, for example to read a Linux-style partition table from the chip. To do so you will have to add appropriate code to `sam9263ek_nand.c`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only JTAG configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.at91sam9263ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `peedi.at91sam9263ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.at91sam9263ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a second-level bootstrap and ROM RedBoot is resident in DataFlash, it will be run.

An issue occurs when the AT91 Ethernet driver is included in your configuration. In order to work around a board hardware design issue, the CPU generates an external reset in order to reset the Ethernet PHY. However this can be interpreted by the PEEDI as an indication that the CPU itself has reset, and if the PEEDI configuration file option `CORE0_STARTUP_MODE` is set to `RESET` then the CPU will be halted at this point. To avoid this issue, the `CORE0_STARTUP_MODE` can be set to `RUN`.

Consult the PEEDI documentation for information on other features.

Running JTAG applications

Applications configured for JTAG startup can be run directly under a JTAG debugger. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USARTs 0 or 1 can be chosen instead by setting the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` configuration option in the platform HAL to channel 1 or 2.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM9263-EK hardware, and should be read in conjunction with that specification. The AT91SAM9263-EK platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the SAM9 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x20000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x20000000, but in order to assign hardware exception vectors vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x30000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x20040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is unused by eCos and is available for application use.

On-chip ROM

This is located at address 0x00100000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x71000000. The same memory is also accessible uncached and unbuffered at virtual location 0x71800000.

USB host port

The USB host port (UHP) registers are located at address 0x00300000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x72800000. Memory accessed at this address is uncached and unbuffered. There is no cached variant.

SPI dataflash

SPI Dataflash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x40000000 for the dataflash slot, the extent will clearly depend on the Dataflash capacity. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers

These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

eCos uses the SDRAM, ethernet PHY, MCI, and SPI dataflash facilities on the AT91SAM9263-EK board. eCos does not currently make any use of any other off-chip peripherals present on this board.

Advanced Interrupt Controller

This port has been designed to exploit benefits of the Advanced Interrupt Controller of the AT91SAM9263, using the facilities of the SAM9 processor HAL. Consult the documentation in that package for details.

SPI Dataflash

eCos supports SPI access to Dataflash on the AT91SAM9263. An external card slot are provided on the board which is typically used to contain RedBoot and flash configuration data.

Accesses to Dataflash are performed via the Flash API, using 0x40000000 as the nominal address of the device, although it does not truly exist in the processor address space. For the external card slot, on driver initialisation, eCos and RedBoot can detect the presence of a card in the socket. In particular, on reset RedBoot will indicate the presence of Flash at the 0x40000000 address range in its startup banner if it has been successfully detected. Hot swapping is not possible.

Since Dataflash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 260.1. sam9263ek Real-time characterization

```
            Startup, main stack : stack used   420 size  3920
             Startup :  Interrupt stack used   528 size  4096
             Startup : Idlethread stack used    96 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    5.95 microseconds (37 raw clock ticks)

Testing parameters:
   Clock samples:            32

```

Other Issues

The AT91SAM9263-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SAM9 processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 261. Atmel AT91SAM9G20 Evaluation Kit Board Support

Name

eCos Support for the Atmel AT91SAM9G20 Evaluation Kit — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel AT91SAM9G20 Evaluation Kit. The AT91SAM9G20 Evaluation Kit contains the AT91SAM9G20 microprocessor, 64Mbytes of SDRAM, 256Mbytes of NAND flash memory, an Atmel Dataflash, an Atmel serial EEPROM, a Davicom DM9161A PHY, a SD/MMC/DataFlash socket, a DAC, external connections for three serial channels (one debug, one full modem, one flow controlled), ethernet, USB host/device, and the various other peripherals supported by the AT91SAM9G20. eCos support for the many devices and peripherals on the boards and the AT91SAM9G20 is described below.

For typical eCos development, a RedBoot image is programmed into the dataflash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the SAM9 processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The Dataflash consists of 8192 blocks of 1056 bytes each. In a typical setup, the first 33792 bytes are reserved for the second-level bootstrap, AT91Bootstrap. The following 164736 bytes are reserved for the use of the ROM RedBoot image (The odd size aligns the end of the RedBoot area to a 1056 block boundary). The topmost block is used to manage the flash and the next block down holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J17 and DTE port at J20 (connected to USART channel 0) and flow controlled port at J18 (connected to USART channel 1) can be used by RedBoot for communication with the host. If any of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the AT91SAM9G20-EK target.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91` for the on-chip ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the AT91SAM9G20-EK board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the board.

There is a driver for the on-chip real-time timer controller (RTTC) at `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC`. This driver is also loaded automatically when configuring for the target.

The SAM9 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91SAM9G20. This type of bus is also known as I²C®. Further documentation may be found in the SAM9 processor HAL documentation.

There is a driver for the MultiMedia Card Interface (MCI) at `CYGPKG_DEVS_MMCSD_ATMEL_SAM_MCI`. This driver is loaded automatically when configuring for the AT91SAM9G20-EK target and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation may be found within that package.

The platform HAL provides definitions to allow access to devices on the SPI bus. The HAL provides information to the more general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board.

Furthermore, the platform HAL package contains support for SPI dataflash cards. The HAL support integrates with the CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH package as well as the above SPI packages. That package is automatically loaded when configuring for the target. Dataflash media is then accessed as a Flash device, using the Flash I/O API within the CYGPKG_IO_FLASH package, if that package is loaded in the configuration.

It is also possible to configure the HAL to access MMC cards in SPI mode, instead of using the MCI interface.

In general, devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM9G20-EK support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Preparing the AT91SAM9G20-EK board for eCos Development

Overview

In a typical development environment, the AT91SAM9G20-EK board boots from the DataFlash and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from Dataflash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from Dataflash by the second-level bootstrap. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The on-chip boot program on the AT91SAM9G20 is only capable of loading programs from Dataflash or NAND flash into 4Kbytes of on-chip SRAM and is therefore quite restrictive. Consequently RedBoot cannot be booted directly and a second-level bootstrap must be used. Such a second-level bootstrap is supplied by Atmel in the form of AT91Bootstrap. This is therefore programmed into the start of Dataflash and is then responsible for initializing the SDRAM and loading RedBoot from Dataflash and executing it.

Caution

There is a size limit on the size of applications which the AT91Bootstrap second level bootstrap will load. Images larger than 320Kbytes will require the AT91Bootstrap application to be rebuilt with a larger `IMG_SIZE` definition in `AT91Bootstrap/board/at91sam9g20ek/dataflash/at91sam9g20ek.h` within the sam9g20ek HAL package in the eCos source repository (`packages/hal/arm/arm9/sam9260ek/current/`).

There are basically two ways to write the second-level bootstrap and RedBoot to the Dataflash. The first is to use the Atmel-supplied SAM-BA program that interacts with the on-chip boot program. The second is to use a JTAG debugger that understands the microcontroller and can write to the dataflash (for example the Ronetix PEEDI). Since the availability of the latter cannot be guaranteed, only the first method will be described here.

Programming RedBoot into DataFlash using SAM-BA

The following gives the steps needed to program the second-level bootstrap and RedBoot into the DataFlash using SAM-BA. The user should refer to the SAM-BA documentation for full details of how to run the program.

1. Download the corresponding AT91 In-system Programmer software package from the Atmel website according to your host operating system and install it on your PC (SAM9 series CPU's require the 2.1.x series version of SAM-BA).
2. From the root directory of your eCosPro installation, copy the file `dataflash_at91sam9g20ek.bin` from the sub-directory `packages/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9g20ek/`

`dataflash` and `redboot_ROM.bin` from the sub-directory `loaders/sam9g20ek` to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the DEBUG serial port of the board and a serial port on a convenient host (which need not be the PC running SAM-BA). Run a terminal emulator (Hyperterm or minicom) at 115200 baud. Connect a USB cable between the PC and the AT91SAM9G20-EK board. Windows may ask you to install a new driver, in which case follow the instructions.

4. Remove Jumper J33 from the board and press the reset button. You should see the following output on the serial line:

   ```
   RomBoot
   >
   ```

   Now reinsert the jumper.

5. Start SAM-BA. Select the appropriate COM port for the communication interface (on Windows hosts this will be of the form "COMx" and on Linux hosts this will be of the form "/dev/ttyUSBx"), and "AT91SAM9G20-EK" for the board. Click on "Connect".

6. In the SAM-BA main window, select the "DataFlash AT45DB/DBC" tab and in the "Scripts" dropdown menu select "Enable Dataflash (SPIO CS1)", to program the on-board Dataflash device. Click Execute and SAM-BA should emit the following in the message area:

   ```
   sam-ba_cdc_linux) 1 % DATAFLASH::Init 1
   -I- DATAFLASH::Init 1 (trace level : 4)
   -I- Loading applet isp-dataflash-at91sam9g20.bin at address 0x200000
   -I- Memory Size : 0x840000 bytes
   -I- Buffer address : 0x202D38
   -I- Buffer size: 0xC60 bytes
   -I- Applet initialization done
   ```

   The actual options and output of SAM-BA may vary according to the version you are using. The behaviour documented here is that of SAM-BA CDC 2.10 on Linux.

7. Now select "Send BootFile" from the "Scripts" menu and "Execute" it. When the file open dialog appears, select the `dataflash_at91sam9g20ek.bin` file and click "Open". The following output should be seen:

   ```
   (sam-ba_cdc_linux) 1 % GENERIC::SendBootFileGUI
   GENERIC::SendFile /tmp/dataflash_at91sam9g20ek.bin at address 0x0
   -I- File size : 0xE7C byte(s)
   -I-     Writing: 0xC60 bytes at 0x0 (buffer addr : 0x202D38)
   -I-     0xC60 bytes written by applet
   -I-     Writing: 0x21C bytes at 0xC60 (buffer addr : 0x202D38)
   -I-     0x21C bytes written by applet
   ```

8. The second-level bootstrap has now been written to DataFlash, we must now write RedBoot.

9. In the "Send File Name" box type in the path name to the `redboot_ROM.bin` file, or use the Open Folder button and browse to it.

10. In the Address field set the value to 0x8400.

11. Click the "Send File" button. SAM-BA will put up a dialog box while it is writing the file to the DataFlash, and will output something similar to the following in the message area:

    ```
    (sam-ba_cdc_linux) 1 % send_file {DataFlash AT45DB/DCB} "/tmp/redboot_ROM.bin" 0x8400 0
    -I- Send File /tmp/redboot_ROM.bin at address 0x8400
    GENERIC::SendFile /tmp/redboot_ROM.bin at address 0x8400
    -I- File size : 0x248D8 byte(s)
    -I-     Writing: 0xC60 bytes at 0x8400 (buffer addr : 0x202D38)
    -I-     0xC60 bytes written by applet
    -I-     Writing: 0xC60 bytes at 0x9060 (buffer addr : 0x202D38)
    ```

```
-I-     0xC60 bytes written by applet
...
-I-     Writing: 0xC60 bytes at 0x2BD40 (buffer addr : 0x202D38)
-I-     0xC60 bytes written by applet
-I-     Writing: 0x338 bytes at 0x2C9A0 (buffer addr : 0x202D38)
-I-     0x338 bytes written by applet
```

12. Shut down SAM-BA and disconnect the USB cable. Press the reset button on the board and something similar to the following should be output on the DEBUG serial line.

```
RomBOOT
>Start AT91Bootstrap...
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
No space to add 'net_device'
AT91_ETH: Waiting for PHY to reset.
AT91_ETH: Waiting for link to come up..
Ethernet eth0: MAC address 12:34:56:78:9a:bc
No IP info for device!

RedBoot(tm) bootstrap and debug environment [ROM]
eCosCentric certified release, version v3_0_22 - built 14:12:12, Sep  7 2010

Copyright (C) 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009
Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: AT91SAM9G20-EK (ARM9)
RAM: 0x20000000-0x24000000 [0x200362e8-0x23ffef80 available]
FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
RedBoot>
```

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x4083fbe0-0x4083ffff: .
... Program from 0x23fffbe0-0x24000000 to 0x4083fbe0: .
RedBoot>
```

2. Now configure RedBoot's Flash configuration with the command:

```
RedBoot> fconfig -i
```

Remember to substitute the appropriate MAC address for this board at the appropriate step. If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.7.11
Local IP address: 192.168.7.83
Local IP address mask: 255.255.255.0
```

```
Default server IP address: 192.168.7.11
Console baud rate: 115200
DNS domain name: farm.ecoscentric.com
DNS server IP address: 192.168.7.11
Network hardware address [MAC]: 0x0E:0x00:0x00:0xEA:0x18:0xF0
GDB connection port: 9000
Force console for special debug messages: false
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x4083f7c0-0x4083fbdf: .
... Program from 0x23fff7c0-0x23fffbe0 to 0x4083f7c0: .
RedBoot>
```

The RedBoot installation is now complete. This can be tested by powering off the board, and then powering on the board again. Output similar to the following should be seen on the DEBUG serial port. Verify the IP settings are as expected.

```
Ethernet eth0: MAC address 0e:00:00:ea:18:e3
IP: 192.168.7.222/255.255.255.0, Gateway: 192.168.7.11
Default server: 192.168.7.11
DNS server IP: 192.168.7.11, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [ROM]
eCosCentric certified release, version v3_0_22 - built 14:12:12, Sep  7 2010

Platform: AT91SAM9G20-EK (ARM9)
RAM: 0x20000000-0x24000000 [0x20036218-0x23ffef80 available]
FLASH: 0x40000000-0x4083ffff, 8192 x 0x420 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the AT91SAM9G20-EK are:

```
$ mkdir redboot_at91sam9g20ek_rom
$ cd redboot_at91sam9g20ek_rom
$ ecosconfig new at91sam9g20ek redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/sam9g20ek/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding AT91Bootstrap

The sources of AT91Bootstrap are found in the `AT91Bootstrap` directory of the sam9260ek package. This is a copy of the software as supplied by Atmel with some slight modifications to permit it to be built with the same tools as eCos.

To rebuild the second-level bootstrap for the AT91SAM9G20-EK execute the following commands:

```
$ cd $ECOS_REPOSITORY/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9g20ek/dataflash
$ make
```

This should result in the creation of a number of files, including `dataflash_at91sam9g20ek.bin` which can be copied out.

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM9G20-EK platform HAL package is loaded automatically when eCos is configured for the `sam9g20ek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into DataFlash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is the startup type which can be used during application development via a JTAG device such as the PEEDI. arm-eabi-gdb is used to load a JTAG startup application into memory and debug it. Hardware setup is divided between the initialization section of the PEEDI configuration file and software in the loaded application.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM9G20-EK board contains an 8Mbyte Atmel AT45DB DataFlash device. The `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the AT91SAM9G20-EK board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Ethernet Driver

The AT91SAM9G20-EK board uses the AT91SAM9G20's internal EMAC ethernet device attached to an external Davicom DM9161A PHY. The `CYGPKG_DEVS_ETH_ARM_AT91` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the AT91SAM9G20-EK board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The AT91SAM9G20-EK board uses the AT91SAM9G20's internal RTTC support. The `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTTC` package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The AT91SAM9G20-EK board uses the AT91SAM9G20's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

Warning

The ATSAM926x processor will boot with watchdog support enabled, and the watchdog configuration is write-once. That is, if it is disabled, it cannot be re-enabled. Due to its nature, RedBoot disables the watchdog when it starts so any eCos applications with watchdog support enabled that are run by RedBoot will not function correctly.

USART Serial Driver

The AT91SAM9G20-EK board uses the AT91SAM9G20's internal USART serial support as described in the SAM9 processor HAL documentation. Three serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/dbg`" in the interrupt-driven driver; USART 0 which is mapped to virtual vector channel 1 and "`/dev/ser0`"; and USART 1 which is mapped to virtual vector channel 2 and "`/dev/ser1`". Only USART 0 supports full modem control signals but USART 1 supports RTS/CTS.

MCI Driver

As the SAM MCI driver is included in the hardware-specific configuration for this target, nothing is required to load it. Similarly the MMC/SD bus driver layer (`CYGPKG_DEVS_DISK_MMC`) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (`CYGPKG_IO_DISK`), along with the intended filesystem, typically, the FAT filesystem (`CYGPKG_FS_FAT`) and any of its package dependencies (including `CYGPKG_LIBC_STRING` and `CYGPKG_LINUX_COMPAT` for FAT).

If the generic disk I/O infrastructure is needed for some other reason, and you do not wish to also include the MCI driver, then the configuration option within this platform HAL `CYGPKG_HAL_ARM_ARM9_SAM9G20EK_MMCSD` can be used to forcibly disable it.

Various options can be used to control specifics of the SAM MCI driver. Consult the SAM MCI driver documentation for information on its configuration.

On this target, it is not possible to detect from the MMC/SD socket whether cards have been inserted or removed. Thus the disk I/O layer's removeable media support will not detect when cards have been inserted or removed, and therefore the only way to detect if a card has been inserted is to attempt mounts.

The MMC/SD socket also does not permit detection of the write-protect (or "lock") switch present on SD cards. "Locked" cards will therefore not be detected which means that despite the switch position, it is still possible to write to them since the lock switch does not physically enforce write protection.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`
The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM926EJ CPU in the AT91SAM9G20.

`-mthumb`
The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Onboard NAND

The HAL port includes a low-level driver to access the on-board Samsung K9F2G08U08 NAND flash memory chip. To enable the driver, activate the CDL option `CYGPKG_HAL_SAM9G20EK_NAND` and ensure that the `CYGPKG_DEVS_NAND_SAMSUNG_K9` package is present in your eCos configuration.

`CYGHWR_HAL_SAM9G20EK_NAND_USE_STATUS_LINE`
If set, this option configures the driver to wait for NAND operations to complete by waiting for the chip to deassert its Busy line. This is the default behaviour and is recommended, but may be disabled if you need to use the line (PIO C13) for some other purpose. (If disabled, the memory controller is configured to stall NAND accesses until they complete, which will interfere with multi-threading.)

`CYGNUM_HAL_SAM9G20EK_NAND_POLL_INTERVAL`
The number of microseconds delay in the polling loops which wait for NAND operations to complete.

Partitioning the NAND chip

The NAND chip must be partitioned before it can become available to applications.

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_DEVS_NAND_SAM9G20EK_PARTITION_MANUAL_CONFIG`); if you choose to use this, the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script sets up a single partition (number 0) encompassing the entire device.

It is possible to configure the partitions in some other way, should it be appropriate for your setup, for example to read a Linux-style partition table from the chip. To do so you will have to add appropriate code to `sam9g20ek_nand.c`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only JTAG configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.at91sam9g20ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `peedi.at91sam9g20ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.at91sam9g20ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a second-level bootstrap and ROM RedBoot is resident in DataFlash, it will be run.

An issue occurs when the AT91 Ethernet driver is included in your configuration. In order to work around a board hardware design issue, the CPU generates an external reset in order to reset the Ethernet PHY. However this can be interpreted by the PEEDI as an indication that the CPU itself has reset, and if the PEEDI configuration file option `CORE0_STARTUP_MODE` is set to `RESET` then the CPU will be halted at this point. To avoid this issue, the `CORE0_STARTUP_MODE` can be set to `RUN`.

Consult the PEEDI documentation for information on other features.

Running JTAG applications

Applications configured for JTAG startup can be run directly under a JTAG debugger. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USARTs 0 or 1 can be chosen instead by setting the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` configuration option in the platform HAL to channel 1 or 2.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM9G20-EK hardware, and should be read in conjunction with that specification. The AT91SAM9G20-EK platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the SAM9 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x20000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x20000000, but in order to assign hardware exception vectors vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x30000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x20040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00200000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is unused by eCos and is available for application use.

On-chip ROM

This is located at address 0x00100000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x71000000. The same memory is also accessible uncached and unbuffered at virtual location 0x71800000.

USB host port

The USB host port (UHP) registers are located at address 0x00300000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x72800000. Memory accessed at this address is uncached and unbuffered. There is no cached variant.

SPI dataflash

SPI Dataflash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x40000000 for the on-board flash and 0x50000000 for the dataflash slot, the extent will clearly depend on the Dataflash capacity. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers
These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals
eCos uses the SDRAM, ethernet PHY, MCI, and SPI dataflash facilities on the AT91SAM9G20-EK board. eCos does not currently make any use of any other off-chip peripherals present on this board.

Advanced Interrupt Controller

This port has been designed to exploit benefits of the Advanced Interrupt Controller of the AT91SAM9G20, using the facilities of the SAM9 processor HAL. Consult the documentation in that package for details.

SPI Dataflash

eCos supports SPI access to Dataflash on the AT91SAM9G20-EK. An on-board device and an external card slot are provided on the board. The on-chip device is typically used to contain RedBoot and flash configuration data. The external slot is available for application use.

Accesses to Dataflash are performed via the Flash API, using 0x40000000 or 0x50000000 as the nominal address of the device, although it does not truly exist in the processor address space. For the external card slot, on driver initialisation, eCos and RedBoot can detect the presence of a card in the socket. In particular, on reset RedBoot will indicate the presence of Flash at the 0x40000000 address range in its startup banner if it has been successfully detected. Hot swapping is not possible.

Since Dataflash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

The MCI driver cannot be enabled simultaneously with the SPI driver, as the drivers need differing pin configurations for the same pins on this board due to the shared socket.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 261.1. sam9g20ek Real-time characterization

```
INFO:<code from 0x20040040 -> 0x2004bad4, CRC eb0a>
            Startup, main stack : stack used   388 size  3920
             Startup :  Interrupt stack used   524 size  4096
             Startup : Idlethread stack used    96 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    2.93 microseconds (24 raw clock ticks)

Testing parameters:
   Clock samples:            32

Other Issues

The AT91SAM9G20-EK platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SAM9 processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 262. Atmel AT91SAM9G45-EKES Evaluation Kit Board Support

Name

eCos Support for the Atmel AT91SAM9G45-EKES Evaluation Kit — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel AT91SAM9G45-EKES Evaluation Kit. The AT91SAM9G45-EKES contains the AT91SAM9G45 microprocessor, 128Mbytes of SDRAM, 256Mbytes of NAND flash memory, an Atmel Dataflash, an Atmel serial EEPROM, a Davicom DM9161A PHY, two SD/MMC sockets, a DAC, external connections for two serial channels (one debug, one flow controlled), ethernet, USB host/device, and the various other peripherals supported by the AT91SAM9G45. eCos support for the devices and peripherals on the boards and the AT91SAM9G45 is described below.

For typical eCos development, a RedBoot image is programmed into the start of NAND, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the SAM9 processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The NAND flash contains the second level bootstrap, AT91Bootstrap, in the first block. This initializes the system clocks and the SDRAM. It then loads a 320KiB program image from offset 0x20000 in the NAND into SDRAM at 0x20008000 and then jumps into it. Typically this image will be a ROM version of RedBoot.

The Dataflash consists of 8192 blocks of 528 bytes each. The topmost block is used to manage the flash and the next four block holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_AT91` which supports both the Debug Unit and USART serial devices. The debug serial port at J10 and flow controlled port at J11 (connected to USART channel 1) can be used by RedBoot for communication with the host. If any of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the AT91SAM9G45-EKES target.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_AT91` for the on-chip ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the AT91SAM9G45-EK board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC`. This driver is also loaded automatically when configuring for the board.

There is a driver for the on-chip real-time timer controller (RTTC) at `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTC`. This driver is also loaded automatically when configuring for the target.

The SAM9 processor HAL contains a driver for the Two-Wire Interface (TWI) controller on the AT91SAM9G45. This type of bus is also known as I²C®. Further documentation may be found in the SAM9 processor HAL documentation. Note that the implementation of the TWI device on this part appears to have changed from earlier parts. This device does not now appear to be able to handle a repeat start sequence.

There is a driver for the MultiMedia Card Interface (MCI) at `CYGPKG_DEVS_MMCSD_ATMEL_SAM_MCI`. This driver is loaded automatically when configuring for the AT91SAM9G45-EKES target and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation may be found within that package.

The platform HAL provides definitions to allow access to devices on the SPI bus. The HAL provides information to the general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board.

Furthermore, the platform HAL package contains support for SPI dataflash cards. The HAL support integrates with the CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH package as well as the above SPI packages. That package is automatically loaded when configuring for the target. Dataflash media is then accessed as a Flash device, using the Flash I/O API within the CYGPKG_IO_FLASH package, if that package is loaded in the configuration.

In general, devices (Caches, PIO, UARTs, EMAC) are initialized only as far as is necessary for eCos to run. Other devices (RTC, I²C, SPI, MCI etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate PIO configuration.

Tools

The AT91SAM9G45-EKES support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 4.3.2, arm-elf-gdb version 6.8, and binutils version 2.18.

Name

Setup — Preparing the AT91SAM9G45-EKES board for eCos Development

Overview

In a typical development environment, the AT91SAM9G45-EKES board boots from the NAND flash and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from NAND to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from NAND by the second-level bootstrap. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The on-chip boot program on the AT91SAM9G45 is only capable of loading programs from Dataflash or NAND flash into on-chip SRAM and is therefore quite restrictive. Consequently RedBoot cannot be booted directly and a second-level bootstrap must be used. Such a second-level bootstrap is supplied by Atmel in the form of AT91Bootstrap. This is therefore programmed into the start of NAND and is then responsible for initializing the SDRAM and loading RedBoot from NAND and executing it.

Caution

There is a size limit on the size of applications which the AT91Bootstrap second level bootstrap will load. Images larger than 320Kbytes will require the AT91Bootstrap application to be rebuilt with a larger `IMG_SIZE` definition in `AT91Bootstrap/board/at91sam9g45ek/nandflash/at91sam9g45ek.h` within the SAM9260 HAL package in the eCos source repository (`packages/hal/arm/arm9/sam9260ek/current/`). A pre-built AT91SAM9G45 specific AT91Bootstrap binary can be found here: `AT91Bootstrap/board/at91sam9g45ekes/nandflash/nandflash_at91sam9g45ekes.bin`. This will required during the SAM-BA based board setup process described below.

There are basically two ways to write the second-level bootstrap and RedBoot to the NAND. The first is to use the Atmel-supplied SAM-BA program that interacts with the on-chip boot program. The second is to use a JTAG debugger that understands the microcontroller and can write to the NAND flash (for example the Ronetix PEEDI). Since the availability of the latter cannot be guaranteed, only the first method will be described here.

Programming RedBoot into NAND Flash using SAM-BA

The following gives the steps needed to program the second-level bootstrap and RedBoot into the NAND Flash using SAM-BA. The user should refer to the SAM-BA documentation for full details of how to run the program. SAM-BA can communicate with the boot program via either USB or serial. The steps are essentially similar for both since USB operates through a driver that simulates a serial port.

1. Download the AT91 SAM-BA software package from the Atmel website and install it. SAM9 series CPU's require the 2.1.x series version of SAM-BA. Atmel provide both Linux and Windows versions of SAM-BA so ensure you select the version appropriate to your host operating system. The remainder of this document describes the process according to a Windows installation. The steps for the Linux version of SAM-BA are similar and can easily be determined from the Windows process.

2. From the root directory of your eCosPro installation, copy the file `nandflash_at91sam9g45ekes.bin` from the sub-directory `packages/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9g45ekes/nandflash` and `redboot_ROM.bin` from the sub-directory `loaders/sam9g45ekes` to a suitable location on the Windows PC.

3. Connect a null-modem serial cable between the J10 DEBUG serial port of the board and a serial port on the host running SAM-BA. If using USB download also connect a USB cable between the host and the J14 HOST/DEV socket.

4. Unplug the power supply from the board and remove JP10(NANDCS) and JP12(NPCS0). Reapply power to the board. If USB is being used follow the instructions in the SAM-BA documentation to set up the Windows device driver for the first time if you are running a Microsoft Windows-based operating system.

5. Start SAM-BA. Select the appropriate COM port for the communication interface (on Windows hosts this will be of the form "COMx" and on Linux hosts this will be of the form "/dev/ttyUSBx"), and "at91sam9g45-ekes" for the board. Click on "Connect".

6. Re-insert JP10 and JP12.

7. In the SAM-BA main window, select the "NandFlash" tab and in the "Scripts" dropdown menu select "Enable NandFlash", to program the on-board NandFlash device. Click Execute and SAM-BA should emit the following in the message area:

   ```
   (SAM-BA v2.10) 1 % NANDFLASH::Init
   -I- NANDFLASH::Init (trace level : 0)
   -I- Loading applet isp-nandflash-at91sam9g45.bin at address 0x70000000
   -I- Memory Size : 0x10000000 bytes
   -I- Buffer address : 0x70003E34
   -I- Buffer size: 0x20000 bytes
   -I- Applet initialization done
   (SAM-BA v2.10) 1 %
   ```

   The actual options and output of SAM-BA may vary according to the version you are using. The behaviour documented here is that of SAM-BA 2.10.

8. Now select "Send BootFile" from the "Scripts" menu and "Execute" it. When the file open dialog appears, select the `nandflash_at91sam9g45ekes.bin` file and click "Open". The following output should be seen:

   ```
   (SAM-BA v2.10) 1 % GENERIC::SendBootFileGUI
   GENERIC::SendFile Z:/eCos/SAM-BA/nandflash_at91sam9g45ekes.bin at address 0x0
   -I- File size : 0x1334 byte(s)
   -I-     Writing: 0x1334 bytes at 0x0 (buffer addr : 0x70003E34)
   -I-     0x1334 bytes written by applet
   (SAM-BA v2.10) 1 %
   ```

9. The second-level bootstrap has now been written to NAND Flash, we must now write RedBoot.

10. In the "Send File Name" box type in the path name to the `redboot_ROM.bin` file, or use the Open Folder button and browse to it.

11. In the Address field set the value to 0x020000.

12. Click the "Send File" button. SAM-BA will put up a dialog box while it is writing the file to the NAND Flash, and will output something similar to the following in the message area:

    ```
    (SAM-BA v2.10) 1 % send_file {NandFlash} "Z:/eCos/SAM-BA/redboot_ROM.bin" 0x020000 0
    -I- Send File Z:/eCos/SAM-BA/redboot_ROM.bin at address 0x020000
    ```

```
GENERIC::SendFile Z:/eCos/SAM-BA/redboot_ROM.bin at address 0x20000
-I- File size : 0x24658 byte(s)
-I-     Writing: 0x20000 bytes at 0x20000 (buffer addr : 0x70003E34)
-I-     0x20000 bytes written by applet
-I-     Writing: 0x4658 bytes at 0x40000 (buffer addr : 0x70003E34)
-I-     0x4658 bytes written by applet
(SAM-BA v2.10) 1 %
```

13. Shut down SAM-BA and start up Hyperterm or similar on the real COM port, not the USB port, configured for 115200 baud 8-N-1 with no flow control. Attach an ethernet cable between the board and a switch on your network. Press the reset button on the board and something similar to the following should be output on the DEBUG serial line.

```
Start AT91Bootstrap...
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.2.1/255.0.0.0, Gateway: 10.0.0.3

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 14:54:15, Aug 20 2010

Copyright (C) 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009
Free Software Foundation, Inc.
Copyright (C) 2003, 2004, 2005, 2006, 2007, 2008 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: AT91SAM9G45-EK (ARM9)
RAM: 0x20000000-0x28000000 [0x20035f78-0x27ffe530 available]
FLASH: 0x50000000-0x5041ffff, 8192 x 0x210 blocks
RedBoot>
```

The board is now running and the flash can be configured.

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x5041fdf0-0x5041ffff: .
... Program from 0x27fffdf0-0x28000000 to 0x5041fdf0: .
RedBoot>
```

2. Now configure RedBoot's Flash configuration with the **fconfig** command. Remember to substitute the appropriate MAC address for this board at the appropriate step. If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: false
Gateway IP address: 192.168.7.11
Local IP address: 192.168.7.83
Local IP address mask: 255.255.255.0
```

```
   Default server IP address: 192.168.7.11
   Console baud rate: 115200
   DNS domain name: farm.ecoscentric.com
   DNS server IP address: 192.168.7.11
   Network hardware address [MAC]: 0x0E:0x00:0x00:0xEA:0x18:0xF0
   GDB connection port: 9000
   Force console for special debug messages: false
   Update RedBoot non-volatile configuration - continue (y/n)? y
   ... Erase from 0x5041ef80-0x5041f7bf: ....
   ... Program from 0x27fff5b0-0x27fffdf0 to 0x5041ef80: ....
   RedBoot>
```

The RedBoot installation is now complete. This can be tested by power cycling the board. Output similar to the following should be seen on the DEBUG serial port. Verify the IP settings are as expected.

```
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 192.168.7.83/255.255.255.0, Gateway: 192.168.7.11
Default server: 192.168.7.11
DNS server IP: 192.168.7.11, DNS domain name: <null>

RedBoot(tm) bootstrap and debug environment [ROM]

Platform: AT91SAM9G45-EK (ARM9)
RAM: 0x20000000-0x28000000 [0x20035f78-0x27ffe530 available]
FLASH: 0x50000000-0x5041ffff, 8192 x 0x210 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the AT91SAM9G45-EKES are:

```
$ mkdir redboot_at91sam9g45ek_rom
$ cd redboot_at91sam9g45ek_rom
$ ecosconfig new at91sam9g45ekes redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/sam9g45ek/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

Rebuilding AT91Bootstrap

The sources of AT91Bootstrap are found in the `AT91Bootstrap` directory of the sam9260ek package. This is a copy of the software as supplied by Atmel with some slight modifications to permit it to be built with the same tools as eCos.

To rebuild the second-level bootstrap for the AT91SAM9G45-EKES execute the following commands:

```
    $ cd $ECOS_REPOSITORY/hal/arm/arm9/sam9260ek/current/AT91Bootstrap/board/at91sam9g45ekes/nandflash
    $ make
```

This should result in the creation of a number of files, including `nandflash_at91sam9g45ekes.bin` which can be copied out.

Name

Configuration — Platform-specific Configuration Options

Overview

The AT91SAM9G45-EKES platform HAL package is loaded automatically when eCos is configured for the `sam9g45ek` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into NAND Flash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

JTAG
: This is the startup type which can be used during application development via a JTAG device such as the PEEDI. arm-eabi-gdb is used to load a JTAG startup application into memory and debug it. Hardware setup is divided between the initialization section of the PEEDI configuration file and software in the loaded application.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The AT91SAM9G45-EKES board contains a 4Mbyte Atmel AT45 DataFlash device. The `CYGPKG_DEVS_FLASH_ATMEL_DATAFLASH` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the AT91SAM9G45-EKES board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

Ethernet Driver

The AT91SAM9G45-EKES board uses the AT91SAM9G45's internal EMAC ethernet device attached to an external Davicom DM9161A PHY. The `CYGPKG_DEVS_ETH_ARM_AT91` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the AT91SAM9G45-EKES board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The AT91SAM9G45-EKES board uses the AT91SAM9G45's internal RTC support. The `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91RTC` package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The AT91SAM9G45-EKES board uses the AT91SAM9G45's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_AT91WDTC` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_AT91WDTC_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

Warning

The ATSAM926x processor will boot with watchdog support enabled, and the watchdog configuration is write-once. That is, if it is disabled, it cannot be re-enabled. Due to its nature, RedBoot disables the watchdog when it starts so any eCos applications with watchdog support enabled that are run by RedBoot will not function correctly.

USART Serial Driver

The AT91SAM9G45-EKES board uses the AT91SAM9G45's internal USART serial support as described in the SAM9 processor HAL documentation. Two serial ports are available: the serial debug port which is mapped to virtual vector channel 0 in the HAL diagnostic driver or "`/dev/dbg`" in the interrupt-driven driver and USART 1 which is mapped to virtual vector channel 1 and "`/dev/ser1`". The debug port has no additional signals, but USART 1 supports RTS/CTS.

MCI Driver

As the SAM MCI driver is included in the hardware-specific configuration for this target, nothing is required to load it. Similarly the MMC/SD bus driver layer (`CYGPKG_DEVS_DISK_MMC`) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (`CYGPKG_IO_DISK`), along with the intended filesystem, typically, the FAT filesystem (`CYGPKG_FS_FAT`) and any of its package dependencies (including `CYGPKG_LIBC_STRING` and `CYGPKG_LINUX_COMPAT` for FAT).

If the generic disk I/O infrastructure is needed for some other reason, and you do not wish to also include the MCI driver, then the configuration option within this platform HAL `CYGPKG_HAL_ARM_ARM9_SAM9G45EK_MMCSD` can be used to forcibly disable it.

Various options can be used to control specifics of the SAM MCI driver. Consult the SAM MCI driver documentation for information on its configuration.

The MCI driver at present can only handle a single MCI interface, the configuration option `CYGHWR_DEVS_MMCSD_ATMEL_SAM_MCI_DEVICE` selects between them.

Only MMC/SD socket 1 permits detection of the write-protect (or "lock") switch present on SD cards. "Locked" cards will therefore not be detected on socket 0 which means that despite the switch position, it is still possible to write to them since the lock switch does not physically enforce write protection.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM926EJ CPU in the AT91SAM9G45.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Onboard NAND

The HAL port includes a low-level driver to access the on-board Micron MT29F2G08ABD NAND flash memory chip. To enable the driver, activate the CDL option `CYGPKG_HAL_SAM9G45EK_NAND` and ensure that the `CYGPKG_DEVS_NAND_MICRON_MT29F` package is present in your eCos configuration.

`CYGHWR_HAL_SAM9G45EK_NAND_USE_STATUS_LINE`
: If set, this option configures the driver to wait for NAND operations to complete by waiting for the chip to deassert its Busy line. This is the default behaviour and is recommended, but may be disabled if you need to use the line (PIO C8) for some other purpose. (If disabled, the memory controller is configured to stall NAND accesses until they complete, which will interfere with multi-threading.)

`CYGNUM_HAL_SAM9G45EK_NAND_POLL_INTERVAL`
: The number of microseconds delay in the polling loops which wait for NAND operations to complete.

Partitioning the NAND chip

The NAND chip must be partitioned before it can become available to applications.

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_DEVS_NAND_SAM9G45EK_PARTITION_MANUAL_CONFIG`); if you choose to use this, the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script sets up a single partition (number 0) encompassing almost the entire device. The first block of the device contains AT91Bootstrap and the second and subsequent blocks contain RedBoot, or a ROM application. The first partition should therefore start above this. The default is set to block 8, leaving 1MiB at the base of NAND for bootstrapping.

It is possible to configure the partitions in some other way, should it be appropriate for your setup, for example to read a Linux-style partition table from the chip. To do so you will have to add appropriate code to `sam9g45ek_nand.c`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only JTAG configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot and ROM applications reset the CPU clock, which may cause the debugger to disconnect.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.at91sam9g45ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `peedi.at91sam9g45ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.at91sam9g45ek.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a second-level bootstrap and ROM RedBoot is resident in NANDFlash, it will be run.

Consult the PEEDI documentation for information on other features.

Running JTAG applications

Applications configured for JTAG startup can be run directly under JTAG. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. USART 1 can be chosen instead by setting the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` configuration option in the platform HAL to channel 1.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the AT91SAM9G45-EKES hardware, and should be read in conjunction with that specification. The AT91SAM9G45-EK platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the SAM9 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x20000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x20000000, but in order to assign hardware exception vectors vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x30000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x20040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x00300000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x70000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70100000 for use by devices. At present this memory is unused by eCos and is available for application use.

On-chip ROM

This is located at address 0x00400000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual address 0x71000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70300000.

NAND

This is located at address 0x40000000 of the physical memory space. The HAL maps this uncached and unbuffered to 0x40000000 in the virtual address space. This mapping is only enabled if the NAND driver is enabled, otherwise it will generate an address fault.

USB

The USB device registers are located at addresses 0x00600000. 0x00700000, 0x00800000 of the physical memory space. However the HAL uses the MMU to relocate this to virtual addresses 0x71000000, 0x71100000 and 0x71200000 respectively. Memory accessed at these addresses is uncached and unbuffered. There is no cached variant.

SPI dataflash

SPI Dataflash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x50000000 This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

RedBoot manages the SPI dataflash using its FIS subsystem and stores system configuration data in the top 5 blocks of the device.

On-chip Peripheral Registers

These are located at address 0xFF000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

eCos uses the SDRAM, ethernet PHY, MCI, NAND flash and SPI dataflash facilities on the AT91SAM9G45-EKES board. eCos does not currently make any use of any other off-chip peripherals present on this board.

Advanced Interrupt Controller

This port has been designed to exploit benefits of the Advanced Interrupt Controller of the AT91SAM9G45, using the facilities of the SAM9 processor HAL. Consult the documentation in that package for details.

SPI Dataflash

eCos supports SPI access to Dataflash on the AT91SAM9G45-EKES board. The device is typically used to contain flash configuration data.

Accesses to Dataflash are performed via the Flash API, using 0x50000000 as the nominal address of the device, although it does not truly exist in the processor address space.

Since Dataflash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provided better performance than Thumb mode.

Example 262.1. sam9g45ek Real-time characterization

```
INFO:<code from 0x20040040 -> 0x2004bad4, CRC eb0a>
            Startup, main stack : stack used   387 size  3920
             Startup :  Interrupt stack used   524 size  4096
             Startup : Idlethread stack used    88 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    2.95 microseconds (24 raw clock ticks)

Testing parameters:
   Clock samples:            32

```

Other Issues

The AT91SAM9G45-EKES platform HAL does not affect the implementation of other parts of the eCos HAL specification. The SAM9 processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 263. ARM Versatile 926EJ-S Board Support

Name

eCos Support for the Versatile 926EJ-S Board — Overview

Description

This document covers the ARM Versatile Platform Baseboard for the ARM926EJ-S development chip, hereafter referred to as the VPB926EJS. The VPB926EJS contains the ARM926EJ-S processor, 128Mb of SDRAM, 64MB of Intel Strataflash memory, 2Mb of static RAM, a SMSC LAN91C111 Ethernet MAC, and external connections for the three on-chip and one off-chip serial channels, ethernet and the various other peripherals supported by the ARM926EJ-S.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of 256 blocks of 256k bytes each. In a typical setup, the first flash block is used for the ROMRAM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining 254 blocks between 0x34040000 and 0x37FBFFFF can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_ARM_PL011` which supports the ARM PL011 PrimeCell UARTs used by the VPB926EJS. The `CYGPKG_IO_SERIAL_ARM_VPB926EJS` package provides customization of this generic driver to the VPB926EJS hardware. These devices can be used by RedBoot for communication with the host. If any of these devices is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver packages are loaded automatically when configuring for the VPB926EJS target.

There is an ethernet driver `CYGPKG_DEVS_ETH_SMSC_LAN91CXX` for the SMSC LAN91C111 ethernet device. A second package `CYGPKG_DEVS_ETH_ARM_VPB926EJS` is responsible for configuring this generic driver to the VPB926EJS hardware. These drivers are also loaded automatically when configuring for the VPB926EJS target.

eCos manages the on-chip interrupt controller. Timer 0 is used to implement the eCos system clock and the microsecond delay function. Other on-chip devices (Caches, UARTs, MPMC, SSMC, I²C etc.) are initialized only as far as is necessary for eCos to run. Other devices (PCI, SSP, SCI, GPIO etc.) are not touched.

Tools

The VPB926EJS port is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.2.1, arm-elf-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing the VPB926EJS board for eCos Development

Overview

In a typical development environment, the VPB926EJS board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
ROM	RedBoot running from flash ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`
SRAM	RedBoot running from static RAM	`redboot_SRAM.ecm`	`redboot_SRAM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. RedBoot also supports ethernet communication and flash management.

Initial Installation

Flash Installation

Installing RedBoot is a matter of downloading a new binary image and overwriting the existing Boot monitor ROM image. This is a two stage process, you must first download an SRAM-resident version of RedBoot and then use that to download the ROM image to be programmed into the flash memory.

The VPB926EJS boards are shipped from ARM with a version of ARM's boot monitor installed. Unfortunately this boot monitor only works in conjunction with ARM's tools, which are not supplied with the board. Hence the only viable approach is to install RedBoot via the JTAG interface. The following directions are necessarily somewhat general since the specifics depend on the exact JTAG device available, and the software used to drive it.

Connect the JTAG device to the JTAG connector on the Versatile board and check that the device is functioning correctly. Using 32 bit memory writes, initialize the static memory controller so that the SRAM and flash are accessible. The following assignments should be made:

```
*(long *)0x10100034 = 0x00303021;
*(long *)0x10100054 = 0x00303021;
*(long *)0x10100074 = 0x00303021;
*(long *)0x10100094 = 0x00303021;
```

Now load the SRAM redboot binary image from the file `redboot_SRAM.bin` into the base of SRAM at 0x38000000. Exactly how you do this depends on the JTAG driver software.

Start RedBoot by executing from location 0x38000040, which should result in RedBoot starting up.

```
+... waiting for BOOTP information
Ethernet eth0: MAC address 00:02:f7:00:0b:34
IP: 10.0.0.208/255.255.255.0, Gateway: 10.0.0.1
Default server: 10.0.0.201
```

```
RedBoot(tm) bootstrap and debug environment [SRAM]
Non-certified release, version UNKNOWN - built 16:03:09, May  5 2004

Platform: ARM Versatile VPB926EJS (ARM9)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x02000000, [0x00013b20-0x01fbd000] available
FLASH: 0x34000000 - 0x38000000, 256 blocks of 0x00040000 bytes each.
RedBoot>
```

Now the ROM image can be downloaded using the following RedBoot command:

```
RedBoot> load -r -b %{FREEMEMLO} -m ymodem
```

Use HyperTerminal's Ymodem support to send the file `redboot_ROMRAM.bin`. This should result in something like the following output:

```
Raw file loaded 0x0002f800-0x0004be6b, assumed entry at 0x0002f800
xyzModem - CRC mode, 911(SOH)/0(STX)/0(CAN) packets, 4 retries
RedBoot>
```

Once the file has been uploaded, you can check that it has been transferred correctly using the **cksum** command. On the host (Linux or Cygwin) run the **cksum** program on the binary file:

```
$ cksum redboot_ROMRAM.bin
140216855 116332 redboot_ROMRAM.bin
```

In RedBoot, run the **cksum** command on the data that has just been loaded:

```
RedBoot> cksum -b %{FREEMEMLO} -l 116332
POSIX cksum = 140216855 116332 (0x085b8a17 0x0001c66c)
```

The second number in the output of the host **cksum** program is the file size, which should be used as the argument to the `-l` option in the RedBoot **cksum** command. The first numbers in each instance are the checksums, which should be equal.

If the program has downloaded successfully, then it can be programmed into the flash using the following commands:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)?y
*** Initialize FLASH Image System
... Unlock from 0x37fc0000-0x38000000: .
... Erase from 0x37fc0000-0x38000000: .
... Program from 0x03fc0000-0x04000000 at 0x37fc0000: .
... Lock from 0x37fc0000-0x38000000: .
RedBoot> fis create -b %{FREEMEMLO} RedBoot
An image named 'RedBoot' exists - continue (y/n)?y
... Unlock from 0x34000000-0x34040000: .
... Erase from 0x34000000-0x34040000: .
... Program from 0x0002f800-0x0006f800 at 0x34000000: .
... Lock from 0x34000000-0x34040000: .
... Unlock from 0x37fc0000-0x38000000: .
... Erase from 0x37fc0000-0x38000000: .
... Program from 0x03fc0000-0x04000000 at 0x37fc0000: .
... Lock from 0x37fc0000-0x38000000: .
RedBoot>
```

The VPB926EJS board may now be reset either by cycling the power, pressing the reset switch, or with the **reset** command. It should then display the startup screen for the ROMRAM version of RedBoot.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROMRAM version of RedBoot for the VPB926EJS are:

```
$ mkdir redboot_vpb926ejs_romram
$ cd redboot_vpb926ejs_romram
$ ecosconfig new vpb926ejs redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/vpb926ejs/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

To rebuild the SRAM version of RedBoot:

```
$ mkdir redboot_vpb926ejs_sram
$ cd redboot_vpb926ejs_sram
$ ecosconfig new vpb926ejs redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/vpb926ejs/current/misc/redboot_SRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This is the case for both the above builds, take care not to mix the two files up, since programming the SRAM RedBoot into the ROM will render the board unbootable.

Name

Configuration — Platform-specific Configuration Options

Overview

The VPB926EJS platform HAL package is loaded automatically when eCos is configured for a `vpb926ejs` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The VPB926EJS platform HAL package supports four separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x34000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROM-RAM
: This startup type can be used for finished applications which will be programmed into flash at physical location 0x34000000. However, when it starts up, the application will first copy itself to RAM at 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

SRAM
: This startup type exists only to support the installation of RedBoot via the JTAG interface. Functionally, it is equivalent to the ROM startup type except that the executable image is loaded into the static RAM at 0x38000000 rather than the flash ROM. It is of little use for other applications.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is required to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for RAM startup, disabled otherwise. It can be manually disabled for RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The VPB926EJS board contains two 32Mb 28F256K3 Intel StrataFlash flash devices, giving 64MB of flash in total. The `CYGPKG_DEVS_FLASH_STRATA_V2` package contains all the code necessary to support these parts and the VPB926EJS platform HAL package contains definitions that customize the driver to the VPB926EJS board.

Ethernet Driver

The VPB926EJS board contains a SMSC LAN91C111 ethernet controller. The `CYGPKG_DEVS_ETH_SMSC_LAN91CXX` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_ARM_VPB926EJS` package contains definitions that customize the driver to the VPB926EJS board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There is just one flag specific to this port:

`-mcpu=arm9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM926E CPU.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the VPB926EJS hardware, and should be read in conjunction with that specification. The VPB926EJS platform HAL package complements the ARM architectural HAL and the ARM9 variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize the on-chip peripherals that are used by eCos. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM, ROMRAM or SRAM startup, the HAL will perform additional initialization, setting up the external SDRAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash

This is located at address 0x34000000 of the physical memory space. The HAL uses the MMU to map it cached and buffered at the same address.

SDRAM

There are two blocks of SDRAM in the system. One block of 64Mb is present at physical address 0x00000000 and is echoed at 0x04000000. The second block is present at physical address 0x08000000. The HAL uses the MMU to map the first block to virtual address 0x00000000 and the second to virtual address 0x04000000, forming a single contiguous 128Mb block of SDRAM starting at 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0x70000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x00040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

This is located at address 0x38000000 of the physical memory space. The HAL uses the MMU to map this to the same virtual address, but cached and buffered. The same memory is also accessible uncached and unbuffered at virtual location 0x78000000 for use by devices. This memory is not used by eCos for any purpose except in the SRAM startup mode, when it contains the system image.

On-chip Peripheral Registers

These are located at address 0x10000000 in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

All off-chip peripherals are also visible in the 0x10000000 address space.

Other Issues

The VPB926EJS platform HAL does not affect the implementation of other parts of the eCos HAL specification. The ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 264. Spectrum Digital OMAP-L137 Board Support

Name

eCos Support for the Spectrum Digital OMAP-L137 Evaluation Module — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Spectrum Digital OMAP-L137 Evaluation Module. This board is fitted with an OMAP L137 processor, 64 MBytes of SDRAM, four megabytes of serial NOR flash attached to the SPI0 bus, 32K of EEPROM attached to the I2C0 bus, a DB9 serial connector for UART2, a KSZ8893MQL ethernet switch/phy, a jtag connector, and a number of other peripherals and expansion sockets. eCos support for the devices and peripherals on the board is described below.

For typical eCos development, a RedBoot image is programmed into the SPI NOR flash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the OMAP L1xx processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

Bootstrap on the OMAP-L137 is complicated. The chip has two processors, a DSP and an ARM. The chip powers up with the DSP running a primary bootloader from on-chip memory, and with the ARM powered down. The primary bootloader checks the state of a number of GPIO pins to determine how to proceed. In a typical setup it will proceed to read in an AIS script from the serial NOR flash on the SPI0 bus and execute the script's instructions. The AIS script will load a secondary bootloader into on-chip memory and transfer control to that. The secondary bootloader will load a tertiary bootloader elsewhere in on-chip memory, activate the ARM processor, and put the DSP to sleep. The tertiary bootloader will initialize more of the hardware, in particular the external SDRAM, load RedBoot or another ROM startup eCos application, and transfer control. RedBoot can then be used to download and debug a RAM startup application, or in production systems it can load such an application from flash or other storage and start it.

There are 4 MBytes of SPI NOR flash, arranged in 64 64K blocks. In a typical setup the first four blocks are used to hold a boot image containing the AIS script for the primary bootloader, the secondary and tertiary bootloaders, and RedBoot. The topmost block is used to manage the flash and also holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

On this board only uart2 is connected, and this is normally used by RedBoot for communication with the host. If the device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication and another communication channel such as ethernet should be used instead. The port also includes support for the ethernet, watchdog, and real-time clock devices and for the SPI and I²C buses. Details of this support can be found below.

In general, devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (RTC, SPI, I²C, etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate power control and pin multiplexing configuration.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 4.4.5, arm-eabi-gdb version 7.2, and binutils version 2.20.

Name

Setup — Preparing the SD-L137 board for eCos Development

Overview

In a typical development environment, the SD-L137 board boots from the SPI NOR and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from SPI NOR flash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.img`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from NOR flash by the first three bootloaders. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

Installation involves writing an image to the start of the serial flash. This image contains the AIS script interpreted by the primary bootloader, the secondary and tertiary bootloaders, and a RedBoot executable. A suitable image `redboot.img` is provided with the release or can be rebuilt using the instructions below.

There are two ways of writing the image. The first is to use a dedicated utility such as TI's Serial Boot and Flash Loading Utility for OMAP-L137. The second is to set up a JTAG emulator. This can then be used to run a RAM-resident RedBoot which will allow the flash to be programmed. The recommended JTAG emulator is the Ronetix PEEDI, but other JTAG emulators will involve a similar setup.

⚠ Caution

The L137 powers up with the ARM processor disabled, and the ARM does not start up until the primary bootloader has executed the AIS script and the secondary bootloader has run to completion. Until that time it will not be possible to attach a PEEDI or other ARM JTAG emulator. If a bogus image is programmed into the flash such that the AIS script or secondary bootloader are missing or corrupt, it will not be possible to recover the board via JTAG. Recovery should still be possible by using the TI utilities and uart2.

Programming RedBoot into SPI NOR flash using the TI Flash Utility

The following gives the steps needed to program RedBoot into the SPI NOR Flash using TI's Serial Boot and Flash Loading Utility for OMAP-L137. This tool and it's associated documentation can be found on the TI wiki http://processors.wiki.ti.com/index.php/Serial_Boot_and_Flash_Loading_Utility_for_OMAP-L137 page.

A RedBoot image file has been provided that combines the required L137 AIS script, DSP and ARM bootloaders, along with RedBoot itself. The `redboot_ROM.img` file can be found in the `loaders/sd_l137` subdirectory of your eCosPro installation.

The basic bootloader installation process is to set the board into a bootstrap update mode, use the TI utility to download and write the provided image to the flash, and then restore the board to normal operational mode.

1. Install the TI tools on your workstation.

2. Make a note of the boards current SW2 BOOT switch pin configuration and then configure SW2 to enable bootstrap update mode. The required pin configuration for your specific board revision can be found in the TI documentation. For example, on revision "C" and later boards: pin 7 ON, pin 2 OFF, pin 1 ON, pin 0 OFF, pin 3 OFF.

3. Connect a serial cable between the board's DB9 serial connector and the host PC. Run a serial terminal emulator (Putty, Hyperterm or minicom) on the host, connecting at 115200 baud 8N1 with no flow control. When the board is reset you should see "BOOTME" output on the serial line.

4. Use the TI **sfh_OMAP-L137** utility to install the `redboot_ROM.img` on the board. You will need to modify the example command **sfh_OMAP-L137 -p com2 -flash_noubl redboot_ROM.img** used in the example output below, substituting "com2" with the serial port corresponding to your setup, and by adding appropriate path prefixes to **sfh_OMAP-L137** and `redboot_ROM.img` corresponding to their installed location on your workstation.

   Once the flash utility starts running you will need to reset the board almost immediately as directed by the utility. Until you do this the benign message "(Serial Port): Read error! (The operation has timed out.)" will be output continously.

   You will also need to be patient as the initial "Loading section..." phase can take many minutes to complete with no obvious output or other signs of life.

```
C:>sfh_OMAP-L137 -p com2 -flash_noubl redboot_ROM.img

GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: Spectrum Digital OMAP-L137 Evaluation Module (ARM9)
RAM: 0xc0000000-0xc4000000 [0xc003be80-0xc3fed000 available]
FLASH: 0x70000000-0x703fffff, 64 x 0x10000 blocks

RedBoot>
```

The flash configuration warning is expected. The ethernet MAC address will have come from the serial EEPROM on the I2C0 bus. The IP and gateway addresses will have been provided by a BOOTP (DHCP) server.

6. Run the following command to initialize RedBoot's flash file system and flash configuration:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x703f0000-0x703fffff: .
... Program from 0xc3ff0000-0xc4000000 to 0x703f0000: .
RedBoot> fis list
Name              FLASH addr  Mem addr    Length      Entry point
RedBoot           0x70000000  0x70000000  0x00040000  0x00000000
FIS directory     0x703F0000  0x703F0000  0x0000F000  0x00000000
RedBoot config    0x703FF000  0x703FF000  0x00001000  0x00000000
RedBoot>
```

If desired the fconfig settings can be initialized at this time using the **fconfig -i** command. Most of the settings relate to ethernet, for example the IP address that RedBoot should use.

7. The RedBoot installation is now complete. The board is now ready for development using **arm-eabi-gdb**, RedBoot's gdb stubs, and eCos applications configured for RAM startup.

Programming RedBoot into NOR flash using the PEEDI

The following gives the steps needed to program RedBoot into the SPI NOR Flash using the PEEDI. The basic process is to load and run a copy of RedBoot, then use that to initialize the flash, download the full image including the AIS script and bootloaders, and write this image to the flash.

1. Set up the PEEDI as described in the Ronetix documentation. The `peedi.sd_l137.cfg` file in the platform HAL's `misc` subdirectory contains the required hardware initialization support. Other parts of this file will need to be edited, for example the license key details.

2. Connect a serial cable between the boards DB9 serial connector and the host PC. Run a serial terminal emulator (Hyperterm or minicom) on the host, connecting at 115200 baud 8N1 with no flow control.

3. Use **arm-eabi-gdb** to run the `redboot.elf` executable from the `loaders/sd_l137` subdirectory of your eCosPro installation. Substitute the appropriate TCP/IP address and port number corresponding to your PEEDI setup.

   ```
   $ arm-eabi-gdb --quiet <path>/redboot.elf
   (gdb) target remote peedi:9000
   Remote debugging using peedi:9000
   0xffff0000 in ?? ()
   (gdb) load
   Loading section .rom_vectors, size 0x40 lma 0xc0008000
   Loading section .text, size 0x1a078 lma 0xc0008040
   Loading section .rodata, size 0x3fac lma 0xc00220b8
   Loading section .data, size 0xd2b4 lma 0xc0026064
   Start address 0xc0008040, load size 176920
   Transfer rate: 34 KB/sec, 13609 bytes/write.
   (gdb) continue
   Continuing.
   ```

   Address 0xffff0000 corresponds to the ARM reset vector. At this point the primary and secondary bootloaders have run and the processor would be about to start the tertiary bootloaders, but the PEEDI will have halted the processor and run its hardware initialization macro instead. RedBoot will start running after the **continue** command, and the following should be sent out of the serial line.

   ```
   +**Warning** FLASH configuration checksum error or invalid key
   Use 'fconfig -i' to [re]initialize database
   Ethernet eth0: MAC address 00:0e:99:03:13:ee
   IP: 10.1.1.147/255.255.255.0, Gateway: 10.1.1.241
   Default server: 0.0.0.0

   FLASH: 0x70000000-0x703fffff, 64 x 0x10000 blocks
   RedBoot>
   ```

   The flash configuration warning is expected at this stage. The ethernet MAC address will have come from the serial EEPROM on the I2C0 bus. The IP and gateway addresses will have been provided by a BOOTP server.

4. Run the following command to initialize RedBoot's flash file system and flash configuration:

   ```
   RedBoot> fis init
   ```

```
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x703f0000-0x703fffff: .
... Program from 0xc3ff0000-0xc4000000 to 0x703f0000: .
RedBoot> fis list
Name              FLASH addr  Mem addr    Length      Entry point
RedBoot           0x70000000  0x70000000  0x00040000  0x00000000
FIS directory     0x703F0000  0x703F0000  0x0000F000  0x00000000
RedBoot config    0x703FF000  0x703FF000  0x00001000  0x00000000
RedBoot>
```

If desired the fconfig settings can be initialized at this time using the **fconfig -i** command. Most of the settings relate to ethernet, for example the IP address that RedBoot should use.

5. Next the full RedBoot image should be loaded into RAM.

```
       RedBoot> load -r -m y -b %{freememlo}
       C
```

From the terminal emulator upload the `redboot.img` file from the `loaders/sd_l137` directory using Y-Modem protocol. When the upload is complete you should see something similar to the following output.

```
CRaw file loaded 0xc003cc00-0xc006ff27, assumed entry at 0xc003cc00
xyzModem - CRC mode, 1641(SOH)/0(STX)/0(CAN) packets, 3 retries
RedBoot>
```

6. Now program the image to flash:

```
RedBoot> fis create RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x70000000-0x7003ffff: .....
... Program from 0xc003cc00-0xc006ff27 to 0x70000000: .....
... Erase from 0x703f0000-0x703fffff: .
... Program from 0xc39f0000-0xc3a00000 to 0x703f0000: .
RedBoot>
```

7. The RedBoot installation is now complete. Terminate the **arm-eabi-gdb** session by hitting ctrl-C and then running the **quit** command. Detach the PEEDI and power cycle the board. RedBoot should now start running after the primary, secondary and tertiary bootloaders and output a banner similar to the one above. The board is now ready for development using **arm-eabi-gdb**, RedBoot's gdb stubs, and eCos applications configured for RAM startup.

If it proves necessary to re-install RedBoot, this may be achieved by repeating the serial download and **fis create** parts of the above process. It is not necessary to reinitialize the FIS and fconfig.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for this board are:

```
$ mkdir redboot_sdl137_rom
$ cd redboot_sdl137_rom
$ ecosconfig new sd_l137 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/sd_l137/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the files `redboot.elf` and `redboot.img`. `redboot.elf` can be executed on the board using **arm-eabi-gdb** and a JTAG emulator. `redboot.img` is an image containing the AIS script for the primary bootloader, the secondary and tertiary bootloaders, and RedBoot. It is this image which should be programmed into flash to install or update RedBoot.

Name

Configuration — Platform-specific Configuration Options

Overview

The SD-L137 platform HAL package is loaded automatically when eCos is configured for the `sd_l137` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM This startup type can be used for applications which will be programmed into flash, or which will be loaded and debugged via JTAG. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

Application binaries cannot just be programmed into flash. Instead it is necessary to incorporate them into a larger image file containing the AIS boot script for the primary bootloader as well as the secondary and tertiary bootloaders. The platform HAL's `misc` subdirectory contains a script `gensdl137aisimg.tcl` which can be used. Given an ELF executable `test` produced by the linker, the steps required are:

```
$ arm-eabi-objcopy -O binary test test.bin
$ tclsh <path>/misc/gensdl137aisimg.tcl test.bin test.img
```

The resulting image file can be programmed into flash instead of RedBoot. The build process for RedBoot will invoke these commands automatically to generate the `redboot.img` file.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The board contains a 4 Mbyte serial NOR flash device. The `CYGPKG_DEVS_FLASH_SPI_M25PXX` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration. The driver only supports 64K block erase operations, not the smaller 4K sector erase operations.

This driver is capable of supporting the JFFS2 filesystem. However, note that the SPI interface means that this file system has reduced bandwidth and increased latency compared with other implementations. All that is required to enable the support is to include the filesystem (CYGPKG_FS_JFFS2) and any of its package dependencies (including CYGPKG_IO_FILEIO and CYGPKG_LINUX_COMPAT) together with the flash infrastructure (CYGPKG_IO_FLASH).

Ethernet Driver

The board uses the OMAP L137's internal EMAC ethernet device attached to an external Micrel KSZ8893 PHY. The CYGPKG_DEVS_ETH_ARM_OMAP package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the board. This driver is not active until the generic Ethernet support package, CYGPKG_IO_ETH_DRIVERS, is included in the configuration. The ethernet MAC address is held in the last 256-byte page of the serial EEPROM attached to the I2C0 bus.

RTC Driver

The board uses the OMAP L137's internal RTC support. The CYGPKG_DEVICES_WALLCLOCK_ARM_OMAP_L1XX package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, CYGPKG_IO_WALLCLOCK, is included in the configuration.

Watchdog Driver

The board uses the OMAP L137's internal watchdog support. The CYGPKG_DEVICES_WATCHDOG_ARM_OMAP_L1XX package contains all the code necessary to support this device. Within that package the CYGNUM_DEVS_WATCHDOG_ARM_OMAP_L1XX_DESIRED_TIMEOUT_MS configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, CYGPKG_IO_WATCHDOG, is included in the configuration.

UART Serial Driver

The board uses the OMAP L137's internal UART serial support as described in the OMAP L1xx processor HAL documentation. Only uart2 has a connector and only the tx and rx lines are connected, so hardware flow control and modem support signals are not available. The uart is normally used by RedBoot for communication with the host. If the device is needed by the application, either directly or via the serial driver, then it cannot be used for RedBoot communication and another channel such as ethernet should be used instead.

Device driver support is through the CYGPKG_IO_SERIAL_GENERIC_16X5X generic driver package which is modified by the CYGPKG_IO_SERIAL_ARM_OMAP_L1XX driver package for the OMAP L1xx. The packages are loaded automatically when configuring for the sd-l137 target but the option CYGPKG_IO_SERIAL_DEVICES has to be enabled to instantiate the device. The default device name is /dev/ser2.

I2C Bus Driver

The OMAP L1XX processor HAL contains a driver for the I²C two wire interface. This driver is loaded automatically when configuring for this target. The platform HAL enables bus 0 by default but leaves bus 1 disabled since there are no attached devices. This can be changed in the configuration if devices are attached via an expansion socket using option CYGHWR_HAL_ARM_SD_L137_I2C1. The bus names are hal_omap_l1xx_i2c_bus0 and hal_omap_l1xx_i2c_bus1.

The platform HAL also instantiates three I²C device objects: hal_i2c_eeprom for the serial EEPROM; hal_i2c_codec for the audio codec; and hal_i2c_eth_switch for the ethernet switch/phy. These devices can be accessed via the generic I²C API. The last 256-byte page of the eeprom is used to hold the ethernet MAC address but the remaining pages are available for use by the application. The ethernet switch is accessed only during ethernet driver initialization. The codec is not used by any eCos code.

The bus and device objects do not have to be enabled explicitly. If they are not used by the application, directly or indirectly, then they will be removed by link-time garbage collection.

SPI Bus Driver

The SPI buses are supported via the OMAP SPI driver CYGPKG_DEVS_SPI_ARM_OMAP. On this board only bus 0 is enabled by default since bus 1 does not ordinarily have any attached devices, but this can be changed via the configuration option CYGHWR_HAL_ARM_SD_L137_SPI1. Additionally, if CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD is set, that will ensure the appropriate bus it is configured to use is enabled (see below). The bus names are cyg_spi_omap_bus0 and cyg_spi_omap_bus1 respectively. The platform HAL also provides an SPI device object cyg_m25pxx_spi_device for the serial flash. Normally this device is used only the flash device driver, not directly by the application.

The bus and device objects do not have to be enabled explicitly. If they are not used by the application, directly or indirectly, then they will be removed by link-time garbage collection.

MMC/SD cards over SPI

The HAL can be configured to support an MMC/SD card socket connected by SPI. Ensure CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD is enabled to include this support, which it is by default if the disk driver package (CYGPKG_IO_DISK) is added to the eCos configuration.

An MMC/SD socket via SPI is not a standard feature of the Spectrum Digital OMAP-L137 platform, however it is possible to add one using a daughterboard connected via an expansion bus. As a result of this there are a number of associated configuration options as it could be connected in a variety of ways:

CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD_BUS

> This option selects which SPI bus number is connected to the socket. It has been observed that some MMC/SD cards do not behave correctly if a second SPI device is present on the same SPI bus, so it is not recommended to share the MMC/SD socket's SPI bus with any other device. Given the dataflash on the SPI0 bus, that would only leave SPI1, which is the default.

CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD_CS

> This component allows configuration of the chip select line used for communicating with the SPI-connected card. With this component enabled, this chip select line will be managed using GPIO. Alternatively, with this component disabled, the default chip select 0 will be used.

CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD_CS_PINMUX_REG

> This option configures the PINMUX register used for the chip select line used to communicate with the card. The SPI1 chip select 0 is multiplexed with a UART2 line, and since that is the UART used for HAL diagnostic output the default is instead to use GPIO3[10] (shared with the unused UART1_TXD). Its PINMUX function is set within PINMUX register 11, which is the default for this option. Consult the OMAP-L137 documentation for values for alternative pins.

CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD_CS_PINMUX_FIELD

> This option configures the field within the PINMUX register used for the chip select line used to communicate with the card. The value of this field is the amount of left bitshifting required in the register to correspond to the correct pin. SPI1 chip select 0 is multiplexed with a UART2 line, and since that is the UART used for HAL diagnostic output the default is instead to use GPIO3[10] (shared with the unused UART1_TXD). Its PINMUX function is set within PINMUX register 11 at bit position 12, which is the default for this option. Consult the OMAP-L137 documentation for values for alternative pins.

CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD_CS_GPIO_BANK

> This option configures the GPIO bank used for the chip select line used to communicate with the card. The SPI1 chip select 0 is multiplexed with a UART2 line, and since that is the UART used for HAL diagnostic output the default is instead to use GPIO3[10] (shared with the unused UART1_TXD), so bank 3 is the default for this option. Consult the OMAP-L137 documentation for values for alternative pins.

`CYGHWR_HAL_ARM_SD_L137_SPI_MMCSD_CS_GPIO_BIT`

> This option configures the GPIO bit used for the chip select line used to communicate with the card. The SPI1 chip select 0 is multiplexed with a UART2 line, and since that is the UART used for HAL diagnostic output the default is instead to use GPIO3[10] (shared with the unused UART1_TXD), so bit 10 is the default for this option. Consult the OMAP-L137 documentation for values for alternative pins.

If using the default chip select via GPIO3[10], then you must ensure the SEL_EXP2_UART1 pin is set high. If you are using the Spectrum Digital prototype daughterboard, you can do this on SW2 by setting switch 4 to the ON position.

Similarly, if using the SPI1 bus, and expansion connector 2, then you must ensure the SEL_SPI1_EXP2_B pin is set high. If you are using the Spectrum Digital prototype daughterboard and have connected your card socket to J4, you can set SEL_SPI1_EXP2_B high by setting switch 3 of SW2 to the ON position.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm9`

> The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm9` is the correct option for the ARM926EJ CPU in the OMAP L1xx.

`-mthumb`

> The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`

> This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only ROM configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.sd_l137.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLLs and SDRAM controller.

The `peedi.sd_l137.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 9000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:9000
```

The target will always run the primary and secondary bootloaders because the ARM is not powered up until the secondary bootloader has activated the ARM and put the DSP to sleep. The PEEDI will then run the initialization section of the `peedi.sd_l137.cfg` file, and halt the target. This behaviour is repeated whenever the board is powercycled. If the PEEDI is given a '**go**' command then the board will continue booting as normal.

Consult the PEEDI documentation for information on other features.

Running ROM applications

Applications configured for ROM startup can be run directly under JTAG. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the hardware, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the OMAP L1xx processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0xC0000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0xC0000000, but in order to assign hardware exception vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0xD0000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0xC0040000, with the bottom 256kB reserved for use by RedBoot.

On-chip SRAM

There are a number of on-chip SRAM areas. These are identity mapped unbuffered and uncached with their physical addresses. eCos does not use any of these areas so they are all available to the application.

SPI NOR Flash

SPI NOR flash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x70000000. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers

These are located at various addresses in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

eCos uses the SDRAM, ethernet PHY, SPI flash, and I^{2}C EEPROM facilities on the board. eCos does not currently make any use of any other off-chip peripherals present on this board.

SPI NOR Flash

eCos supports SPI access to the NOR flash on the board. The device is typically used to contain RedBoot and flash configuration data.

Accesses to SPI flash are performed via the Flash API, using 0x70000000 or as the nominal address of the device, although it does not truly exist in the processor address space.

Since SPI flash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The OMAP L1xx processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 265. Logic Zoom Board Support

Name

eCos Support for the Logic Zoom Board — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Logic Zoom eXperimenter board. The board comes in two versions, one fitted with an TI OMAP L138 processor and the other with a TI Sitara AM1808 processor. The boards and processors are functionally identical as far as eCos and this documentation are concerned. To simplify the text below the board is generally referred to as the Zoom and where the text doesn't differentiate between the two processors, all references to the OMAP-L138 should be taken to refer to either processor. In addition, all OMAP-L138 specific processor configuration and target names referred to below the should also be used for the Sitara AM1808 prcoessor. The Zoom board consists of a base board and a CPU module. The CPU module containing either the OMAP L138 or Sitara AM1808 processors. The base board contains the CPU module, 64Mbytes of SDRAM, 8Mbytes of serial NOR flash memory on SPI0, a LAN87810A PHY, a MMC/SD socket, external connections for one serial channel, ethernet, USB host/device, and the various other peripherals supported by the CPUs. eCos support for the devices and peripherals on the board and the CPU is described below.

For typical eCos development, a RedBoot image is programmed into the SPI NOR flash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

This documentation is expected to be read in conjunction with the OMAP L1xx processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The SPI NOR flash consists of 128 blocks of 64Ki bytes each. In a typical setup, the first block is reserved for the second-level bootstrap, the User Boot Loader. The following two blocks are reserved for the use of the ROM RedBoot image. The topmost block is used to manage the flash and the next block down holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

Serial support is through the `CYGPKG_IO_SERIAL_GENERIC_16X5X` generic driver package which is modified by the `CYGPKG_IO_SERIAL_ARM_OMAP_L1XX` driver package for the OMAP L1xx. These packages can support all the serial devices on the OMAP L138. However, this board only has UART2 connected to an external connector which this HAL indicates by implementing the `CYGINT_HAL_L1XX_UART2` interface. This serial channel is used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver package is loaded automatically when configuring for the Zoom-L138 target.

There is an ethernet driver `CYGPKG_DEVS_ETH_ARM_OMAP` for the on-chip ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the Zoom-l138 board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_OMAP_L1XX`. This driver is also loaded automatically when configuring for the board.

There is a driver for the on-chip real-time clock (RTC) at `CYGPKG_DEVS_WALLCLOCK_ARM_OMAP_L1XX`. This driver is also loaded automatically when configuring for the target.

The OMAP L1XX processor HAL contains a driver for the MultiMedia Card Interface (MMC/SD). This driver is loaded automatically when configuring for this target and allows use of MMC and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation on the driver may be found in the OMAP L1XX processor HAL documentation.

The platform HAL provides definitions to allow access to devices on the SPI bus. The HAL provides information to the more general OMAP SPI driver (`CYGPKG_DEVS_SPI_ARM_OMAP`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board.

Furthermore, the platform HAL package contains support for the SPI NOR flash. The HAL support integrates with the CYGPKG_DEVS_FLASH_SPI_M25PXX package as well as the above SPI packages. That package is automatically loaded when configuring for the target. This driver is capable of supporting the JFFS2 filesystem.

In general, devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (RTC, SPI, MMC/SD etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate power control and pin multiplexing configuration.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 4.3.2, arm-eabi-gdb version 6.8, and binutils version 2.18.

Name

Setup — Preparing the Zoom board for eCos Development

Overview

In a typical development environment, the Zoom board boots from the SPI NOR and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from SPI NOR flash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from NOR flash by the User Boot Loader. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The Zoom board comes with U-Boot installed by default. The booting mechanism is that the on-chip firmware loads a small User Boot Loader from the start of NOR flash which then loads U-Boot from later in the flash. Our strategy is to leave the User Boot Loader in place and replace U-Boot with RedBoot.

To write RedBoot to the SPI NOR flash, there are two possibilities: either run a RAM-resident RedBoot using a JTAG emulator and use that to program RedBoot into the SPI NOR flash; or use a Serial Boot and Flash Utility for OMAP-L138.

The following section describes this process using the Ronetix PEEDI; other JTAG emulators will have similar steps.

Programming RedBoot into NOR flash using the PEEDI

The following gives the steps needed to program RedBoot into the SPI NOR Flash using the PEEDI. The basic process is to load and run a copy of RedBoot, then use that to initialize the flash, download a new copy of RedBoot and write that to the flash.

1. Set up the PEEDI as described in the Ronetix documentation. The `peedi.zoom.cfg` file should be used to setup and configure the hardware.
2. Connect a null-modem serial cable between the serial port of the board and a serial port on a convenient host. Run a terminal emulator (Hyperterm or minicom) at 115200 baud.
3. Copy `redboot_ROM.srec` to to a TFTP server that the PEEDI can access. Copy `redboot_ROM.img` to the machine running the terminal emulator.
4. Connect a telnet session to the PEEDI and issue the following command, substituting your own TFTP server address:

```
        zoom>> mem load tftp://10.0.1.1/redboot.srec srec
        ++ info: Loading image file:  tftp://10.0.1.1/redboot.srec
        ++ info: At absolute address: 0xC0008000
        loading at 0xC0008000
        loading at 0xC000C000
```

```
       loading at 0xC0010000
       loading at 0xC0014000
       loading at 0xC0018000
       loading at 0xC001C000

       Successfully loaded 88KB (90336 bytes) in 20.4s
       zoom>
```

5. Now issue the go command:

   ```
          zoom> go 0xC0008000
   ```

   You should see the following output on the Zoom board serial line:

   ```
   +M25PXX : Init device with JEDEC ID 0x202017.
   **Warning** FLASH configuration checksum error or invalid key
   Use 'fconfig -i' to [re]initialize database

   RedBoot>
   ```

6. Run the following command to initialize RedBoot's flash file system and flash configuration:

   ```
   RedBoot> fis init
   About to initialize [format] FLASH image system - continue (y/n)? y
   *** Initialize FLASH Image System
   ... Erase from 0x707f0000-0x707fffff: .
   ... Program from 0xc3ff0000-0xc4000000 to 0x707f0000: .
   RedBoot> fconfig -i
   Initialize non-volatile configuration - continue (y/n)? y
   Run script at boot: false
   Console baud rate: 115200
   Update RedBoot non-volatile configuration - continue (y/n)? y
   ... Erase from 0x707e0000-0x707e0fff: .
   ... Program from 0xc3fef000-0xc3ff0000 to 0x707e0000: .
   RedBoot>
   ```

7. We now need to download a copy of RedBoot and program it into the flash. Give the following command to RedBoot:

   ```
          RedBoot> load -r -m y -b %{freememlo}
          C
   ```

   From the terminal emulator upload the `redboot_ROM.img` file using Y-Modem protocol. When the upload is complete you should see something similar to the following output.

   ```
   RedBoot> load -r -m y -b %{freememlo}
   CRaw file loaded 0xc0022400-0xc00384ef, assumed entry at 0xc0022400
   xyzModem - CRC mode, 708(SOH)/0(STX)/0(CAN) packets, 4 retries
   RedBoot>
   ```

8. Now program the RedBoot image to flash:

   ```
   RedBoot> fis cre RedBoot
   ```

```
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x70010000-0x7002ffff: ..
... Program from 0xc0022400-0xc00384f0 to 0x70010000: ..
... Erase from 0x707f0000-0x707fffff: .
... Program from 0xc3ff0000-0xc4000000 to 0x707f0000: .
RedBoot>
```

The RedBoot installation is now complete. This can be tested by issuing the **reset run** command to the PEEDI, or by detaching the PEEDI and power cycling the board. Output similar to the following should be seen on the serial port.

```
+M25PXX : Init device with JEDEC ID 0x202017.
RedBoot(tm) bootstrap and debug environment [ROM]

Platform: Logic Zoom OMAP L138 eXperimenter (ARM9)
RAM: 0xc0000000-0xc4000000 [0xc0022128-0xc3fed000 available]
FLASH: 0x70000000-0x707fffff, 128 x 0x10000 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the serial download and **fis create** parts of the above process. It is not necessary to reinitialize the FIS and fconfig.

Note

If the board has been supplied with a TI User Boot Loader (UBL) version prior to 1.65, then on startup the board may output a string on the serial port saying "No magic number found". Earlier Zoom boards were known to be supplied with version 1.30. In this situation you will need to locate the script `flashimg.tcl` in the `misc` subdirectory of the Zoom platform HAL (i.e. `packages/hal/arm/arm9/zoom_l138/`*`VERSION`*`/misc/flashimg.tcl`) along with the `redboot_ROM.bin` file in the `loaders` subdirectory of your eCosPro installation, and run the following command at a command prompt:

```
flashimg.tcl -oldubl redboot_ROM.bin redboot-oldubl.img
```

You can then follow the above instructions for installing RedBoot, but use `redboot-oldubl.img` in place of uses of `redboot_ROM.img`.

You will also need to perform this step on any ROM startup user applications to be programmed into Flash using a JTAG device and booted by UBL.

Programming RedBoot into NOR flash using the TI Serial Boot and Flash utility

Texas Instruments have made available a command-line Serial Boot and Flash Loading Utility for OMAP-L138. More information including download and usage instructions is available here on their website.

With this utility, you can program a ROM startup version of RedBoot in raw binary format (a prebuilt version of which may be found at `loaders/zoom_l138/redboot_ROM.bin` within your eCos installation). On Windows, we advise running the utility from a Command Prompt, rather than from a Cygwin bash shell.

Before running the utility, first you need to connect your PC to the board's serial port using a null-modem RS232 serial cable. Secondly, (with the board powered off) you must set DIP switch bank S7 so that switches 7, and 8 are set to the ON position and the rest are set to the OFF position. If you wish to confirm the board is configured correctly, then you can start a terminal emulator application (such as Hyperterminal on some versions of Windows) and connect to the serial port at 115200 baud, 8-N-1 with no hardware flow control, then you should see a "BOOTME" prompt when you power on the board.

To program the `redboot_ROM.bin` image, change directory to the directory containing the UBL binary file (which is included with the Serial Boot and Flash utility download), copy the `redboot_ROM.bin` into that directory, and then run the utility as follows:

```
sfh_OMAP-L138.exe -flash ubl_OMAPL138_SPI_MEM.bin redboot_ROM.bin -APPStartAddr 0xC0008040 -APPLoadAddr 0xC0008000
```

After successful completion, RedBoot will be resident in SPI NOR Flash. To return to the normal boot mode, you must reset the SW7 DIP switches to their default position allowing booting from SPI NOR Flash. To do so, set all S7 switches to their OFF positions.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the Zoom L138 are:

```
$ mkdir redboot_zoom_l138_rom
$ cd redboot_zoom_l138_rom
$ ecosconfig new zoom_l138 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/zoom_l138/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the files `redboot.srec` and `redboot.img`. `redboot.img` is a binary file that includes a 16 byte header needed by the User Boot Loader to load RedBoot successfully.

Name

Configuration — Platform-specific Configuration Options

Overview

The Zoom L138 platform HAL package is loaded automatically when eCos is configured for the `zoom-l138` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into Flash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type can also be used for applications loaded via JTAG.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The Zoom board contains an 8Mbyte Numonyx M25P64 SPI serial NOR flash device. The `CYGPKG_DEVS_FLASH_SPI_M25PXX` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the Zoom L138 board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

This driver is capable of supporting the JFFS2 filesystem. However, note that the SPI interface means that this file system has reduced bandwidth and increased latency compared with other implementations. All that is required to enable the support is to include the filesystem (`CYGPKG_FS_JFFS2`) and any of its package dependencies (including `CYGPKG_IO_FILEIO` and `CYGPKG_LINUX_COMPAT`) together with the flash infrastructure (`CYGPKG_IO_FLASH`).

Ethernet Driver

The Zoom L138 board uses the OMAP L138's internal EMAC ethernet device attached to an external SMSC LAN8710A PHY. The `CYGPKG_DEVS_ETH_ARM_OMAP` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the ZOOM L138 board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RTC Driver

The ZOOM L138 board uses the OMAP L138's internal RTC support. The `CYGPKG_DEVICES_WALLCLOCK_ARM_OMAP_L1XX` package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, `CYGPKG_IO_WALLCLOCK`, is included in the configuration.

Watchdog Driver

The Zoom L138 board uses the OMAP L138's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_ARM_OMAP_L1XX` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_OMAP_L1XX_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

UART Serial Driver

The Zoom L138 board uses the OMAP L138's internal UART serial support as described in the OMAP L1xx processor HAL documentation. Only one serial connector is available on the board, which is connected to UART2. This connector has the RTS/CTS hardware flow control lines connected in addition to the data lines.

MMC/SD Driver

As the OMAP L1xx MMC/SD driver is part of the OMAP L1xx HAL, nothing is required to load it. Similarly the MMC/SD bus driver layer (`CYGPKG_DEVS_DISK_MMC`) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (`CYGPKG_IO_DISK`), along with the intended filesystem, typically, the FAT filesystem (`CYGPKG_FS_FAT`) and any of its package dependencies (including `CYGPKG_LIBC_STRING` and `CYGPKG_LINUX_COMPAT` for FAT).

Various options can be used to control specifics of the MMC/SD driver. Consult the OMAP L1xx HAL documentation for information on its configuration.

This board has the MMC/SD socket's card detect and write protect lines connected to GPIO lines. The card detect line is additionally monitored by an interrupt handler. Thus the disk I/O layer's removeable media support will detect when cards have been inserted or removed, and the FILEIO layer's automounter can be used.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm926ej-s`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm926ej-s` is the correct option for the ARM926EJ-S CPU in the OMAP L1xx.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only ROM configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.zoom.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLLs and SDRAM controller.

The `peedi.zoom.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.zoom.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a second-level bootstrap and ROM RedBoot is resident in flash, it will be run.

Consult the PEEDI documentation for information on other features.

Running ROM applications

Applications configured for ROM startup can be run directly under JTAG. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port.

Installing user applications into Flash with JTAG

If you wish to install a ROM startup application into Flash to be automatically booted, you can follow a similar procedure to installing RedBoot into Flash. However before you can do so, you must first prepend a header to your application image in order for the TI User Boot Loader (UBL) to recognise it as a valid application.

You will need to locate the script **flashimg.tcl** in the `misc` subdirectory of the Zoom platform HAL (i.e. `packages/hal/arm/arm9/zoom_l138/`*`VERSION`*`/misc/flashimg.tcl`) and generate a binary image of your program using the **arm-eabi-objcopy** command. The following gives an example simplified command sequence which can be run at a command shell prompt:

```
arm-eabi-objcopy -O binary myapp myapp.bin
flashimg.tcl myapp.bin myapp.img
```

You will need to subsitute your own paths and filenames where applicable. Additionally, if your board is installed with a UBL version earlier than 1.65, you are likely to need to use the extra option *`-oldubl`* to **flashimg.tcl**, otherwise you may receive errors about missing magic numbers from UBL at boot time.

Once you have the `.img` file, you can follow the same process as installing RedBoot via JTAG.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Zoom L138 hardware, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the OMAP L1xx processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0xC0000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0xC0000000, but in order to assign hardware exception vectors vectors at address 0x00000000, the HAL also uses the MMU to create a clone of this memory at virtual address 0x00000000. The same memory is also accessible uncached and unbuffered at virtual location 0xD0000000 for use by devices. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0xC0040000, with the bottom 256kB reserved for use by RedBoot. ROM applications are loaded starting at 0xC0008000, which leaves space for the User Boot Loader.

On-chip SRAM

There are a number of on-chip SRAM areas. These are identity mapped unbuffered and uncached with their physical addresses.

SPI NOR Flash

SPI NOR flash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x70000000. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers

These are located at various addresses in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

eCos uses the SDRAM, ethernet PHY, MMC/SD, and SPI flash facilities on the Zoom L138 board. eCos does not currently make any use of any other off-chip peripherals present on this board.

SPI NOR Flash

eCos supports SPI access to the NOR flash on the board. The device is typically used to contain RedBoot and flash configuration data.

Accesses to SPI flash are performed via the Flash API, using 0x70000000 or as the nominal address of the device, although it does not truly exist in the processor address space.

Since SPI flash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provides better performance than Thumb mode.

Example 265.1. zoom_l138 Real-time characterization

```
            Startup, main stack : stack used   392 size  3920
             Startup :  Interrupt stack used   504 size  4096
             Startup : Idlethread stack used    88 size  2048

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    4.52 microseconds (9 raw clock ticks)

Testing parameters:
   Clock samples:            32

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The OMAP L1xx processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 266. Freescale i.MXxx Processor Support

Name

Support for the Freescale i.MXxx Processor — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Freescale i.MXxx processor family. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, ARM9 variant HAL and the platform HAL. It provides functionality common to all i.MXxx-based board implementations.

This support is found in the eCos package located at `packages/hal/arm/arm9/imx` within the eCos source repository.

The i.MXxx processor HAL package is loaded automatically when eCos is configured for an i.MXxx-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the i.MXxx processor within this processor HAL package include:

- i.MXxx-specific hardware definitions
- Interrupt controller
- Timers
- Serial UARTs
- Pin Configuration and GPIO Support
- Peripheral Clock Control

Support for the on-chip SPI device, SPI NOR flash, I²C, interrupt-driven serial, Ethernet and watchdog features of the i.MXxx are also present and can be found in separate packages, outside of this processor HAL.

Name

i.Mxx Hardware Definitions — Details on obtaining hardware definitions for i.MXxx

Register definitions

The file `<cyg/hal/imx.h>` can be included from application and eCos package sources to provide definitions related to IMX subsystems. These include register definitions for the interrupt controller, clock management controller, pin multiplexing, GPIO, UART, timers and watchdog subsystems. Register definitions for some devices are to be found in the appropriate driver packages and only base addresses and configuration definitions are provided here. This file will normally be included automatically if `<cyg/hal/hal_io.h>` is included, which is the preferred way of getting these definitions.

Initialization Helper Macros

The file `<cyg/hal/imx_init.inc>` contains definitions of helper macros which may be used by i.MXxx platform HALs in order to initialize common subsystems without excessive duplication between the platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary. NOTE: At present, the only extant i.MXxx port relies on either the on-chip boot loader, or the JTAG initialization script, to initialize the PLLs and memory controller, so these macros currently largely contain ARM9-generic setup only.

Name

i.MXxx Interrupt Controller — Advanced Interrupt Controller Definitions And Usage

Interrupt controller definitions

The file `<cyg/hal/var_ints.h>` (located at `hal/arm/arm9/imx/`*`VERSION`*`/include/var_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs.

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt Controller Functions

The source file `src/imx_misc.c` within this package provides most of the support functions to manipulate the interrupt controller. The `hal_IRQ_handler` queries the IRQ status register to determine the interrupt cause. Functions `hal_interrupt_mask` and `hal_interrupt_unmask` enable or disable interrupts within the interrupt controller.

Interrupts are configured in the `hal_interrupt_configure` function. Only GPIO interrupts are configurable, and at present we do not support full decoding of these, so this function is empty.

The `hal_interrupt_acknowledge` function acknowledges an interrupt. Since there is no action needed to acknowledge an interrupt, this function is empty.

The `hal_interrupt_set_level` is used to set the priority level of the supplied interrupt within the interrupt controller. The level value may range from 0 to 15, with 0 being the highest priority.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (`HAL_INTERRUPT_MASK` et al) or preferably the kernel or driver APIs should be used to control interrupts.

Name

Timers — Use of on-chip timers

System Clock

The eCos kernel system clock is implemented using EPIT1 By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to `CYGNUM_HAL_RTC_DENOMINATOR`, then the configuration option `CYGNUM_HAL_RTC_NUMERATOR` may also be adjusted and the value of `CYGNUM_HAL_RTC_PERIOD` adjusted to match.

The same timer is used to implement the HAL microsecond delay function, `HAL_DELAY_US`. This is used by some device drivers, and in non-kernel configurations such as with RedBoot where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Timer-based profiling support

Timer-based profiling support is implemented using EPIT2 If the gprof package, `CYGPKG_PROFILE_GPROF`, is included in the configuration, then EPIT2 reserved for use by the profiler.

Name

Serial UARTs — Configuration and Implementation Details of Serial UART Support

Overview

Support is included in this processor HAL package for up to five of the i.MXxx's on-chip serial UART devices. Interfaces `CYGINT_HAL_IMX_UART1` to `CYGINT_HAL_IMX_UART5` indicate for each UART whether it is connected to an external port and should be **implemented** as appropriate by the platform HAL CDL.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 115200,8,N,1 with no flow control.

HAL Diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems. This can operate on any port, according to the configuration settings.

There are several configuration options usually found within a platform HAL which affect the use of this support in the IMX processor HAL. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, `diag_printf()`. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL` selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the `CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS` CDL option in the HAL. Baud rates for each channel are set with the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD` options.

Interrupt-driven Serial Driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (`CYGPKG_IO_SERIAL`). This support can be enabled on any port.

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent ctrl-c operation when debugging.

The main part of this driver is contained in the generic `CYGPKG_IO_SERIAL_ARM_IMX` package. A platform specific package, for example `CYGPKG_IO_SERIAL_ARM_MCIMX25`, contains definitions that configure the generic driver for the platform. That driver package should also be consulted for documentation and configuration options. The driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Support for hardware flow control and modem control lines is present in the driver, but will only be enabled if these control signals are brought out to the physical serial port.

Name

Pin Configuration and GPIO Support — Use of pin configuration and GPIO

Synopsis

#include <cyg/hal/hal_io.h>

pin = **CYGHWR_HAL_IMX_PINMUX**(*padctl_off*, *padctl*, *muxctl_off*, *muxmode*, *selinput_off*, *selinput*);

CYGHWR_HAL_IMX_GPIO_INTSTAT (*pin*, *stat*);

CYGHWR_HAL_IMX_GPIO_INTMASK (*pin*, *enable*);

CYGHWR_HAL_IMX_GPIO_INTCLR (*pin*);

Description

The i.MXxx HAL provides a number of macros to support the encoding of pin multiplexing information and GPIO pin modes into descriptors. This is useful to drivers and other packages that need to configure and use different lines for different devices. Because there is not a simple correspondence between pin multiplexing information and GPIO bank and pin identities, these two things are treated separately.

Pin Multiplexing

There is no systematic relationship between the various registers that control the properties of a single io pin. So all the information needed to identify and configure a pin is encoded into a 64 bit descriptor. To define a new pin descriptor it is necessary to consult the appropriate processor reference manual for the register offsets and valid settings. A pin multiplexing descriptor is represented by the hal_imx_pin and is created with `CYGHWR_HAL_IMX_PINMUX()` which takes the following arguments:

padctl_off
: The offset of the pad control register in the IO multiplexor. If this is zero, no pad control configuration is performed.

padctl
: Pad control settings. This is just the last part of the name of a `CYGHWR_HAL_IMX_PINMUX_PADCTL_*` macro. Macros are defined to correspond to the fields of this register, and combination macros are defined to set several fields. The user can also define their own macros if the default set do not contain the required values.

muxctl_off
: The offset of the multiplexing control register in the IO multiplexor. If this is zero, no multiplexing is performed.

muxmode
: This sets the multiplexing mode for the pin. It may be either `MUX(x)` or `MUX_SION(x)` where *x* is the multiplexing mode to attach this pin to the selected device.

selinput_off Some device inputs can be attached to more than one pin. In this case this parameter contains the offset of the input select register that controls this. If this value is zero, no input selection is made.

selinput This is the input selection value. It may either be `NONE` or `SEL(x)`, where *x* is the selection value.

The following examples show how this macro may be used:

```
// UART1 RX line, with 100K Ohm pull down, mux 0
#define CYGHWR_HAL_IMX_UART1_RX \
        CYGHWR_HAL_IMX_PINMUX( 0x368, PUS_100KD, 0x170, MUX_SION(0),     0, NONE   )

// UART4 RX line, 100K Ohm pull down, mux 1, input selection 1
#define CYGHWR_HAL_IMX_UART4_RX \
        CYGHWR_HAL_IMX_PINMUX( 0x3B0, PUS_100KD, 0x1B8, MUX_SION(1), 0x570, SEL(1) )

// GPIO line, floating, mix 5
#define CYGHWR_HAL_IMX_FEC_RESET \
        CYGHWR_HAL_IMX_PINMUX( 0x238,     FLOAT, 0x01C, MUX(5),     0, NONE   )
```

The macro `CYGHWR_HAL_IMX_PINMUX_SET( pin )` sets the pin multiplexing setting according to the descriptor passed in.

GPIO Support

A GPIO descriptor is created with `CYGHWR_HAL_IMX_GPIO( bank, bit, mode)` which takes the following arguments:

bank This identifies the GPIO bank to which the pin is attached. This is a value between 1 and 4.

bit This gives the bit offset within the bank of the GPIO pin. This is a value between 0 and 31.

mode This defines whether this is an input or an output pin, and may take the values `INPUT` or `OUTPUT` respectively.

Additionally, the macro `CYGHWR_HAL_IMX_GPIO_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used.

The following examples show how this macro may be used:

```
// PHY Reset pin on GPIO4, pin 8, output
#define CYGHWR_HAL_IMX_FEC_RESET_GPIO   CYGHWR_HAL_IMX_GPIO( 4, 8, OUTPUT )

// CSPI 1, chip select 0 on GPIO1, pin 16, output
#define CYGHWR_HAL_IMX_CSPI1_SS0_GPIO   CYGHWR_HAL_IMX_GPIO( 1, 16, OUTPUT )
```

The remaining macros all take a GPIO pin descriptor as an argument. `CYGHWR_HAL_IMX_GPIO_SET` configures the pin according to the descriptor and must be called before any other macros. `CYGHWR_HAL_IMX_GPIO_OUT` sets the output to the value of the least significant bit of the *`val`* argument. The *`val`* argument of `CYGHWR_HAL_IMX_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

There is also support for GPIO interrupts. `CYGHWR_HAL_IMX_GPIO_INTCFG( pin, mode )` configures the interrupt mode of the pin. It may be either `LOW_LEVEL`, `HIGH_LEVEL`, `RISING_EDGE`, `FALLING_EDGE` or `EITHER_EDGE` to configure the pin, respectively, to interrupt on active-low, active-high, rising edge, falling edge or both rising and falling edges. For example:

```
// PHY interrupt on GPIO3 pin 19
#define CYGHWR_HAL_IMX_FEC_INTERRUPT_GPIO CYGHWR_HAL_IMX_GPIO( 3, 19, INPUT )

// Configure active-LOW interrupt
CYGHWR_HAL_IMX_GPIO_INTCFG( CYGHWR_HAL_IMX_FEC_INTERRUPT_GPIO, LOW_LEVEL );
```

The second argument to `CYGHWR_HAL_IMX_GPIO_INTSTAT( pin, stat )` must be a pointer to an int, which will be set to 1 if an interrupt has be received on the given pin, and 0 otherwise.

Note

GPIO interrupts are currently not decoded into per-pin interrupt vectors, only the shared per-bank vectors are available. If an application needs to get interrupts from more than one pin on a bank, it needs to install a shared ISR and decode the specific pins itself.

The second argument to `CYGHWR_HAL_IMX_GPIO_INTMASK( pin, enable )` when set to 1 will enable the relevant GPIO interrupt source for the configured pin, with 0 disabling the source. If required, `CYGHWR_HAL_IMX_GPIO_INTCLR( pin )` can be used to explicitly clear the interrupt status for a specific GPIO pin.

Name

Peripheral Clock Control — Description

Synopsis

#include <cyg/hal/hal_io.h>

`pin = `**`CYGHWR_HAL_IMX_CLOCK`**`(`*`cgcr`*`, `*`device`*`);`

`CYGHWR_HAL_IMX_CLOCK_ENABLE`` (`*`desc`*`);`

`CYGHWR_HAL_IMX_CLOCK_DISABLE`` (`*`desc`*`);`

Description

The i.MXxx HAL provides a number of macros to support the management of peripheral clocks. The macro `CYGHWR_HAL_IMX_CLOCK( cgcr, device )` encodes a clock control descriptor into a 32 bit value. The arguments are the clock group register name, and the name of the clock to be controlled.

The remaining functions all take a peripheral clock descriptor as an argument. `CYGHWR_HAL_IMX_CLOCK_ENABLE( desc )` enables the given clock. Likewise `CYGHWR_HAL_IMX_CLOCK_DISABLE( desc )` disables the clock.

The following examples show how a clock descriptor may be defined.

```
// EPIT input clock and EPIT1 device clock
#define CYGHWR_HAL_IMX_EPIT_PER_CLOCK   CYGHWR_HAL_IMX_CLOCK( CGCR0, PER_EPIT )
#define CYGHWR_HAL_IMX_EPIT1_CLOCK      CYGHWR_HAL_IMX_CLOCK( CGCR1, IPG_EPIT1 )

// UART1 clock
#define CYGHWR_HAL_IMX_UART1_CLOCK      CYGHWR_HAL_IMX_CLOCK( CGCR2, IPG_UART1 )
```

Chapter 267. Freescale MCIMX25WPDK Board Support

Name

eCos Support for the Freescale MCIMX25WPDK Board — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Freescale MCIMX25WPDK board. The board consists of a base board, a CPU module and a debug board. The CPU module contains the i.MX25 processor, RAM, NAND flash and a connector carrying most on-chip peripherals to the Personality board. The Personality board contains the CPU module, 2Mbytes of serial NOR flash memory on CSPI1, a DP83640 PHY, external connections for Ethernet, and the various other peripherals supported by the CPUs. The Debug board connects to the Personality boards and carries power, RS232 serial, and JTAG connectors; it also contains a second Ethernet device which is not used. An LCD is connected to the Personality board, and is supported by a frame buffer driver. eCos support for the devices and peripherals on the board and the CPU is described below.

For typical eCos development, a RedBoot image is programmed into the SPI NOR flash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either the serial line or over Ethernet.

This documentation is expected to be read in conjunction with the i.MXxx processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The SPI NOR flash consists of 32 blocks of 64Ki bytes each. In a typical setup, the first four blocks are reserved for the ROM RedBoot image. The topmost block is used to manage the flash and also holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

Serial support is through the `CYGPKG_IO_SERIAL_ARM_IMX` driver package which is modified by the `CYGPKG_IO_SERIAL_ARM_MCIMX25` driver package for the MCIMX25WPDK. These packages can support all the serial devices on the i.MX25. However, this board only has UART1 connected to an external connector which this HAL indicates by implementing the `CYGINT_HAL_IMX_UART1` interface. This serial channel is used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as Ethernet should be used instead. The serial driver package is loaded automatically when configuring for the `mcimx25x` target.

There is an Ethernet driver `CYGPKG_DEVS_ETH_FREESCALE_ENET` for the on-chip FEC Ethernet device. The platform HAL package is responsible for configuring this generic driver to the hardware. This driver is also loaded automatically when configuring for the mcimx25x board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_ARM_IMX`. This driver is also loaded automatically when configuring for the board.

The platform HAL provides definitions to allow access to devices on the SPI bus. The HAL provides information to the more general CSPI driver (`CYGPKG_DEVS_SPI_ARM_CSPI`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board.

Furthermore, the platform HAL package contains support for the SPI NOR flash. The HAL support integrates with the `CYGPKG_DEVS_FLASH_SPI_M25PXX` package as well as the above SPI packages. That package is automatically loaded when configuring for the target. This driver is capable of supporting the JFFS2 filesystem.

I²C support is provided by the `CYGPKG_DEVS_I2C_FREESCALE_I2C` package. Only I²C bus 1 is directly supported, to which are attached an EEPROM and power management chips. There is a test program to test access to the former and the latter are accessed to enable the Ethernet PHY during initialization.

ADC support is provided by the `CYGPKG_DEVS_ADC_ARM_TSC` package. Only ADC inputs `INAUX0`, `INAUX1` and `INAUX2` are supported at present.

LCD support is provided by the `CYGPKG_DEVS_FRAMEBUF_ARM_IMX` package. This supports a fixed 640x480 16 bits per pixel display mode.

In general, devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (SPI, Watchdog etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate power control and pin multiplexing configuration. Devices not used by eCos (MMC/SD, Audio, CAN etc.) are not touched at all.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 4.7.3, arm-eabi-gdb version 7.2, and binutils version 2.23.2.

Name

Setup — Preparing the board for eCos Development

Overview

In a typical development environment, the board boots from the SPI NOR and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from SPI NOR flash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports Ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from NOR flash by the on-chip boot loader. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The board comes with Windows CE installed by default. The booting mechanism is that the on-chip boot loader examines a set of switches and based on their settings, reads a header, initialization data and an application from the selected external device. It then executes the application at a given address. Possible boot devices include NAND flash, SPI NOR flash and an MMC/SD card. For eCos we use the SPI NOR flash.

To write RedBoot to the SPI NOR flash we need to run RedBoot and then use that to download and program an image to SPI flash. There are two ways to do this: use a JTAG debugger to load and run RedBoot under GDB, or use an MMC/SD card to load it.

Note

The RedBoot image files referred to in the setup instructions below can be found in the `loaders/mcimx25wpdk` directory, and the PEEDI JTAG debugger configuration file and ECM files for rebuilding RedBoot can be found in the `packages/hal/arm/arm9/mcimx25x/<version>/misc` directory of the eCosPro installation. On a Linux host eCosPro is typically installed in the `/opt/ecospro/ecospro-<version>` sub-directory. On a Windows host eCosPro will typically be installed in the `C:\eCosPro\ecos-<version>` sub-directory.

The following section describes this process using the Ronetix PEEDI; other JTAG emulators will have similar steps. The next section describes how to do this using an MMC/SD card. A third common section then describes how to use that RedBoot to initialize the SPI NOR flash and program RedBoot into it.

Programming RedBoot into NOR flash using the PEEDI

The following gives the steps needed load RedBoot using the PEEDI.

1. Set up the PEEDI as described in the Ronetix documentation. The `peedi.mcimx25x.cfg` file should be used to setup and configure the hardware.
2. Connect a null-modem serial cable between the serial port of the Debug board and a serial port on a convenient host. Run a terminal emulator (TeraTerm or minicom) at 115200 baud.

3. Attach an Ethernet cable to the Personality board FEC socket, not the Debug board Ethernet socket. Make sure this is on the same network as the PEEDI and host.

4. Copy `redboot_ROM.img` to to a TFTP server on the same network as the PEEDI and MCIMX25WPDK board.

5. Apply power to the PEEDI.

6. Connect a telnet session to the PEEDI and power up the MCIMX25WPDK board. You should see something similar to the following output:

```
++ info: RESET and TRST asserted
++ info: TRST released
++ info: BYPASS check passed, 4 TAP controller(s) detected
++ info: TAP 0 : invalid IDCODE = 0x0
++ info: TAP 1 : invalid IDCODE = 0x0
++ info: TAP 2 : IDCODE = 0x07926041, ARM926E -> CORE0
++ info: TAP 3 : IDCODE = 0x1B900F0F, ARM ETB
++ info: RESET released
++ info: core 0: initialized

mx25>
```

7. Issue the following command, substituting your own TFTP server address:

```
mx25>> mem load tftp://10.0.1.1/redboot_ROM.img bin 0x80000000
++ info: Loading image file: tftp://10.0.1.1/redboot_ROM.img
++ info: At absolute address: 0x80000000
loading at 0x80000000
loading at 0x80008000
loading at 0x80010000
loading at 0x80018000
loading at 0x80020000

++ info: successfully loaded 149.00 KB in 0.59 sec
mx25>
```

8. Now set the CPSR to disable thumb mode (which the on-chip boot loader uses) and issue the go command:

```
       mx25> set cpsr 0xd3
       mx25> go 0x80008000
```

   You should see output similar to the following on the board serial line:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.2.4/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.1

RedBoot(tm) bootstrap and debug environment [ROM]

Platform: Freescale MCIMX25WPDK (ARM9)
RAM: 0x80000000-0x84000000 [0x800318f8-0x83fed000 available]
FLASH: 0x70000000-0x701fffff, 32 x 0x10000 blocks
RedBoot>
```

Now go to this section to complete the installation.

Programming RedBoot into NOR flash using an MMC/SD card

The following gives the steps needed to load RedBoot using an MMC/SD card.

1. Connect a null-modem serial cable between the serial port of the Debug board and a serial port on a convenient host. Run a terminal emulator (for example, TeraTerm or minicom) at 115200 baud.

2. Attach an Ethernet cable to the Personality board FEC socket, not the Debug board Ethernet socket. Make sure this is on the same network as your TFTP server.

3. Copy `redboot_ROM.img` to the TFTP server.

4. Locate an SD card whose existing content can be lost.

5. Using a suitable tool such as **dd** on Linux or an equivalent on Windows (e.g. dd for windows or win32 diskimager), write `redboot_ROM.img` into the first sectors of the SD card. For example, on Linux:

```
       $ sudo dd if=/path/to/redboot_ROM.img of=/dev/sdX
```

6. Set the Personality board switches as follows: SW21 all off except switches 1 and 2; SW22 all off. On the Debug board SW5..SW10 should all be off and SW4 all off except 1 and 8 (these are the default settings).

7. Insert the SD card into the SD card socket on the Personality board and apply power to the board. You should see output similar to the following on the board serial line:

```
+**Warning** FLASH configuration checksum error or invalid key
Use 'fconfig -i' to [re]initialize database
Ethernet eth0: MAC address 0e:00:00:ea:18:f0
IP: 10.0.2.4/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.1

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 16:55:09, Apr 14 2014

Copyright (C) 2000-2009 Free Software Foundation, Inc.
Copyright (C) 2003-2014 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: Freescale MCIMX25WPDK (ARM9)
RAM: 0x80000000-0x84000000 [0x800318f8-0x83fed000 available]
FLASH: 0x70000000-0x701fffff, 32 x 0x10000 blocks
RedBoot>
```

Now follow the instructions in the following section to complete the RedBoot installation.

Initialize and Install RedBoot

With a RedBoot now running on the board, the following steps are common between the two methods.

1. Run the following command to initialize RedBoot's flash file system and flash configuration:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x701f0000-0x701fffff: .
... Program from 0x83ff0000-0x84000000 to 0x701f0000: .
RedBoot> fconfig -i
```

```
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 10.0.1.1
Console baud rate: 115200
DNS domain name: example.com
DNS server IP address: 10.0.0.5
Network hardware address [MAC] for eth0: 0xec:0x05:0x00:0x00:0x02:0x24
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Default network device: enet0_eth
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x701f0000-0x701fffff: .
... Program from 0x83ff0000-0x84000000 to 0x701f0000: .
RedBoot>
```

Substitute your own IP addresses and domain name in place of those above. If multiple boards are to be run on the same network, also ensure that they have unique MAC addresses.

2. We now need to download a copy of RedBoot and program it into the flash. Give the following command to RedBoot, substituting in your tftp server's IP address:

```
RedBoot> load -h 10.0.1.1 -r -b %{freememlo} redboot_ROM.img
Using default protocol (TFTP)
Raw file loaded 0x80031c00-0x80056fff, assumed entry at 0x80031c00
RedBoot>
```

3. Now program the RedBoot image to flash:

```
RedBoot> fis create RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x70000000-0x7003ffff: ....
... Program from 0x80031c00-0x80057000 to 0x70000000: ...
... Erase from 0x701f0000-0x701fffff: .
... Program from 0x83ff0000-0x84000000 to 0x701f0000: .
RedBoot>
```

4. RedBoot installation is now complete. It is now necessary to set the board switches to select SPI NOR flash boot. Set the Personality board switches as follows: SW21 all off except switches 1, 2, 3, 4 and 7; SW22 all off. On the Debug board SW5..SW10 should all be off and SW4 all off except 1 and 8 (these are the default settings). If you have already booted via the MMC/SD card, you just need to move SW21 switches 3, 4 and 7 to on.

5. Disconnect the PEEDI or pop the SD card from the socket and power cycle the board. You should see output similar to the following on the serial line:

```
+Ethernet eth0: MAC address ec:05:00:00:02:24
IP: 10.0.2.9/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.1

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 16:55:09, Apr 14 2014

Copyright (C) 2000-2009 Free Software Foundation, Inc.
Copyright (C) 2003-2014 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: Freescale MCIMX25WPDK (ARM9)
RAM: 0x80000000-0x84000000 [0x800318f8-0x83fed000 available]
FLASH: 0x70000000-0x701fffff, 32 x 0x10000 blocks
RedBoot>
```

If it proves necessary to re-install RedBoot, this may be achieved by repeating the **load** and **fis create** parts of the above process. It is not necessary to use a PEEDI, or an SD card, or to reinitialize the FIS and fconfig.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the MCIMX25WPDK are:

```
$ mkdir redboot_mcimx25x_rom
$ cd redboot_mcimx25x_rom
$ ecosconfig new mcimx25x redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/mcimx25x/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the files `redboot.img`. `redboot.img` is a binary file that includes the headers needed by the on-chip boot loader to load RedBoot successfully.

Note

The `flashimg_imx` host executable provided within your eCosPro installation is required on the build host to wrap the RedBoot binary image into an image that can be loaded by the on-chip boot loader. This executable must be on your path when you build RedBoot and will normally be copied into the `ecospro/ecoshosttools/bin` sub-directory by the eCosPro installer from the `ecospro/ecos-<version>/host/bin-<hostos>` sub-directory of your eCosPro installation. The `ecospro/ecoshosttools/bin` sub-directory will be on your path if you use the eCos GUI configuration tool or the eCos CLI Shell environment provided by `ecosprofileenv`.

Name

Configuration — Platform-specific Configuration Options

Overview

The MCIMX25X platform HAL package is loaded automatically when eCos is configured for the `mcimx25x` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. RAM applications can also be downloaded to the board, programmed into flash and then run from the RedBoot prompt. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into Flash. The application will be self-contained with no dependencies on services provided by other software. An initialization table in the image header and eCos startup code will perform all necessary hardware initialization.

JTAG
: This startup type can be used for finished applications which will be loaded via JTAG. The application will be self-contained with no dependencies on services provided by other software. The JTAG init file plus eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The board contains an 2Mbyte Macronix MX25L1605D SPI serial NOR flash device. The `CYGPKG_DEVS_FLASH_SPI_M25PXX` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

This driver is capable of supporting the JFFS2 filesystem. However, note that the SPI interface means that this file system has reduced bandwidth and increased latency compared with other implementations. All that is required to enable the support is to include the filesystem (`CYGPKG_FS_JFFS2`) and any of its package dependencies (including `CYGPKG_IO_FILEIO` and `CYGPKG_LINUX_COMPAT`) together with the flash infrastructure (`CYGPKG_IO_FLASH`).

Ethernet Driver

The board uses the internal FEC Ethernet device attached to an external Texas Instruments DP83640 PHY. The `CYGPKG_DEVS_ETH_FREESCALE_ENET` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

Watchdog Driver

The board uses the i.MXxx internal watchdog. The `CYGPKG_DEVICES_WATCHDOG_ARM_IMX` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_ARM_IMX_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

UART Serial Driver

The board uses the i.MXxx internal UART serial support as described in the i.MXxx processor HAL documentation. Only one serial connector is available on the board, which is connected to UART1. This connector has the RTS/CTS hardware flow control lines connected in addition to the data lines.

ADC Driver

ADC support is provided by the `CYGPKG_DEVS_ADC_ARM_TSC` package. Only ADC inputs `INAUX0`, `INAUX1` and `INAUX2` are supported at present. In addition to the TSC ADC device, this driver uses GPT1 to provide the sample rate clock. Application code should avoid using this timer if the ADC is to be used. This driver is only active if the generic ADC support package, `CYGPKG_IO_ADC`, is included in the configuration.

LCD Driver

LCD support is provided by the `CYGPKG_DEVS_FRAMEBUF_ARM_IMX` package. It supports a single frame buffer format, 640 by 480 pixels, 16 bits per pixel true colour. The frame buffer is placed at a fixed address in memory at 0x83F00000. This driver is only active if the generic framebuffer support package, `CYGPKG_IO_FRAMEBUF`, is included in the configuration.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just three flags specific to this port:

`-mcpu=arm926ej-s`

The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=arm926ej-s` is the correct option for the ARM926EJ-S CPU in the i.MX25.

`-mthumb`

The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`

This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only JTAG and ROM configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.mcimx25x.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLLs and SDRAM controller.

The `peedi.mcimx25x.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_ARM]` section. Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.mcimx25x.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal.

Consult the PEEDI documentation for information on other features.

Running JTAG applications

Applications configured for either JTAG or ROM startup can be run directly under JTAG. Once loaded and running via JTAG, HAL diagnostic output will appear by default on the serial debug port. There is in fact minimal difference between ROM and JTAG applications and these can mostly be used interchangeably.

Installing user applications into Flash with JTAG

If you wish to install a ROM startup application into Flash to be automatically booted, you can follow a similar procedure to installing RedBoot into Flash. However before you can do so, you must first prepend a header to your application image in order for the on-chip boot loader to recognize it as a valid application.

You will need to locate the program **flashimg_imx** supplied with the eCosPro installation and generate a binary image of your program using the **arm-eabi-objcopy** command. The following gives an example simplified command sequence which can be run at a command shell prompt:

```
arm-eabi-objcopy -O binary myapp myapp.bin
flashimg_imx myapp.bin myapp.img
```

You will need to substitute your own paths and filenames where applicable.

Once you have the `.img` file, you can follow the same process as installing RedBoot via JTAG. Alternatively, you can write it to an SD card and boot it directly after changing the board switches.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the board hardware, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the ARM9 variant HAL and the i.MXxx processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x80000000 of the physical memory space and is 64MiB in size. The HAL configures the MMU to retain the SDRAM at virtual address 0x80000000, but in order to assign hardware exception vectors vectors at address 0x00000000, the HAL also uses the MMU to create an uncached clone of this memory at virtual address 0x00000000. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. 1MiB at 0x83f00000 is reserved for the LCD display frame buffer and is identity mapped uncached. For ROM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x80100000, with the bottom 1MB reserved for use by RedBoot. ROM applications are relocated starting at 0x80008000.

On-chip SRAM

There is 128KiB of SRAM which is identity mapped uncached at 0x78000000. eCos makes no current use of this memory, so it is available for application use.

SPI NOR Flash

SPI NOR flash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x70000000. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

On-chip Peripheral Registers

These are located at various addresses in the physical memory space. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

Off-chip Peripherals

eCos uses the SDRAM, Ethernet PHY, and SPI flash and I^{2}C power controllers on the board. eCos does not currently make any use of any other off-chip peripherals present on this board.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM mode, which provides better performance than Thumb mode.

Example 267.1. mcimx25x Real-time characterization

```
             Startup, main thrd : stack used   380 size  1792
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    96 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    3.09 microseconds (3 raw clock ticks)

Testing parameters:
   Clock samples:            32

Timing complete - 29810 ms total

PASS:<Basic timing OK>
EXIT:<done>
```

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The i.MXxx processor HAL, ARM9 variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Bonjour Conformance Test

This section just provides information regarding the specific MCIMX25WPDK platform Bonjour test. For more detail regarding Bonjour testing please reference the Bonjour Conformance Test section of the mDNS package documentation.

For the mDNS Responder package testing the following equipment was used.

- Unit-Under-Test (UUT)

  The `mcimx25wpdk` target platform being tested, executing a suitable eCosPro mDNS configuration.

- Mac Mini (OS: 10.9.3)

  Executing the BonjourConformanceTest v1.3.0 in a Terminal shell window, and the Safari v7.0.4 web-browser.

- Billion BiPAC 7800N

  10base-T (wired) Ethernet connections to the UUT and the Mac Mini.

The result for an actual BCT run using the `mdns_example` application, executing on the MCIMX25WPDK platform, is available in the `doc/bct_mcimx25wpdk_result.txt` file. This file is the original, as produced by the BCT application. For reference, the `doc/bct_mcimx25wpdk_terminal.txt` contains the execution output captured from the MacOS Terminal window. Both of these files can be found in the mcimx25x HAL documentation directory: `packages/hal/arm/arm9/mcimx25x/<version>/doc`

The following is a listing of the `doc/bct_mcimx25wpdk_result.txt` file.

Chapter 268. Intel IQ80321 Board Support

Name

eCos Support for the Intel IQ80321 Board — Overview

Description

This document covers the Intel IQ80321 development board for the IOP321 XScale device. The IQ80321 contains the IOP321 processor, 128MB of SDRAM, 8MB of Intel Strataflash memory, an Intel i82544 Ethernet MAC and a TL16C550C UART.

For typical eCos development, a RedBoot image is programmed into the flash memory, and the board will boot this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over ethernet.

Supported Hardware

The flash memory consists of 64 blocks of 128k bytes each. In a typical setup, the first two flash blocks are used for the ROM RedBoot image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining 62 blocks between 0xF0040000 and 0xF07DFFFF can be used by application code.

There is a serial driver `CYGPKG_IO_SERIAL_GENERIC_16X5X` which supports the 16C550 UART. The `CYGPKG_IO_SERIAL_ARM_IQ80321` package provides customization of this generic driver to the IQ80321 hardware. This device can be used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as ethernet should be used instead. The serial driver packages are loaded automatically when configuring for the IQ80321 target.

There is an ethernet driver `CYGPKG_DEVS_ETH_INTEL_I82544` for the Intel i82544 ethernet device. A second package `CYGPKG_DEVS_ETH_ARM_IQ80321` is responsible for configuring this generic driver to the IQ80321 hardware. These drivers are also loaded automatically when configuring for the IQ80321 target.

eCos manages the on-chip interrupt controller. Timer 0 is used to implement the eCos system clock and the microsecond delay function. Other on-chip devices (Caches, MEMC, INTC, PCI bridge, ATU, MMU, I²C) are initialized only as far as is necessary for eCos to run. Other devices are not touched.

Tools

The IQ80321 port is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.2.1, arm-elf-gdb version 5.3, and binutils version 2.13.1.

Name

Setup — Preparing the IQ80321 board for eCos Development

Overview

In a typical development environment, the IQ80321 board boots from flash into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from flash ROM boot sector	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running from RAM with RedBoot in the flash boot sector	`redboot_RAM.ecm`	`redboot_RAM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. RedBoot also supports ethernet communication and flash management.

Hardware Setup

The 80321 board is highly configurable through a number of switches and jumpers. RedBoot and eCos make some assumptions about board configuration and attention must be paid to these assumptions for reliable operation:

- The onboard ethernet and the secondary slot may be placed in a private space so that they are not seen by a PC BIOS. If the board is to be used in a PC with BIOS, then the ethernet should be placed in this private space so that RedBoot/eCos and the BIOS do not conflict.
- RedBoot assumes that the board is plugged into a PC with BIOS. This requires RedBoot to detect when the BIOS has configured the PCI-X secondary bus. If the board is placed in a backplane, RedBoot will never see the BIOS configure the secondary bus. To prevent this wait, set switch S7E1-3 to ON when using the board in a backplane.
- For the remaining switch settings, the following is a known good configuration:

S1D1	All OFF
S7E1	7 is ON, all others OFF
S8E1	2,3,5,6 are ON, all others OFF
S8E2	2,3 are ON, all others OFF
S9E1	3 is ON, all others OFF
S4D1	1,3 are ON, all others OFF
J9E1	2,3 jumpered
J9F1	2,3 jumpered
J3F1	Nothing jumpered
J3G1	2,3 jumpered
J1G2	2,3 jumpered

Initial Installation

Flash Installation

The IQ80321 is supplied with a version of RedBoot in flash. It is recommended that this version of RedBoot be replaced with one that is built from the same set of sources as the eCos system to be run on it. There are several ways of doing this.

The board manufacturer provides a DOS application which is capable of programming the flash over the PCI bus, and this is required for initial installations of RedBoot. Please see the board manual for information on using this utility. In general, the process involves programming the ROM mode RedBoot image to flash. RedBoot should be programmed to flash address 0x00000000 using the DOS utility.

If a JTAG debugger is available (such as the Abatron BDI2000) that supports programming the flash, then this may be used to install the new RedBoot. See the documentation for the JTAG device to find out how to initialize the board and program the flash. RedBoot needs to be programmed to flash address 0x00000000.

Finally, RedBoot may be installed by using the resident RedBoot. Installing RedBoot is a matter of downloading a new binary image and overwriting the existing Boot monitor ROM image. This is a two stage process, you must first download a RAM-resident version of RedBoot and then use that to download the ROM image to be programmed into the flash memory.

Connect to RedBoot as described in the IQ80321 documentation using a terminal emulator (for example **HyperTerminal** on Windows, **minicom** on Linux). You should see the RedBoot startup banner, similar to the following:

```
RedBoot(tm) bootstrap and debug environment [ROM]

Platform: IQ80321 (XScale)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.

RAM: 0x00000000-0x08000000, [0x0001b068-0x07fd1000] available
FLASH: 0xf0000000 - 0xf0800000, 64 blocks of 0x00020000 bytes each.
RedBoot>
```

The RAM image can be downloaded using the following RedBoot command:

```
RedBoot> load -m ymodem
```

Use the terminal emulator's Ymodem support to send the file `redboot_RAM.srec`. This should result in something like the following output:

```
Entry point: 0x00020040, address range: 0x00020000-0x000479f8
xyzModem - CRC mode, 2(SOH)/456(STX)/0(CAN) packets, 5 retries
RedBoot>
```

Now start the RAM version of RedBoot:

```
RedBoot> go
+No network interfaces found

RedBoot(tm) bootstrap and debug environment [RAM]
Non-certified release, version v2_0_24a1 - built 12:57:43, Sep 14 2004

Platform: IQ80321 (XScale)
Copyright (C) 2000, 2001, 2002, Free Software Foundation, Inc.
Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x08000000, [0x00059668-0x07dd1000] available
FLASH: 0xf0000000 - 0xf0800000, 64 blocks of 0x00020000 bytes each.
RedBoot>
```

Now, the ROM image can be downloaded using the following RedBoot command:

```
RedBoot> load -r -b %{FREEMEMLO} -m ymodem
```

Use the terminal emulator's Ymodem support to send the file `redboot_ROM.bin`. This should result in something like the following output:

```
Raw file loaded 0x0005a000-0x000819f8, assumed entry at 0x0005a000
xyzModem - CRC mode, 911(SOH)/0(STX)/0(CAN) packets, 4 retries
RedBoot>
```

Once the file has been uploaded, you can check that it has been transferred correctly using the **cksum** command. On the host (Linux or Cygwin) run the **cksum** program on the binary file:

```
$ cksum redboot_ROM.bin
140216855 116332 redboot_ROM.bin
```

In RedBoot, run the **cksum** command on the data that has just been loaded:

```
RedBoot> cksum -b %{FREEMEMLO} -l 116332
POSIX cksum = 140216855 116332 (0x085b8a17 0x0001c66c)
```

The second number in the output of the host **cksum** program is the file size, which should be used as the argument to the `-l` option in the RedBoot **cksum** command. The first numbers in each instance are the checksums, which should be equal.

If the program has downloaded successfully, then it can be programmed into the flash using the following commands:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)?y
*** Initialize FLASH Image System
... Unlock from 0xf07e0000-0xf0800000: .
... Erase from 0xf07e0000-0xf0800000: .
... Program from 0x07cc0000-0x07d00000 at 0xf07e0000: .
... Lock from 0xf07e0000-0xf0800000: .
RedBoot> fis create -b %{FREEMEMLO} RedBoot
An image named 'RedBoot' exists - continue (y/n)?y
... Unlock from 0xf0000000-0xf0040000: ..
... Erase from 0xf0000000-0xf0040000: ..
... Program from 0x0001c000-0x0005c000 at 0xf0000000: .
... Lock from 0xf0000000-0xf0040000: .
... Unlock from 0xf07e0000-0xf0800000: .
... Erase from 0xf07e0000-0xf0800000: .
... Program from 0x07cc0000-0x07d00000 at 0xf07e0000: .
... Lock from 0xf07e0000-0xf0800000: .
RedBoot>
```

The IQ80321 board may now be reset either by cycling the power, or with the **reset** command. It should then display the startup screen for the ROM version of RedBoot:

```
+No network interfaces found

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version v2_0_24a1 - built 12:59:55, Sep 14 2004

Platform: IQ80321 (XScale)

Copyright (C) 2003, 2004, eCosCentric Limited

RAM: 0x00000000-0x08000000, [0x0001b068-0x07fd1000] available
FLASH: 0xf0000000 - 0xf0800000, 64 blocks of 0x00020000 bytes each.
RedBoot>
```

LED Codes

RedBoot uses the two digit LED display to indicate status during board initialization. Possible codes are:

LED   Actions

Power-On/Reset

88
Set the CPSR
Enable coprocessor access
Drain write and fill buffer
Setup PBIU chip selects

A1
Enable the Icache

A2
Move FLASH chip select from 0x0 to 0xF0000000
Jump to new FLASH location

A3
Setup and enable the MMU

A4
I^{2}C interface initialization

90
Wait for I^{2}C initialization to complete

91
Send address (via I^{2}C) to the DIMM

92
Wait for transmit complete

93
Read SDRAM PD data from DIMM

94
Read remainder of EEPROM data.
An error will result in one of the following
error codes on the LEDs:
77 BAD EEPROM checksum
55 I^{2}C protocol error
FF bank size error

A5
Setup DDR memory interface

A6
Enable branch target buffer
Drain the write & fill buffers
Flush Icache, Dcache and BTB
Flush instruction and data TLBs
Drain the write & fill buffers

SL
ECC Scrub Loop

SE

A7
Clean, drain, flush the main Dcache

A8
Clean, drain, flush the mini Dcache
Flush Dcache
Drain the write & fill buffers

A9
Enable ECC

AA
Save SDRAM size
Move MMU tables into RAM

AB
Clean, drain, flush the main Dcache

Clean, drain, flush the mini Dcache

Drain the write & fill buffers

AC

Set the TTB register to DRAM mmu_table

AD

Set mode to IRQ mode

A7

Move SWI & Undefined "vectors" to RAM (at 0x0)

A6

Switch to supervisor mode

A5

Move remaining "vectors" to RAM (at 0x0)

A4

Copy DATA to RAM

Initialize interrupt exception environment

Initialize stack

Clear BSS section

A3

Call platform specific hardware initialization

A2

Run through static constructors

A1

Start up the eCos kernel or RedBoot

Special RedBoot Commands

A special RedBoot command, **diag**, is used to access a set of hardware diagnostics. To access the diagnostic menu, enter **diag** at the RedBoot prompt:

```
RedBoot> diag
Entering Hardware Diagnostics - Disabling Data Cache!

  IQ80321 Hardware Tests

 1 - Memory Tests
 2 - Repeating Memory Tests
 3 - Repeat-On-Fail Memory Tests
 4 - Rotary Switch S1 Test
 5 - 7 Segment LED Tests
 6 - i82544 Ethernet Configuration
 7 - Battery Status Test
 8 - Battery Backup SDRAM Memory Test
 9 - Timer Test
10 - PCI Bus test
11 - CPU Cache Loop (No Return)
 0 - quit
Enter the menu item number (0 to quit):
```

Tests for various hardware subsystems are provided, and some tests require special hardware in order to execute normally. The Ethernet Configuration item may be used to set the board ethernet address.

Memory Tests

This test is used to test installed DDR SDRAM memory. Five different tests are run over the given address ranges. If errors are encountered, the test is aborted and information about the failure is printed. When selected, the user will be prompted to enter the base address of the test range and its size. The numbers must be in hex with no leading “0x”

```
Enter the menu item number (0 to quit): 1
```

```
Base address of memory to test (in hex): 100000

Size of memory to test (in hex): 200000

Testing memory from 0x00100000 to 0x002fffff.

Walking 1's test:
0000000100000002000000040000000800000010000000200000004000000080
0000010000000200000004000000080000001000000020000000400000008000
0001000000020000000400000008000000100000002000000040000000800000
0100000002000000040000000800000010000000200000004000000080000000
passed
32-bit address test: passed
32-bit address bar test: passed
8-bit address test: passed
Byte address bar test: passed
Memory test done.
```

Repeating Memory Tests

The repeating memory tests are exactly the same as the above memory tests, except that the tests are automatically rerun after completion. The only way out of this test is to reset the board.

Repeat-On-Fail Memory Tests

This is similar to the repeating memory tests except that when an error is found, the failing test continuously retries on the failing address.

Rotary Switch S1 Test

This tests the operation of the sixteen position rotary switch. When run, this test will display the current position of the rotary switch on the LED display. Slowly dial through each position and confirm reading on LED.

7 Segment LED Tests

This tests the operation of the seven segment displays. When run, each LED cycles through 0 through F and a decimal point.

i82544 Ethernet Configuration

This test initializes the ethernet controller‚s serial EEPROM if the current contents are invalid. In any case, this test will also allow the user to enter a six byte ethernet MAC address into the serial EEPROM.

```
Enter the menu item number (0 to quit): 6

Current MAC address: 00:80:4d:46:00:02
Enter desired MAC address: 00:80:4d:46:00:01
Writing to the Serial EEPROM... Done

******** Reset The Board To Have Changes Take Effect ********
```

Battery Status Test

This tests the current status of the battery. First, the test checks to see if the battery is installed and reports that finding. If the battery is installed, the test further determines whether the battery status is one or more of the following:

- Battery is charging.
- Battery is fully discharged.

- Battery voltage measures within normal operating range.

Battery Backup SDRAM Memory Test

This tests the battery backup of SDRAM memory. This test is a three step process:

1. Select Battery backup test from main diag menu, then write data to SDRAM.
2. Turn off power for 60 seconds, then repower the board.
3. Select Battery backup test from main diag menu, then check data that was written in step 1.

Timer Test

This tests the internal timer by printing a number of dots at one second intervals.

PCI Bus Test

This tests the secondary PCI-X bus and socket. This test requires that an IQ80310 board be plugged into the secondary slot of the IOP80321 board. The test assumes at least 32MB of installed memory on the IQ80310. That memory is mapped into the IOP80321 address space and the memory tests are run on that memory.

CPU Cache Loop

This test puts the CPU into a tight loop run entirely from the ICache. This should prevent all external bus accesses.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot for the IQ80321 are:

```
$ mkdir redboot_iq80321_rom
$ cd redboot_iq80321_rom
$ ecosconfig new iq80321 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/iq80321/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

To rebuild the RAM RedBoot:

```
$ mkdir redboot_iq80321_ram
$ cd redboot_iq80321_ram
$ ecosconfig new iq80321 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/arm9/iq80321/current/misc/redboot_RAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This is the case for both the above builds, take care not to mix the two files up, since programming the RAM RedBoot into the ROM will render the board unbootable.

Name

Configuration — Platform-specific Configuration Options

Overview

The IQ80321 platform HAL package is loaded automatically when eCos is configured for a `iq80321` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The IQ80321 platform HAL package supports two separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default, the application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0xF0000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is required to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for RAM startup, disabled otherwise. It can be manually disabled for RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The IQ80321 board contains an 8MB Intel StrataFlash flash device. The `CYGPKG_DEVS_FLASH_STRATA` package contains all the code necessary to support these parts and the `CYGPKG_DEVS_FLASH_IQ80321` package contains definitions that customize the driver to the IQ80321 board.

Ethernet Driver

The IQ80321 board contains an Intel i82544 ethernet controller. The `CYGPKG_DEVS_ETH_INTEL_I82544` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_ARM_IQ80321` package contains definitions that customize the driver to the IQ80321 board.

System Clock

By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There is just one flag specific to this port:

`-mcpu=xscale`

The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=xscale` is the correct option for the XScale CPU on the IOP321.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the IQ80321 hardware, and should be read in conjunction with that specification. The IQ80321 platform HAL package complements the ARM architectural HAL, the XScale core HAL and the IOP321 (VERDE) variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize the on-chip peripherals that are used by eCos. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization, setting up the external SDRAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Memory Maps

The RAM based page table is located at RAM start + 0x4000.

NOTE

The virtual memory map in this section uses a C, B, and X column to indicate the caching policy for the region.

```
X C B  Description
- - -  ---------------------------------------------
0 0 0  Uncached/Unbuffered
0 0 1  Uncached/Buffered
0 1 0  Cached/Buffered    Write Through, Read Allocate
0 1 1  Cached/Buffered    Write Back, Read Allocate
1 0 0  Invalid -- not used
1 0 1  Uncached/Buffered  No write buffer coalescing
1 1 0  Mini DCache - Policy set by Aux Ctl Register
1 1 1  Cached/Buffered    Write Back, Read/Write Allocate

Physical Address Range     Description
-----------------------    ----------------------------------
0x00000000 - 0x7fffffff    ATU Outbound Direct Window
0x80000000 - 0x900fffff    ATU Outbound Translate Windows
0xa0000000 - 0xbfffffff    SDRAM
0xf0000000 - 0xf0800000    FLASH               (PBIU CS0)
0xfe800000 - 0xfe800fff    UART                (PBIU CS1)
0xfe840000 - 0xfe840fff    Left 7-segment LED  (PBIU CS3)
0xfe850000 - 0xfe850fff    Right 7-segment LED (PBIU CS2)
0xfe8d0000 - 0xfe8d0fff    Rotary Switch       (PBIU CS4)
0xfe8f0000 - 0xfe8f0fff    Battery Status      (PBIU CS5)
0xfff00000 - 0xffffffff    Verde Memory mapped Registers

Default Virtual Map      X C B  Description
-----------------------  - - -  ----------------------------------
0x00000000 - 0x1fffffff  1 1 1  SDRAM
0x20000000 - 0x9fffffff  0 0 0  ATU Outbound Direct Window
0xa0000000 - 0xb00fffff  0 0 0  ATU Outbound Translate Windows
0xc0000000 - 0xdfffffff  0 0 0  Uncached alias for SDRAM
0xe0000000 - 0xe00fffff  1 1 1  Cache flush region (no phys mem)
0xf0000000 - 0xf0800000  0 1 0  FLASH               (PBIU CS0)
0xfe800000 - 0xfe800fff  0 0 0  UART                (PBIU CS1)
```

```
0xfe840000 - 0xfe840fff  0 0 0  Left 7-segment LED  (PBIU CS3)
0xfe850000 - 0xfe850fff  0 0 0  Right 7-segment LED (PBIU CS2)
0xfe8d0000 - 0xfe8d0fff  0 0 0  Rotary Switch       (PBIU CS4)
0xfe8f0000 - 0xfe8f0fff  0 0 0  Battery Status      (PBIU CS5)
0xfff00000 - 0xffffffff  0 0 0  Verde Memory mapped Registers
```

Other Issues

The IQ80321 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The XScale core HAL, the IOP321 (VERDE) variant HAL, and the ARM architectural HAL documentation should be consulted for further details.

Chapter 269. Intel XScale IXP4xx Network Processor Support

Name

Support for Intel XScale IXP4xx Network Processors — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Intel XScale IXP4xx Network Processor series, including the IXP425 and IXP465. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, XScale variant HAL and the platform HAL. It provides functionality common to IXP4xx-based board implementations.

This support is found in the eCos package located at `packages/hal/arm/xscale/ixp425` within the eCos source repository.

For historical reasons many of the definitions, filenames and configuration options in this package refer to the IXP425 specifically. In fact, unless otherwise noted, these definitions, filenames and configuration options apply equally to all members of the IXP4xx family.

The IXP4xx processor HAL package is loaded automatically when eCos is configured for an IXP4xx-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the Intel XScale IXP4xx processors within this processor HAL package include:

- IXP4xx-specific hardware definitions
- Interrupt controller
- General-purpose timers
- Watchdog timer
- Serial UARTs
- PCI bus controller
- PCI bus IDE controllers
- CompactFlash cards in TrueIDE mode
- General Purpose I/O (GPIO)

For licensing-related reasons, support for the Network Processing Engines (NPEs) at this time is only available with an add-on EPK package from Intel. eCosCentric is unable to provide support for this add-on package.

Name

IXP4xx hardware definitions — Details on obtaining hardware definitions for IXP4xx

Register definitions

The file `<cyg/hal/hal_ixp425.h>` can be included from application and eCos package sources to provide definitions related to IXP4xx subsystems. These include register definitions for the PCI bus controller, SDRAM controller, DDR controller for IXP46x, expansion bus controller, I^{2}C® controller for IXP46x, General purpose I/O (GPIO), interrupt controller, general-purpose timers and watchdog timer.

I/O Definitions

The file `<cyg/hal/var_io.h>` contains definitions used by the PCI support, as well as memory mapping details and macros to read and write the I/O space (including the PCI I/O space) at a variety of widths. If PCI IDE support has been enabled, it also provides the relevant support macros.

Name

IXP4xx interrupt controller — Interrupt controller definitions and usage

Interrupt controller definitions

The file `<cyg/hal/hal_var_ints.h>` (located at `hal/arm/xscale/ixp425/VERSION/include/hal_var_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs:

```
#define CYGNUM_HAL_INTERRUPT_NONE        -1
#define CYGNUM_HAL_INTERRUPT_NPEA         0
#define CYGNUM_HAL_INTERRUPT_NPEB         1
#define CYGNUM_HAL_INTERRUPT_NPEC         2
#define CYGNUM_HAL_INTERRUPT_QM1          3
#define CYGNUM_HAL_INTERRUPT_QM2          4
#define CYGNUM_HAL_INTERRUPT_TIMER0       5
#define CYGNUM_HAL_INTERRUPT_GPIO0        6
#define CYGNUM_HAL_INTERRUPT_GPIO1        7
#define CYGNUM_HAL_INTERRUPT_PCI_INT      8
#define CYGNUM_HAL_INTERRUPT_PCI_DMA1     9
#define CYGNUM_HAL_INTERRUPT_PCI_DMA2     10
#define CYGNUM_HAL_INTERRUPT_TIMER1       11
#define CYGNUM_HAL_INTERRUPT_USB          12
#define CYGNUM_HAL_INTERRUPT_UART2        13
#define CYGNUM_HAL_INTERRUPT_TIMESTAMP    14
#define CYGNUM_HAL_INTERRUPT_UART1        15
#define CYGNUM_HAL_INTERRUPT_WDOG         16
#define CYGNUM_HAL_INTERRUPT_AHB_PMU      17
#define CYGNUM_HAL_INTERRUPT_XSCALE_PMU   18
#define CYGNUM_HAL_INTERRUPT_GPIO2        19
#define CYGNUM_HAL_INTERRUPT_GPIO3        20
#define CYGNUM_HAL_INTERRUPT_GPIO4        21
#define CYGNUM_HAL_INTERRUPT_GPIO5        22
#define CYGNUM_HAL_INTERRUPT_GPIO6        23
#define CYGNUM_HAL_INTERRUPT_GPIO7        24
#define CYGNUM_HAL_INTERRUPT_GPIO8        25
#define CYGNUM_HAL_INTERRUPT_GPIO9        26
#define CYGNUM_HAL_INTERRUPT_GPIO10       27
#define CYGNUM_HAL_INTERRUPT_GPIO11       28
#define CYGNUM_HAL_INTERRUPT_GPIO12       29
#define CYGNUM_HAL_INTERRUPT_SW_INT1      30
#define CYGNUM_HAL_INTERRUPT_SW_INT2      31

#ifdef CYGHWR_HAL_ARM_XSCALE_CPU_IXP46x
#define CYGNUM_HAL_INTERRUPT_USB_HOST     32
#define CYGNUM_HAL_INTERRUPT_I2C          33
#define CYGNUM_HAL_INTERRUPT_SPI          34
#define CYGNUM_HAL_INTERRUPT_TIMESYNC     35
#define CYGNUM_HAL_INTERRUPT_EAU_DONE     36
#define CYGNUM_HAL_INTERRUPT_SHA_DONE     37
#define CYGNUM_HAL_INTERRUPT_SWCP_PERR    58
#define CYGNUM_HAL_INTERRUPT_QMGR_PERR    60
#define CYGNUM_HAL_INTERRUPT_MCU_ERR      61
#define CYGNUM_HAL_INTERRUPT_EXP_PERR     62
#endif
```

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt controller functions

The source file src/ixp425_misc.c within this package provides most of the support functions to manipulate the interrupt controller. The hal_IRQ_handler queries the IRQ status register to determine the interrupt cause. Functions hal_interrupt_mask and hal_interrupt_unmask enable or disable interrupts within the interrupt controller.

GPIO interrupts are configured in the hal_interrupt_configure function, where the level and up arguments are interpreted as follows:

level	up	interrupt on
0	0	Falling Edge
0	1	Rising Edge
0	-1	Either Edge
1	0	Low Level
1	1	High Level

Some interrupts are acknowledged in the hal_interrupt_acknowledge function, although for many of the IXP4xx on-chip peripherals, the means to stop the interrupt from triggering again is to remove the cause of the interrupt in a device dependent way. This function does however clear GPIO interrupts.

Macros of the following forms may be defined by the platform HAL via the header file defined by its CYGBLD_HAL_PLATFORM_H macro definition in order to extend support to further vectors:

```
HAL_PLF_INTERRUPT_MASK(vector)
HAL_PLF_INTERRUPT_UNMASK(vector)
HAL_PLF_INTERRUPT_ACKNOWLEDGE(vector)
HAL_PLF_INTERRUPT_CONFIGURE(vector)
```

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (HAL_INTERRUPT_MASK et al) or preferably the kernel or driver APIs should be used to control interrupts.

Interrupt handling withing standalone applications

For non-eCos standalone applications running under RedBoot, it is possible to install an interrupt handler into the interrupt vector table manually. Memory mappings are platform-dependent and so the platform documentation should be consulted, but in general the address of the interrupt table can be determined by analyzing RedBoot's symbol table, and searching for the address of the symbol name hal_interrupt_handlers. Table slots correspond to the interrupt numbers above. Pointers inserted in this table should be pointers to a C/C++ function with the following prototype:

```
extern unsigned int isr( unsigned int vector, unsigned int data );
```

For non-eCos applications run from RedBoot, the return value can be ignored. The vector argument will also be the interrupt vector number. The data argument is extracted from a corresponding table named hal_interrupt_data which immediately follows the interrupt vector table. It is still the responsibility of the application to enable and configure the interrupt source appropriately if needed.

IXP46x

Support exists for the IXP46x in order to query and manipulate the extended interrupt controller registers handling interrupt numbers of 32 and above. Also on the IXP46x an interrupt handler is attached to handle ECC errors from the MCU.

Name

General-purpose timers — Use of IXP4xx general-purpose timers

General-purpose timer 0

The IXP4xx processor HAL provides general-purpose timer 0 (`OST_TIM0`) to the eCos kernel for use as a real-time clock. This timer is also used for implementing the `HAL_DELAY_US` functionality, which is used by some device drivers, and in non-kernel configurations such as with RedBoot where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Available timers

General-purpose timer 1 and the timestamp timer are available for application use.

System clock configuration

By default for eCos applications, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to `CYGNUM_HAL_RTC_DENOMINATOR`, then the configuration option `CYGNUM_HAL_RTC_NUMERATOR` may also be adjusted, and again clock-related settings will automatically be recalculated.

Name

Watchdog — Describes use of the hardware watchdog

Description

This HAL package includes the hardware driver required to support the generic watchdog support defined in the `CYGPKG_IO_WATCHDOG` package. The functionality allows the watchdog either to cause the IXP4xx to reset, or to cause a callback function to be triggered as defined in the generic watchdog API.

The watchdog is also used to perform platform resets, such as with the **reset** command in the RedBoot CLI. Note that there is an IXP425 erratum affecting use of the watchdog on IXP425s with stepping level of A0. Stepping levels of B0 and above no longer have this issue.

Configuration

It is not possible to enable support for the IXP4xx on-chip watchdog unless the `CYGPKG_IO_WATCHDOG` package is included in the eCos configuration. Once included, the configuration options for this hardware support can then be found in the watchdog part of the eCos configuration tree under the CDL component name `CYGPKG_HAL_IXP4XX_WATCHDOG`, rather than in the HAL.

The option `CYGNUM_HAL_IXP4XX_WATCHDOG_DESIRED_TIMEOUT_US` allows the watchdog timeout interval to be set. An application must ensure that the watchdog is reset more frequently than this period. The units are microseconds, and depending on the selected period, values may be rounded up to the next clock tick..

If the option `CYGSEM_HAL_IXP4XX_WATCHDOG_RESET` is enabled, watchdog expiration will cause the IXP4xx to perform a soft reset. If this option is instead disabled, a callback function can be registered with the generic watchdog API, which will be called by an interrupt handler associated with the watchdog.

Name

Serial UARTs — Configuration and implementation details of serial UART support

Overview

There are two forms of support for the built-in high-speed and console serial UARTs. In all cases the default serial port settings are 115200,8,N,1 with no flow control.

HAL diagnostic I/O

One form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus is not usually suitable for deployed systems. This can operate on either port, according to the configuration settings.

Several configuration options within the IXP4xx processor HAL affect HAL diagnostic operation. The CDL option CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL selects the serial port channel to use as the console at startup time. Channel 0 is the debug serial port, channel 1 is the high-speed serial port. This will be the channel that receives output from, for example, diag_printf(). The CDL option CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS CDL option in the HAL. Baud rates for each channel are set with the CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD and CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD options.

Interrupt-driven serial driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (CYGPKG_IO_SERIAL). This support can be enabled on either port. Note that if this form of serial driver is enabled on a port, it will prevent ctrl-c operation when debugging.

This driver uses the eCos generic 16x5x UART driver found in CYGPKG_IO_SERIAL_GENERIC_16X5X to provide most of the support. That driver package should also be consulted for documentation and configuration options.

Note that a standard 16550A compatible UART has receive FIFO trigger levels that can be set with the CYGPKG_IO_SERIAL_GENERIC_16X5X_FIFO_RX_THRESHOLD to 1, 4, 7, 8 or 14 bytes. However the IXP4xx family has a larger 64-byte FIFO, and so these values should be mapped to 1, 8, 16 or 32. In other words setting the CYGPKG_IO_SERIAL_GENERIC_16X5X_FIFO_RX_THRESHOLD option to 8 bytes would in fact cause the receive FIFO to trigger at 16 bytes and so forth.

The maximum baud rate supported by the generic eCos infrastructure is 230,400 and so at this time the higher baud rates of 460,800 and 921,600 baud are not supported.

Name

PCI bus controller — PCI bus controller support implementation details

Implementation details

The PCI bus controller is supported with the files <cyg/hal/var_io.h> and the source file src/ixp425_pci.c. These files provide almost all the required underlying support for use with the generic PCI package CYGPKG_IO_PCI.

Platform HALs are still required to provide any extra initialisation steps such as pin routing, involving GPIO, particularly for the interrupt pins. Accordingly any such interrupt pins will also require treatment with an implementation of the following function:

```
extern void cyg_hal_plf_pci_translate_interrupt(cyg_uint32 bus, cyg_uint32 devfn,
                                                CYG_ADDRWORD *vec, cyg_bool *valid);
```

Name

PCI bus IDE controllers — Configuring and using IDE controllers on the PCI bus

Overview

Support is included for IDE bus controllers connected via the PCI bus. This includes support for generic PCI IDE controllers as well as Promise 20275 or 20269 IDE controllers.

Configuration

This support can be enabled with the `CYGFUN_HAL_IXP4XX_PCI_IDE_SUPPORT` configuration option and is mutually exclusive with support for TrueIDE mode disks connected via a CompactFlash interface.

Use with RedBoot

Enabling this option allows RedBoot to be used to load program images off an IDE disk connected via a PCI IDE controller, for example a Linux kernel from an EXT2 partition of an IDE disk using the "disk" load method.

Files

The file `src/ixp_pci_ide.c` within this package is used to provide the necessary underlying support.

Name

CompactFlash cards in TrueIDE mode — Using CompactFlash cards in TrueIDE mode on the IXP4xx expansion bus

Overview

The IXP4xx processor HAL includes support for CompactFlash IDE devices accessed in True IDE mode directly on the IXP4xx expansion bus.

The hardware configuration for attaching the CF IDE devices must follow the specification described in Intel Application Note 30245603: “Intel IXP42X Product Line of Network Processors and IXC1100 Control Plane Processor: Using CompactFlash”. This describes use of the EXP_CS_N_1 (CS1) and EXP_CS_N_2 (CS2) signals to control the CF IDE device.

Configuration

Support for CF True IDE devices is contained within the IXP4xx variant HAL and is controlled with the `CYGFUN_HAL_IXP4XX_CF_TRUE_IDE_SUPPORT` configuration option. It is not possible to include PCI IDE support within the same configuration - eCos only allows one ID controller driver at the present time.

The driver requires the presence of the generic disk layer (`CYGPKG_IO_DISK`), as well as the IDE disk driver (`CYGPKG_DEVS_DISK_IDE`).

The block device name used to identify the disk is configured with the option `CYGDAT_HAL_IXP4XX_CF_TRUE_IDE_DISK_NAME` and defaults to `/dev/hd0/`. An MBR is expected to be present on the CF card, and individual partitions can be accessed as e.g. `/dev/hd0/1`, `/dev/hd0/2`, etc. or the whole device as `/dev/hd0/0`.

With this support it is possible to access filesystems on the CF IDE card with the further inclusion of the generic file I/O layer package (`CYGPKG_IO_FILEIO`) along with a standard eCos filesystem implementation such as FAT (`CYGPKG_FS_FAT`).

Use from RedBoot

Similarly, it is possible for RedBoot to load images from a filesystem using the "file" load method. For example:

```
RedBoot> fs mount -d /dev/hd0/1 -t fatfs
RedBoot> fs list
   2 -rwxrwxrwx  1 size 3961588 VMLINUX
1937 -rwxrwxrwx  1 size 1588984 ZIMAGE
RedBoot> load -m file -r -b %{freememlo} /ZIMAGE
Raw file loaded 0x00079800-0x001fd6f7, assumed entry at 0x00079800
RedBoot> exec
Using base address 0x00079800 and length 0x00183ef8
Uncompressing Linux...................................................................................................
Linux version 2.6.12 (root@andy) (gcc version 3.4.4) #43 Tue Nov 15 16:40:04 GMT 2005
CPU: XScale-IXP42x Family [690541c1] revision 1 (ARMv5TE)
CPU0: D VIVT undefined 5 cache
CPU0: I cache: 32768 bytes, associativity 32, 32 byte lines, 32 sets
CPU0: D cache: 32768 bytes, associativity 32, 32 byte lines, 32 sets
Machine: Intel IXDP425 Development Platform
[etc.]
```

Implementation details

The implementation assumes that the platform HAL will map memory accesses at 0x51000000 to expansion bus accesses with CS1 enabled, and similarly 0x52000000 to expansion bus accesses with CS2 enabled.

This driver operates in polled mode (PIO) only with no interrupt-driven operation nor DMA, and uses conservative bus configuration timings to allow for maximum compatibility with CF IDE cards. Note that some CF cards are not fully compliant with the CompactFlash standard and do not fully or correctly implement True IDE mode.

Name

GPIO — General purpose I/O

GPIO functions

As well as hardware definitions, the file `<cyg/hal/hal_ixp425.h>` provides a set of macros to assist GPIO manipulation:

```
HAL_GPIO_OUTPUT_ENABLE(line)
HAL_GPIO_OUTPUT_DISABLE(line)
HAL_GPIO_OUTPUT_SET(line)
HAL_GPIO_OUTPUT_CLEAR(line)
```

As described earlier, HAL support already exists for handling GPIO lines configured as interrupts.

Chapter 270. Intel XScale IXDP425 Network Processor Evaluation Board Support

Name

eCos and RedBoot Support for the Intel XScale IXDP425 Network Processor Evaluation Board — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Intel XScale IXDP425 Network Processor Evaluation Board. The IXDP425 board contains the Intel XScale IXP425 processor, 256Mbytes of SDRAM, 16MByte of parallel NOR flash memory, an I²C EEPROM, hexadecimal debug display, LEDs, and external connections for two serial channels, two NPE ethernet daughterboards and an expansion bus based on the Utopia-2 interface standard. eCos and RedBoot support for the devices and peripherals on this board is described below.

In normal operation, a RedBoot image is programmed into the flash memory, and the board will boot into this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone applications via the gdb debugger. RedBoot can also load and execute Linux kernels. This can happen over either a serial line or over ethernet.

This document should be read in conjunction with the *Intel XScale IXP4xx Network Processor Support* processor HAL documentation in the eCos documentation set, as well as the generic HAL documentation.

Supported Hardware

The parallel NOR flash memory supplied by default with the IXDP425 - a single Intel StrataFlash 28F128J3 - consists of 128 blocks of 128Kbytes each. In a typical setup, the first four blocks, 512 Kbytes, are reserved for the use of the RedBoot ROM image. The topmost block is used to manage the flash and hold RedBoot **fconfig** values. The remaining blocks can be used by application code. There are 123 blocks available between 0x50080000 and 0x50FE0000.

RedBoot supports the built-in high-speed and console UARTs. The default serial port settings are 115200,8,N,1.

There is an ethernet driver `CYGPKG_DEVS_ETH_INTEL_I82559` intended for use with a PCI I82559-based ethernet device to allow communication and downloads. A separate package, `CYGPKG_DEVS_ETH_ARM_IXDP425_I82559`, is responsible for configuring this generic driver to the IXDP425 hardware. This driver is also loaded automatically when configuring for the IXDP425 target.

IDE support is available to support most PCI IDE controllers. Separate support is also available to support CompactFlash cards fitted to an optional daughterboard, in True IDE mode. These features are described in the IXP4xx processor HAL documentation.

Tools

The IXDP425 support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-elf-gcc version 3.4.4, arm-elf-gdb version 6.3, and binutils version 2.15.

Name

Setup — Setting up the IXDP425 board

Overview

In a typical development environment, the IXDP425 board boots from the parallel NOR Flash and runs the RedBoot ROM monitor directly. Applications are then downloaded into RAM and run directly on the board using the command line interface, or for standalone applications, via the debugger **arm-eabi-gdb**. Alternatively applications can be stored in Flash to be subsequently loaded into RAM for execution. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot running from ROM	`redboot_ROM.ecm`	`redboot_ROM.bin`
RAM	RedBoot running from RAM	`redboot_RAM.ecm`	`redboot_RAM.bin`
ROMRAM	RedBoot running from RAM, but contained in the board's flash boot sector	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`
ROM_CFIDE	Same as ROM, but with additional CompactFlash IDE and FAT FS support	`redboot_ROM_CFIDE.ecm`	`redboot_ROM_CFIDE.bin`
ROMRAM_CFIDE	Same as ROMRAM, but with additional CompactFlash IDE and FAT FS support	`redboot_ROMRAM_CFIDE.ecm`	`redboot_ROMRAM_CFIDE.bin`
ROMLE	RedBoot running from ROM configured for little-endian operation	`redboot_ROMLE.ecm`	`redboot_ROMLE.bin`
RAMLE	RedBoot running from RAM configured for little-endian operation	`redboot_RAMLE.ecm`	`redboot_RAMLE.bin`
ROMRAMLE	RedBoot running from RAM and configured for little-endian operation, but contained in the board's flash boot sector	`redboot_ROMRAMLE.ecm`	`redboot_ROMRAMLE.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports ethernet communication and flash management.

If the ROM version is to be chosen, then the RAM version is provided to allow for updating the resident RedBoot image in Flash. The ample provision of RAM memory on the board allows the ROMRAM version of RedBoot to be used instead of the standard ROM version which executes directly from Flash.

Initial Installation

Installation with a Flash programmer

This approach to initial installation may be used if a Flash device programmer is available. The IXDP425 Flash is socketed at U22. Although the supplied Flash part is an Intel StrataFlash 28F128J3, any 28FxxxJ3 part may be substituted - RedBoot will use the Common Flash Interface (CFI) to determine the Flash device geometry.

In this mode, the ROM mode RedBoot is programmed into the boot flash at offset 0x00000000.

Installation via JTAG

A JTAG device may also be used to perform initial programming. Some JTAG devices have in-built capabilities that permit programming of the Flash part. Other JTAG devices are able to load a RAM RedBoot image into SDRAM, from where a ROM RedBoot image can then in turn be loaded and then programmed.

If using a JTAG device that supports direct programming of the Flash part, the Flash is usually located at 0x50000000 in the CPU memory map, assuming the JTAG device initialisation has not remapped it elsewhere. It will usually need to first unlocked and then erased before programming.

For other JTAG devices, to load a RAM RedBoot image into SDRAM it will first be required to initialise the memory interface, and in particular configure the SDRAM controller. Consult your JTAG device documentation on how to access IXP425 registers.

One example of a JTAG device capable of direct programming of Flash is the Abatron BDI2000, and in the following sections are the steps required to program RedBoot using it.

Preparing the Abatron BDI2000 JTAG debugger

The BDI2000 must first be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. The following steps should be followed:

1. Prepare a PC to act as a host PC and start a TFTP server on it.

2. Connect the Abatron BDI2000 JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the BDI2000.

3. Install the Abatron BDI2000 bdiGDB support software on the host PC.

4. Confirm that the XScale firmware is resident in the BDI2000. For example, using the **bdisetup** utility:

   ```
   $ bdisetup -v -s
   BDI Type : BDI2000 Rev.C (SN: xxxxxxxx)
   Loader   : V1.05
   Firmware : V1.08 bdiGDB for XScale
   Logic    : V1.03 XScale
   MAC      : 00-0c-01-96-64-92
   IP Addr  : 192.168.7.220
   Subnet   : 255.255.255.0
   Gateway  : 192.168.7.1
   Host IP  : 192.168.7.9
   Config   : /ixdp425.cfg
   ```

   To upload firmware if needed, follow the procedures in the BDI2000 manual, for example using the **bdisetup** utility:

   ```
   $ bdisetup -u -p/dev/ttyS0 -b57 -aGDB -tXSCALE
   Connecting to BDI loader
   Erasing CPLD
   Programming firmware with ./b20xscgd.108
   Erasing firmware flash ....
   Erasing firmware flash passed
   Programming firmware flash ....
   Programming firmware flash passed
   Programming CPLD with ./xscjed21.103
   ```

5. Locate the file `ixdp425.cfg` within the BDI2000 software installation.

6. Locate the file `regIXP425.def` within the installation of the BDI2000 bdiGDB support software.

7. Place the `ixdp425.cfg` file in a location on the PC accessible to the TFTP server. Later you will configure the BDI2000 to load this file via TFTP as its configuration file.

8. Similarly place the file `regIXP425.def` in a location accessible to the TFTP server.

9. Open `ixdp425.cfg` in an editor such as emacs or notepad and if necessary adjust the path of the `regIXP425.def` file in the `[REGS]` section to match its location relative to the TFTP server root. Also comment out with a ';' the IP line in the `[HOST]` section, or update it to refer to the development PC.

10. Install and configure the Abatron BDI2000 in line with the bdiGDB instruction manual. Configure the BDI2000 to use the `ixdp425.cfg` configuration file at the appropriate point of this process. For example, using the **bdisetup** utility:

```
$ bdisetup -c -p/dev/ttyS0 -b57 -i192.168.7.220 -h192.168.7.9 -m255.255.255.0 -g192.168.7.1 -f/ixdp425.cfg
Connecting to BDI loader
Writing network configuration
Configuration passed
```

    The above command uses the first serial port at 57,600 baud to set the BDI2000's IP address to 192.168.7.220, its default TFTP host to 192.168.7.9, the network mask to 255.255.255.0, the default gateway to 192.168.7.1, and the configuration file to load to `/ixdp425.cfg`.

Preparing the IXDP425 board for programming

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the JTAG device.

1. First you must connect a straight through DB9 serial cable between the high speed serial port labelled UART0 on the board and a serial port on the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** or HyperTerminal. Set the communication parameters to 115200 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

3. If using a PCI ethernet card, connect the board to your host PC's LAN with an Ethernet cable.

4. If using a PCI ethernet card, you may need to designate the ethernet interface with a new Ethernet MAC address. The RedBoot binary image contains a default address, but each board requires its own unique address. It is advisable to mark each board with its programmed MAC address for future identification.

5. Connect the board to the BDI2000 using a 20-pin ARM/Xscale cable from the JTAG/ICE interface connector (J12) to the Target A port on the BDI2000.

6. Power up the IXDP425 board. You should see the hex display and various LEDs illuminate.

7. Connect to the BDI2000's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see usage information followed by the prompt:

```
Core#0>
```

8. Confirm correct connection with the BDI2000 with the **reset halt** command as follows:

```
Core#0> reset halt
- TARGET: processing reset request
- TARGET: BDI asserts RESET and TRST
- TARGET: BDI removed TRST
- TARGET: Bypass check: 0x000000001 => 0x00000001
- TARGET: JTAG exists check passed
- Core#0: ID code is 0x19274013
- Core#0: BDI sets hold_rst and halt mode
- TARGET: BDI removes RESET
- Core#0: BDI sets hold_rst and halt mode again
- Core#0: BDI loads debug handler to mini IC
- Core#0: BDI clears hold_rst
- TARGET: resetting target passed
- TARGET: processing target startup ....
- TARGET: processing target startup passed
Core#0>
```

9. Locate the `redboot_ROM.bin` image within the `loaders` subdirectory of the base of the eCos installation.

10. Copy the `redboot_ROM.bin` file into a location on the host computer accessible to its TFTP server.

Using the BDI2000 to directly program RedBoot into Flash

As previously mentioned, there are two methods of programming a RedBoot image into the parallel NOR Flash via JTAG, depending on the capabilities of the JTAG device. The BDI2000 supports direct programming of the Flash device and so that is the approach described here.

This is a three stage process. The relevant Flash blocks must first be unlocked, then erased, and finally programmed. This can be accomplished with the following steps:

1. Connect to the BDI2000 telnet port as before.

2. Use the following commands in the BDI2000 telnet session to unlock and then erase the relevant Flash blocks that will contain RedBoot.

```
Core#0>unlock 0x50000000 0x20000 4
Unlocking flash at 0x50000000
Unlocking flash at 0x50020000
Unlocking flash at 0x50040000
Unlocking flash at 0x50060000
Unlocking flash passed
Core#0>erase 0x50000000 0x20000 4
Erasing flash at 0x50000000
Erasing flash at 0x50020000
Erasing flash at 0x50040000
Erasing flash at 0x50060000
Erasing flash passed
```

3. Program the RedBoot image into Flash with the following command, replacing *`/RBPATH`* with the location of the redboot_ROM.bin file relative to the TFTP server root directory:

```
Core#0>prog 0x50000000 /RBPATH/redboot_ROM.bin bin
Programming /RBPATH/redboot_ROM.bin , please wait ....
Programming flash passed
Core#0>
```

   This operation can take some time.

The RedBoot installation is now complete. This can be tested by powering off the board, disconnecting the JTAG, and then powering on the board again. The RedBoot banner should be visible on the serial port.

```
flash configuration checksum error or invalid key
```

This message does not indicate a problem at this stage of installation. It just means that RedBoot Flash configuration has yet to be performed, as described below.

If it proves necessary to re-install RedBoot, this may be achieved by repeating the above process. Alternatively, a new image may be downloaded and programmed into flash more directly using RedBoot's own commands. See the RedBoot documentation for details.

RedBoot Flash configuration

The following steps describe how to initialize RedBoot's Flash configuration. This must be performed when using a RAM RedBoot to program Flash, but is also applicable to initial configuration of a ROM or ROMRAM RedBoot loaded using JTAG or with a Flash device programmer.

1. Use the following command to initialize RedBoot's Flash Information System (FIS):

   ```
   RedBoot> fis init -f
   About to initialize [format] FLASH image system - continue (y/n)? y
   *** Initialize FLASH Image System
   ... Erase from 0x50080000-0x50fdffff: .............................................................................
   ... Unlocking from 0x50fe0000-0x50ffffff: .
   ... Erase from 0x50fe0000-0x50ffffff: .
   ... Program from 0x0ffd0000-0x0fff0000 to 0x50fe0000: .
   ... Locking from 0x50fe0000-0x50ffffff: .
   RedBoot>
   ```

2. Now configure RedBoot's Flash configuration with the command:

   ```
   RedBoot> fconfig -i
   ```

   If a BOOTP/DHCP server is not available, then IP configuration may be set manually. The default server IP address can be set to a PC that will act as a TFTP host for future RedBoot load operations, or may be left unset. The following gives an example configuration:

   ```
   RedBoot> fconfig -i
   Initialize non-volatile configuration - continue (y/n)? y
   Run script at boot: false
   Use BOOTP for network configuration: false
   Gateway IP address: 192.168.7.11
   Local IP address: 192.168.7.222
   Local IP address mask: 255.255.255.0
   Default server IP address: 192.168.7.9
   Console baud rate: 115200
   DNS server IP address: 192.168.7.11
   GDB connection port: 9000
   Force console for special debug messages: false
   Network debug at boot time: false
   Update RedBoot non-volatile configuration - continue (y/n)? y
   ... Unlocking from 0x50fe0000-0x50ffffff: .
   ... Erase from 0x50fe0000-0x50ffffff: .
   ... Program from 0x0ffd0000-0x0fff0000 to 0x50fe0000: .
   ... Locking from 0x50fe0000-0x50ffffff: .
   RedBoot>
   ```

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of RedBoot for the IXDP425 are:

```
$ mkdir redboot_ixdp425_romram
$ cd redboot_ixdp425_romram
$ ecosconfig new ixdp425 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/xscale/ixdp425/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`.

The other versions of RedBoot - RAM, ROMRAM or the little-endian variants - may be similarly built by choosing the appropriate alternative .ecm file.

Name

Configuration — Platform-specific Configuration Options

Overview

The IXDP425 platform HAL package is loaded automatically when eCos is configured for the `ixdp425` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Configuring for the `ixdp425` target also causes the IXP4xx processor HAL to be included. Many configuration options in relation to the peripheral IXP425 devices including serial UARTs, clocks, etc. are described in the IXP4xx processor HAL documentation, which should be referred to.

Startup

The platform HAL package supports three separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default a standalone application will use the eCos virtual vectors mechanism to obtain certain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into flash at physical address 0x50000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

ROMRAM
: This startup type can be used for finished applications which will be programmed into flash at physical location 0x50000000. However, when it starts up, the application will first copy itself to RAM at virtual address 0x00000000 and then run from there. RAM is generally faster than flash memory, so the program will run more quickly than a ROM-startup application. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The IXDP425 is supplied by default with a 16Mbyte Intel StrataFlash 28F128J3 parallel Flash device.

The `CYGPKG_DEVS_FLASH_STRATA_V2` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the IXDP425 board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

The device is located in a socket on a board labelled both U22 and "BOOT ROM", and can be replaced with compatible Intel StrataFlash 28FxxxJ3 parts. RedBoot will use the Common Flash Interface (CFI) to determine the Flash device geometry.

Ethernet Driver

The IXDP425 development kit includes an Intel i82559-based PCI Ethernet NIC. The `CYGPKG_DEVS_ETH_INTEL_I82559` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_ARM_IXDP425_I82559` package contains definitions that customize the driver to the IXDP425 board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

The IXDP425 is also supplied with Network Processing Engine (NPE) modules, however these are not supported in this release.

CompactFlash True IDE Driver

The IXP425 variant HAL includes support for CompactFlash IDE devices accessed in True IDE mode directly on the IXP425 expansion bus. This is described further in the IXP4xx processor HAL documentation.

However note that the use of CS2 conflicts with use of the hex display, which also operates from the CS2 chip select, and so the use of the hex display by eCos/RedBoot will be disabled if CF IDE support is enabled. In addition it is expected that the hex display will show random unpredictable values during CF IDE accesses.

Other IXP425 peripherals

Details in relation to on-chip IXP425 peripherals such as PCI IDE driver, watchdog support, serial support, clocks, interrupts and so forth are described further in the IXP4xx processor HAL documentation.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. There are just two flags specific to this port:

`-mcpu=xscale`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=xscale` is the correct option for the XScale IXP425 CPU.

`-mbig-endian`
: The arm-eabi-gcc compiler will compile all code into big endian (most significant byte first) format. This is the default endianness for this port. Without this flag, arm-eabi-gcc generates little endian code. You must ensure your application is built for the same endianness as RedBoot.

  Although RedBoot endianness can be controlled by enabling or disabling the configuration option `CYGHWR_HAL_ARM_BIGENDIAN`, it is more convenient to use the minimal configuration files (.ecm files) as described earlier.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mthumb-interwork`
: This option allows programs to be created that mix ARM and Thumb instruction sets. Without this option, some memory can be saved. This option should be used if -mthumb is used. The best way to build eCos with Thumb interworking is to enable the configuration option `CYGBLD_ARM_ENABLE_THUMB_INTERWORK`.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded RAM applications, or even applications resident in ROM, including RedBoot.

Debugging of ROM applications is only possible if using hardware breakpoints. The XScale only supports four such hardware breakpoints - two for instruction breakpoints and two for data breakpoints, and so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

Abatron BDI2000 notes

On the Abatron BDI2000, the `ixdp425.cfg` file that is included with the BDI2000 software should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the SDRAM controller.

The `ixdp425.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. Edit this file if you wish to use software break points, and remember to use the **boot** command on the BDI2000 command line interface to make the changes take effect.

On the BDI2000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the bdiGDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI2000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI2000 is powered up, the target will always run the initialization section of the `ixdp425.cfg` file (which configures the SDRAM among other things), and halts the target. This behavior is repeated with the **reset halt** command.

If the board is reset when in '**reset halt**' mode (either with the '**reset halt**' or '**reset**' commands, or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. If a ROMRAM RedBoot is resident in Flash, it will be run.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the IXDP425 hardware, and should be read in conjunction with that specification. The IXDP425 platform HAL package complements the ARM architectural HAL, the XScale variant HAL and the IXP425 processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM or ROMRAM startup, the HAL will perform additional initialization, setting up the external RAM and programming the various internal registers. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

LED Codes

Unless the Compact Flash IDE configuration option is selected, RedBoot uses the 4 digit LED display to indicate status during board initialization. Possible codes are:

LED   Actions

    Power-On/Reset
        Set the CPSR
        Enable coprocessor access
        Drain write and fill buffer
        Setup expansion bus chip selects
1001
        Enable Icache
1002
        Initialize SDRAM controller
1003
        Switch flash (CS0) from 0x00000000 to 0x50000000
1004
        Copy MMU table to RAM
1005
        Setup TTB and domain permissions
1006
        Enable MMU
1007
        Enable DCache
1008
        Enable branch target buffer
1009
        Drain write and fill buffer
        Flush caches
100A
        Start up the eCos kernel or RedBoot
0001

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Flash

This is located at address 0x50000000 of the physical memory space. At initialization, the HAL uses the MMU to retain it at virtual address 0x50000000, while also providing an uncached mapping at 0xB0000000 and a data coherent mapping at 0xA0000000.

SDRAM

This is located at address 0x00000000 of the physical memory space. The HAL uses the MMU to retain this at virtual address 0x00000000, along with an alias at 0x10000000. The same memory is also accessible uncached at virtual location 0x20000000 for use by devices, and at 0x30000000 for data coherent access. The first 32 bytes are used for hardware exception vectors. The next 32 bytes are used for the VSR table and the next 256 bytes are normally used for the eCos virtual vectors, allowing RAM-based applications to use services provided by the ROM monitor. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x4000 to 0x8000. For ROM/ROMRAM startup, all remaining SDRAM is available. For RAM startup, available RAM starts at virtual location 0x00080000, with the bottom 512 kilobytes reserved for use by RedBoot.

On-chip Peripheral Registers

There are several regions in the memory map devoted to on-chip peripherals or on-chip device controllers. When the MMU is enabled, all these regions are set up with a direct, uncached and unbuffered mapping so that these registers remain accessible at their physical locations.

As such, the address space for the AHB Queue Manager (AQM) resides at 0x60000000; the PCI controller resides at 0xC0000000; the expansion bus controller configuration registers reside at 0xC4000000; the SDRAM controller configuration registers resides at 0xCC000000; and all remaining IXP425 on-chip peripherals reside in the block at 0xC8000000. This latter block includes peripheral control for on-chip high-speed and console UARTs, internal bus performance monitoring unit, interrupt controller, GPIO controller, timers, WAN/Voice and Ethernet NPEs, Ethernet MACs, and the USB controller.

Off-chip Peripherals

RedBoot and eCos access the SDRAM, parallel NOR flash, and hex display on CS2 (mapped to 0x52000000). In addition a CompactFlash True IDE mode disk may be accessed via the expansion bus on CS1/CS2 (0x51000000/0x52000000), although the hex display is not usable in that case.

In addition a 64MiB PCI window is mapped to 0x48000000, for communication with devices on the PCI bus.

RedBoot and eCos do not currently make any use of any other off-chip peripherals present on the IXDP425 board.

Memory map summary

The virtual memory maps in this section use a C, B, and X column to indicate the caching policy for the region.

```
X C B  Description
- - -  ---------------------------------------------
0 0 0  Uncached/Unbuffered
0 0 1  Uncached/Buffered
0 1 0  Cached/Buffered    Write Through, Read Allocate
```

```
0 1 1  Cached/Buffered    Write Back, Read Allocate
1 0 0  Invalid - not used
1 0 1  Uncached/Buffered  No write buffer coalescing
1 1 0  Mini DCache - Policy set by Aux Ctl Register
1 1 1  Cached/Buffered    Write Back, Read/Write Allocate

Virtual Address   Physical Address  XCB  Size (MB)  Description
   0x00000000       0x00000000      010     256     SDRAM (cached)
   0x10000000       0x00000000      010     256     SDRAM (alias)
   0x20000000       0x00000000      000     256     SDRAM (uncached)
   0x30000000       0x00000000      010     256     SDRAM (cached, DC)
   0x48000000       0x48000000      000      64     PCI Data
   0x50000000       0x50000000      010      16     Flash (CS0, cached)
   0x51000000       0x51000000      000      16     CF True IDE mode chip select #0 (CS1)
   0x52000000       0x52000000      000      16     Hex display/CF True IDE mode chip select #1 (CS2)
   0x53000000       0x53000000      000      80     CS3 - CS7
   0x60000000       0x60000000      000      64     Queue Manager
   0xA0000000       0x50000000      010      16     Flash (CS0, cached, DC)
   0xB0000000       0x50000000      000      16     Flash (CS0, uncached)
   0xC0000000       0xC0000000      000       1     PCI Controller
   0xC4000000       0xC4000000      000       1     Exp. Bus Config
   0xC8000000       0xC8000000      000       1     Misc IXP425 IO
   0xCC000000       0xCC000000      000       1     SDRAM Config
```

Other Issues

The IXDP425 platform HAL does not affect the implementation of other parts of the eCos HAL specification. The XScale variant HAL, the IXP4xx processor HAL documentation and the ARM architectural HAL documentation should be consulted for further details.

Chapter 271. Altera Hard Processor System Support

Name

Support for the Altera HPS — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Hard Processor System (HPS) present on the Cyclone V and Arria 10 FPGAs. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, Cortex-A variant HAL and the platform HAL. It provides functionality common to all HPS-based implementations.

This support is found in the eCos package located at `packages/hal/arm/cortexa/altera_hps` within the eCos source repository.

The Altera HPS HAL package is loaded automatically when eCos is configured for an HPS-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the HPS within this processor HAL package include:

- HPS-specific hardware definitions
- Interrupt controller selection
- Timers
- Serial UART configuration
- I²C two wire interface configuration
- Pin Configuration and GPIO Support

Support for the on-chip QSPI device, SPI NOR flash, interrupt-driven serial, watchdog and wallclock (RTC) features of the HPS are also present and can be found in separate packages, outside of this processor HAL.

Support for SMP operation of the two Cortex-A9 CPUs in the HPS is available, although debugging support is restricted to use of an external JTAG debugger. The HAL does not contain support for the Cortex-A's NEON SIMD engine.

Name

HPS Hardware Definitions — Details on obtaining hardware definitions for HPS

Register definitions

The file `<cyg/hal/altera_hps.h>` can be included from application and eCos package sources to provide definitions related to HPS subsystems. These include base addresses for various devices and register definitions for HPS-specific devices such as the system manager, reset manager, pin multiplexing and GPIO. The registers for various devices, such as QSPI, I²C, Ethernet, and the UARTs are defined in the drivers for those devices. The interrupt controller and system timer are implemented in the Cortex-A HAL. This file will normally be included automatically if `<cyg/hal/hal_io.h>` is included, which is the preferred way of getting these definitions.

Initialization Helper Macros

The file `<cyg/hal/altera_hps_init.inc>` contains definitions of helper macros which may be used by HPS platform HALs in order to initialize common subsystems without excessive duplication between these platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary. NOTE: At present, the only extant HPS port relies on the Altera preloader to initialize the PLLs and memory controller, so these macros currently largely contain Cortex-A-generic setup only.

Name

GIC Interrupt Controller — Advanced Interrupt Controller Definitions And usage

Interrupt controller definitions

The file `<cyg/hal/var_ints.h>` (located at `hal/arm/cortexa/altera_hps/*VERSION*/include/var_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs.

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt Controller Functions

The HPS uses a standard ARM Generic Interrupt Controller (GIC), which is implemented in the Cortex-A HAL. The Cortex-A HAL exports the standard interrupt vector management functions. The `hal_IRQ_handler` queries the IRQ status register to determine the interrupt cause. Functions `hal_interrupt_mask` and `hal_interrupt_unmask` enable or disable interrupts within the interrupt controller.

Interrupts are configured in the `hal_interrupt_configure` function. Refer to the HPS documentation for any limitations as to what types of signal can be detected.

The `hal_interrupt_eoi` function performs End-Of-Interrupt processing and is called automatically by the architecture HAL. The `hal_interrupt_acknowledge` function is intended to acknowledge an interrupt, although for the GIC it is a NUL function since the necessary work it handled by the EOI function.

The `hal_interrupt_set_level` is used to set the priority level of the supplied interrupt within the GIC. Priorities may range between 0 and 255, with lower values mapping to higher priority. The GIC in the HPS only implements the top 5 bits of the priority value, so there are actually 32 distinct priority levels available.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (`HAL_INTERRUPT_MASK` et al) or preferably the kernel or driver APIs should be used to control interrupts.

Name

Timers — Use of on-chip timers

System Clock

The eCos kernel system clock is implemented using the private timer of CPU0. By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to `CYGNUM_HAL_RTC_DENOMINATOR`, then the configuration option `CYGNUM_HAL_RTC_NUMERATOR` may also be adjusted. However, if this is done then `CYGNUM_HAL_RTC_PERIOD` must be changed to provide the described clock frequency.

The same Timer is also used to implement the HAL microsecond delay function, `HAL_DELAY_US`. This is used by some device drivers, and in non-kernel configurations, such as RedBoot, where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

If SMP is enabled, then the HAL switches to using the global timer. This is because it is necessary to read the timer from any CPU, not just from CPU0.

Timer-based profiling support

If the gprof package, `CYGPKG_PROFILE_GPROF`, is included in the configuration, then the MPCore global timer is reserved for use by the profiler.

Profiling is only supported in single-core systems. If SMP is enabled then the profiling timer is disabled. This is because the SMP scheduler needs to use the global timer rather than the private timers. Additionally, the `CYGPKG_PROFILE_GPROF` package is not SMP-aware and the results would, in any case, be invalid.

If profiling is wanted, then it is recommended that a hardware tool like the Lauterbach Trace32 debugger be used.

Name

Serial UARTs — Configuration and Implementation Details of Serial UART Support

Overview

Support is included in this processor HAL package for the on-chip serial UART devices.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 57600,8,N,1 with no flow control.

HAL Diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems. This can operate on any port, according to the configuration settings.

There are several configuration options usually found within a platform HAL which affect the use of this support in the HPS processor HAL. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL` selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, `diag_printf()`. The CDL option `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL` selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the `CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS` CDL option in the HAL. Baud rates for each channel are set with the `CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` and `CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD` options.

Interrupt-driven Serial Driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (`CYGPKG_IO_SERIAL`). This support can be enabled on any port.

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent Ctrl-C operation when debugging.

The main part of this driver is contained in the generic `CYGPKG_IO_SERIAL_GENERIC_16X5X` package. The package `CYGPKG_IO_SERIAL_ARM_ALTERA_HPS` contains definitions that configure the generic driver for the HPS. That driver package should also be consulted for documentation and configuration options. The driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Support for hardware flow control and modem control lines is present in the driver, but should only be enabled if these control signals are brought out to the physical serial port.

Name

Multimedia Card Interface (MMC/SD) Driver — Using MMC/SD cards with block drivers and filesystems

Overview

The MultiMedia Card Interface (MMC/SD) driver in this processor HAL package allows use of MultiMedia Cards (MMC cards) and Secure Digital (SD) flash storage cards within eCos, exported as block devices. This makes them suitable for use as the underlying devices for filesystems such as FAT.

The HPS architecture only has support for one SDMMC controller.

Configuration

This driver provides the necessary support for the generic MMC bus layer within the `CYGPKG_DEVS_DISK_MMC` package to export a disk block device. The disk block device is only available if the generic disk I/O layer found in the package `CYGPKG_IO_DISK` is included in the configuration.

The block device may then be used as the device layer for a filesystem such as FAT. Example devices are "`/dev/mmcsd0/1`" to refer to the first partition on the card, or "`/dev/mmcsd0/0`" to address the whole device including potentially the partition table at the start.

The driver may be forcibly disabled within this processor HAL package with the configuration option `CYGPKG_HAL_ARM_CORTEXA_ALTERA_HPS_MMC`.

If the driver is enabled, the following options are available to control it:

`CYGPKG_HAL_ARM_CORTEXA_ALTERA_HPS_MMC_DMA_DESCRIPTORS`

> This option specifies the number of descriptors in the DMA ringbuffer. This value can be tuned if needed to optimise performance vs the memory footprint.

`CYGIMP_HAL_ARM_CORTEXA_ALTERA_HPS_MMC_INTMODE`

> This indicates that the driver should operate in interrupt-driven mode if possible. This is enabled by default if the eCos kernel is enabled. Note though that if the driver finds that global interrupts are off when running, then it will fall back to polled mode even if this option is enabled. This allows for use of the MMC/SD driver in an initialisation context.

`CYGNUM_HAL_ARM_CORTEXA_ALTERA_HPS_MMC_INT_PRI`

> This is the MMC/SD bus interrupt priority. It may range from 0 to 255.

`CYGPKG_HAL_SDMMC_DWC_INSTRUMENTATION`

> When the `CYGPKG_KERNEL_INSTRUMENTATION` support is configured, this option allows control over whether SDMMC device driver instrumentation is generated. Sub-options are provided to control which event code instrumentation records are generated. Normally this option is only useful when developing/debugging the driver; but it can be used to monitor performance of the driver in a running system.

Usage Notes

The driver will detect the appropriate card sizes.

The MMC/SD bus layer will parse partition tables, although it can be configured to allow handling of cards with no partition table.

This driver implements multi-sector I/O operations. If you are using the FAT filesystem, see the generic MMC/SD driver documentation which describes how to exploit this feature when using FAT.

Note

Any cards removed from a socket before an explicit unmounting or a `sync()` call to flush filesystem buffers will likely result in a corrupted filesystem on the removed card.

Name

I2C Interface — Using I²C devices

Overview

The I²C driver in the `CYGPKG_DEVS_I2C_DWI2C` supports the use of I²C devices within eCos. Access to the driver will be via the standard I²C interface subsystem.

This driver provides support for all four I²C busses available on the HPS. The number of interfaces supported is defined by the platform HAL.

Configuration

The HAL contains the following configuration options for each the I²C busses:

`CYGINT_HAL_ARM_CORTEXA_ALTERA_HPS_I2C_BUSX`

> This interface controls the inclusion of support for I²C bus *X*. This will normally be implemented by the platform HAL to indicate that there are I²C devices attached to the given bus, or that the SCL and SDA lines are routed to an external connector.

`CYGNUM_HAL_ARM_CORTEXA_ALTERA_HPS_I2C_BUSX_CLOCK`

> This is the I²C bus *X* clock speed in Hz. Frequencies of either 100kHz or 400kHz can be chosen, the latter sometimes known as fast mode.

`CYGNUM_HAL_ARM_CORTEXA_ALTERA_HPS_I2C_BUSX_INTR_PRI`

> This is the I²C bus *X* interrupt priority. It may range from 1 to 255; the default of 128 places it in the centre of the priority range.

Usage Notes

The design of the I²C device does not make it possible to start a new bus transfer without also sending a START condition on the bus. This means that divided transactions are not possible. A divided transaction would look like this:

```
    cyg_i2c_transaction_begin(&cyg_aardvark_at24c02);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 1, tx_buf1, 1, 0);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 0, tx_buf2, 2, 0);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 0, tx_buf3, 6, 1);
    cyg_i2c_transaction_end(&cyg_aardvark_at24c02);
```

In this transaction a START and one byte are sent from tx_buf1, then 2 bytes of data from tx_buf2, finishing with 6 bytes from tx_buf3 followed by a STOP. The device will not allow the tx_buf2 and tx_buf3 transfers to happen without also sending a START. The only solution to this is to combine the data into a single buffer and perform a single transfer:

```
    memcpy( tx_buf, tx_buf1, 1);
    memcpy( tx_buf+1, tx_buf2, 2);
    memcpy( tx_buf+3, tx_buf3, 6);
    cyg_i2c_tx(&cyg_aardvark_at24c02, tx_buf, 9);
```

Name

Pin Configuration and GPIO Support — Use of pin configuration and GPIO

Synopsis

#include <cyg/hal/hal_io.h>

`pin = **CYGHWR_HAL_HPS_PINMUX**(*reg*, *func*);`

CYGHWR_HAL_HPS_PINMUX_SET (*pin*);

pin = **CYGHWR_HAL_HPS_GPIO**(*line*, *mode*);

CYGHWR_HAL_HPS_GPIO_SET (*pin*);

CYGHWR_HAL_HPS_GPIO_OUT (*pin*, *val*);

CYGHWR_HAL_HPS_GPIO_IN (*pin*, *val*);

Description

The HPS HAL provides a number of macros to support the encoding of pin multiplexing information and GPIO pin modes into 32 bit descriptors. This is useful to drivers and other packages that need to configure and use different lines for different devices. Because there is not a simple correspondence between pin multiplexing information and GPIO line numbers, these two things are treated separately.

Pin Multiplexing

A pin multiplexing descriptor is created with `CYGHWR_HAL_HPS_PINMUX( reg, func )` which takes the following arguments:

reg This identifies the PINMUX register which controls this pin. This consists of the name of a pin group parameterized by the pin within that group.

func This defines the function code to program into the PINMUX register. There is no systematic consistency between functions and function codes, and the same function for a pin may be represented by different codes in different PINMUX registers. You should refer to the HPS documentation for the correct value to be used here.

The following examples show how this macro may be used:

```
// UART0 RX line is controlled by register GENERALIO(17), function 2 = UART0.RX
#define CYGHWR_HAL_HPS_UART0_RX                 CYGHWR_HAL_HPS_PINMUX(GENERALIO(17),2)

// GPIO 41 is controlled by register FLASHIO(5), function 0 = GPIO 41
#define CYGHWR_HAL_HPS_LED0                     CYGHWR_HAL_HPS_PINMUX(FLASHIO(5),0)
```

The macro `CYGHWR_HAL_HPS_PINMUX_SET( pin )` sets the pin multiplexing setting according to the descriptor passed in.

GPIO Support

A GPIO descriptor is created with `CYGHWR_HAL_HPS_GPIO( line, mode)` which takes the following arguments:

line This gives the GPIO line number, between 0 and 70.

mode This defines whether this is an input or an output pin, and whether it is de-bounced. It may take the values `IN` or `OUT`, or `INDB` for de-bounced input. GPIO lines 48 to 70 can take their input from one of two pins; modes `IN_ALT` and `INDB_ALT` cause the GPIO line to be connected to the alternate input pin.

Additionally, the macro `CYGHWR_HAL_HPS_GPIO_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used.

The following examples show how this macro may be used:

```
// LED 0 is at GPIO41, bank 1 bit 13, output mode
#define CYGHWR_HAL_HPS_LED0_GPIO                CYGHWR_HAL_HPS_GPIO( 41, OUT )
```

The remaining macros all take a GPIO pin descriptor as an argument. `CYGHWR_HAL_HPS_GPIO_SET` configures the pin according to the descriptor and must be called before any other macros. `CYGHWR_HAL_HPS_GPIO_OUT` sets the output to the value of the least significant bit of the *val* argument. The *val* argument of `CYGHWR_HAL_HPS_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

Chapter 272. Broadcom IProc Support

Name

Support for the Broadcom IProc — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the IProc subsystem present on some Broadcom devices. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, Cortex-A variant HAL and the platform HAL. It provides functionality common to all IProc-based implementations.

This support is found in the eCos package located at `packages/hal/arm/cortexa/broadcom_iproc` within the eCos source repository.

The Broadcom IProc HAL package is loaded automatically when eCos is configured for an IProc-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the IProc within this processor HAL package include:

- IProc-specific hardware definitions
- Interrupt controller selection
- Timers
- Serial UART configuration

Support for the on-chip QSPI device, SPI NOR flash and interrupt-driven serial are also present and can be found in separate packages, outside of this processor HAL.

Note that the HAL does not currently contain support for the Cortex-A's NEON SIMD engine.

Name

IProc Hardware Definitions — Details on obtaining hardware definitions for IProc

Register definitions

The file `<cyg/hal/broadcom_iproc.h>` can be included from application and eCos package sources to provide definitions related to IProc subsystems. These include base addresses for various devices and register definitions for IProc-specific devices such as the Clock Reset Manager and Device Management Unit. The registers for various devices, such as QSPI and the UARTs, are defined in the drivers for those devices. The interrupt controller and system timer are implemented in the Cortex-A HAL. This file will normally be included automatically if `<cyg/hal/hal_io.h>` is included, which is the preferred way of getting these definitions.

Initialization Helper Macros

The file `<cyg/hal/broadcom_iproc_init.inc>` contains definitions of helper macros which may be used by IProc platform HALs in order to initialize common subsystems without excessive duplication between these platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary.

Name

GIC Interrupt Controller — Advanced Interrupt Controller Definitions and Usage

Interrupt Controller Definitions

The file `<cyg/hal/var_ints.h>` (located at `hal/arm/cortexa/broadcom_iproc/`*`VERSION`*`/include/var_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs.

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt Controller Functions

The IProc uses a standard ARM Generic Interrupt Controller (GIC), which is implemented in the Cortex-A HAL. The Cortex-A HAL exports the standard interrupt vector management functions. The `hal_IRQ_handler` queries the IRQ status register to determine the interrupt cause. Functions `hal_interrupt_mask` and `hal_interrupt_unmask` enable or disable interrupts within the interrupt controller.

Interrupts are configured in the `hal_interrupt_configure` function. Refer to the IProc documentation for any limitations as to what types of signal can be detected.

The `hal_interrupt_eoi` function performs End-Of-Interrupt processing and is called automatically by the architecture HAL. The `hal_interrupt_acknowledge` function is intended to acknowledge an interrupt, although for the GIC it is a NUL function since the necessary work it handled by the EOI function.

The `hal_interrupt_set_level` is used to set the priority level of the supplied interrupt within the GIC. Priorities may range between 0 and 255, with lower values mapping to higher priority. The GIC in the IProc only implements the top 5 bits of the priority value, so there are actually 32 distinct priority levels available.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (`HAL_INTERRUPT_MASK` et al) or preferably the kernel or driver APIs should be used to control interrupts.

Name

Timers — Use of on-chip timers

System Clock

The eCos kernel system clock is implemented using the private timer of CPU0. By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to `CYGNUM_HAL_RTC_DENOMINATOR`, then the configuration option `CYGNUM_HAL_RTC_NUMERATOR` may also be adjusted. However, if this is done then `CYGNUM_HAL_RTC_PERIOD` must be changed to provide the described clock frequency.

The same Timer is also used to implement the HAL microsecond delay function, `HAL_DELAY_US`. This is used by some device drivers, and in non-kernel configurations, such as RedBoot, where this timer is needed for loading program images via X/Y-modem protocols and debugging. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Timer-based profiling support

If the gprof package, `CYGPKG_PROFILE_GPROF`, is included in the configuration, then the MPCore global timer is reserved for use by the profiler.

Name

Serial UARTs — Configuration and Implementation Details of Serial UART Support

Overview

Support is included in this processor HAL package for the on-chip serial UART devices.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 115200,8,N,1 with no flow control.

HAL Diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems. This can operate on any port, according to the configuration settings.

There are several configuration options usually found within a platform HAL which affect the use of this support in the IProc processor HAL. The CDL option CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, diag_printf(). The CDL option CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS CDL option in the HAL. Baud rates for each channel are set with the CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD and CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD options.

Interrupt-driven Serial Driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (CYGPKG_IO_SERIAL). This support can be enabled on any port.

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent Ctrl-C operation when debugging.

The main part of this driver is contained in the generic CYGPKG_IO_SERIAL_GENERIC_16X5X package. The package CYGPKG_IO_SERIAL_ARM_BROADCOM_IPROC contains definitions that configure the generic driver for the IProc. That driver package should also be consulted for documentation and configuration options. The driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option within the generic serial driver support package CYGPKG_IO_SERIAL is enabled in the configuration.

Support for hardware flow control and modem control lines is present in the driver, but should only be enabled if these control signals are brought out to the physical serial port.

Chapter 273. Broadcom BCM283X Processor Support

Name

Support for the Broadcom BCM283X Processor Family — Overview

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Broadcom BCM283X devices present on the Raspberry Pi boards. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor HAL package complements the ARM architectural HAL, Cortex-A variant HAL and the Raspberry Pi platform HAL. It provides functionality common to all BCM283X-based implementations.

This support is found in the eCos package located at `packages/hal/arm/cortexa/bcm283x` within the eCos source repository.

The BCM283X HAL package is loaded automatically when eCos is configured for any Raspberry Pi board. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Supported Hardware

Supported features of the BCM283X within this processor HAL package include:

- BCM283X-specific hardware definitions
- Interrupt Controller Support
- Timers
- Serial UART configuration
- I²C two wire interface configuration
- GPIO Support
- DMA Support

Support for I²C, SPI, USB, Ethernet, MMC/SD and interrupt-driven serial features of the BCM283X are also present and can be found in separate packages, outside of this processor HAL.

Support for SMP operation of the four Cortex-A CPUs in the BCM2836 and BCM2837 is available, although debugging support is restricted to use of an external JTAG debugger.

Name

Hardware Definitions — Details on obtaining hardware definitions for BCM283X

Register definitions

The file `<cyg/hal/bcm283x.h>` can be included from application and eCos package sources to provide definitions related to BCM283X subsystems. These include base addresses for various devices and register definitions for BCM283X-specific devices such as the interrupt controller, timers, mailboxes, DMA and GPIO. The registers for various devices, such as I²C, SPI, MMC/SD, and the UARTs are defined in the drivers for those devices. This file will normally be included automatically if `<cyg/hal/hal_io.h>` is included, which is the preferred way of getting these definitions.

Initialization Helper Macros

The file `<cyg/hal/bcm283x_init.inc>` contains definitions of helper macros which may be used by platform HALs in order to initialize common subsystems without excessive duplication between these platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary. NOTE: At present, the only extant BCM283X port relies on the GPU to initialize the PLLs and memory controller, so these macros currently largely contain Cortex-A-generic setup only.

Name

Interrupt Controller — Interrupt Controller Definitions and Usage

Interrupt Vector Assignments

The file `<cyg/hal/var_ints.h>` (located at `hal/arm/cortexa/bcm283x/`*`VERSION`*`/include/var_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs.

The BCM283X interrupt controller is somewhat unsystematic and in order to derive some efficiency from it, the eCos interrupt vector table is large and in some places sparse. Some secondary decoding is also performed to demultiplex some shared vectors. The following table shows the overall interrupt mapping scheme.

Range	**Description**
0..31	IRQ pending register 1
32..63	IRQ pending register 2
64..84	IRQ basic pending register
85..95	Unused, reserved for expansion
96..111	CPU0, per-CPU vectors
112..127	CPU1, per-CPU vectors
128..143	CPU2, per-CPU vectors
144..159	CPU3, per-CPU vectors
160..162	Auxiliary device vectors -- demultiplexed
163..216	GPIO pin vectors -- demultiplexed

Interrupt Controller Functions

The BCM283X HAL exports the standard interrupt vector management functions which are in turn called by the generic interrupt management macros.

The `hal_IRQ_handler()` function queries the IRQ pending registers to determine the interrupt cause. Functions `hal_interrupt_mask()` and `hal_interrupt_unmask()` enable or disable interrupts within the interrupt controller.

The BCM283X does not have any provision for prioritizing interrupts, setting their edge/level, per-vector CPU affinity, or even acknowledge individual vectors. So the functions `hal_interrupt_set_level`, `hal_interrupt_configure`, `hal_interrupt_set_cpu`, `hal_interrupt_get_cpu` and `hal_interrupt_acknowledge` are all empty functions.

The only available mechanism in the BCM283X for redirecting interrupts to different CPUs is to move all device interrupt to a given CPU. This does not match the model to which eCos has been implemented. So, all device interrupts are directed to CPU0, which cannot be changed. CPUs 1 to 3 only handle explicitly multi-core interrupts.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (`HAL_INTERRUPT_MASK` et al) or preferably the kernel or driver APIs should be used to control interrupts.

Name

Timers — Use of on-chip timers

System Clock

The eCos kernel system clock is implemented using the BCM283X System Timer device. By default, the system timer is programmed to interrupt once every 10ms, corresponding to a 100Hz clock. This can be changed with the configuration option `CYGNUM_HAL_RTC_DENOMINATOR` which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. The system timer is clocked at 1MHz, so there are limits on the accuracy of any frequency that is not a factor of 1000000.

The same timer is also used to implement the HAL microsecond delay function, `HAL_DELAY_US`. This is used by some device drivers, and in non-kernel configurations, such as RedBoot, where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

Timer-based Profiling Support

At present timer based profiling is not supported. This is mainly because the current profiling support is not SMP-aware.

Name

Serial UARTs — Configuration and Implementation Details of Serial UART Support

Overview

Support is included in this processor HAL package for the auxiliary mini UART device.

There are two forms of support: HAL diagnostic I/O; and a fully interrupt-driven serial driver. Unless otherwise specified in the platform HAL documentation, for all serial ports the default settings are 115200,8,N,1 with no flow control.

HAL Diagnostic I/O

This first form is polled mode HAL diagnostic output, intended primarily for use during debug and development. Operations are usually performed with global interrupts disabled, and thus this mode is not usually suitable for deployed systems.

There are several configuration options usually found within a platform HAL which affect the use of this support in the BCM283X processor HAL. The CDL option CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL selects the serial port channel to use as the console at startup time. This will be the channel that receives output from, for example, diag_printf(). The CDL option CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL selects the serial port channel to use for GDB communication by default. Note that when using RedBoot, these options are usually inactive as it is RedBoot that decides which channels are used. Applications may override RedBoot's selections by enabling the CYGSEM_HAL_VIRTUAL_VECTOR_CLAIM_COMMS CDL option in the HAL. Baud rates for each channel are set with the CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD and CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD options.

Interrupt-driven Serial Driver

The second form of support is an interrupt-driven serial driver, which is integrated into the eCos standard serial I/O infrastructure (CYGPKG_IO_SERIAL).

Note that it is not recommended to share this driver when using the HAL diagnostic I/O on the same port. If the driver is shared with the GDB debugging port, it will prevent Ctrl-C operation when debugging.

The main part of this driver is contained in the generic CYGPKG_IO_SERIAL_GENERIC_16X5X package. The package CYGPKG_IO_SERIAL_ARM_BCM283X contains definitions that configure the generic driver for the BCM283X. That driver package should also be consulted for documentation and configuration options. The driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option within the generic serial driver support package CYGPKG_IO_SERIAL is enabled in the configuration.

Support for hardware flow control is present in the driver, but should only be enabled if the RTS and CTS control signals are connected to accessible GPIO lines. The mini UART is also lacking some 16550 functionality, it is only capable of 7 or 8 bit characters, and only supports one stop bit and no parity; attempts to select other settings will be accepted, but will have no effect.

Name

I²C Interface — Using I²C devices

Overview

The I²C driver in the CYGPKG_DEVS_I2C_BSC package supports the use of I²C devices within eCos. Access to the driver will be via the standard I²C interface subsystem.

This driver can provide support for all three I²C busses available on the BCM283X. However, I2C0 is reserved for use by the GPU and I2C2 is dedicated to the HDMI interface, so in practice only I2C1 is available.

Configuration

The HAL contains the following configuration options for each the I²C busses:

CYGINT_HAL_ARM_CORTEXA_BCM283X_I2C_BUSX

> This interface controls the inclusion of support for I²C bus *X*. This will normally be implemented by the platform HAL to indicate that there are I²C devices attached to the given bus, or that the SCL and SDA lines are routed to an external connector.

CYGNUM_HAL_ARM_CORTEXA_BCM283X_I2C_BUSX_CLOCK

> This is the I²C bus *X* clock speed in Hz. Frequencies of either 100kHz or 400kHz can be chosen, the latter sometimes known as fast mode.

Usage Notes

The design of the I²C device does not make it possible to start a new bus transfer without also sending a START condition on the bus. This means that divided transactions are not possible. A divided transaction would look like this:

```
    cyg_i2c_transaction_begin(&cyg_aardvark_at24c02);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 1, tx_buf1, 1, 0);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 0, tx_buf2, 2, 0);
    cyg_i2c_transaction_tx(&cyg_aardvark_at24c02, 0, tx_buf3, 6, 1);
    cyg_i2c_transaction_end(&cyg_aardvark_at24c02);
```

In this transaction a START and one byte are sent from tx_buf1, then 2 bytes of data from tx_buf2, finishing with 6 bytes from tx_buf3 followed by a STOP. The device will not allow the tx_buf2 and tx_buf3 transfers to happen without also sending a START. The only solution to this is to combine the data into a single buffer and perform a single transfer:

```
    memcpy( tx_buf, tx_buf1, 1);
    memcpy( tx_buf+1, tx_buf2, 2);
    memcpy( tx_buf+3, tx_buf3, 6);
    cyg_i2c_tx(&cyg_aardvark_at24c02, tx_buf, 9);
```

Name

GPIO Support — Use of GPIO

Synopsis

#include <cyg/hal/hal_io.h>

`desc =` **`CYGHWR_HAL_BCM283X_GPIO`**`(`*`pin`*`, `*`alt`*`, `*`mode`*`);`

`desc =` **`CYGHWR_HAL_BCM283X_GPIO_VAR`**`(`*`pin`*`, `*`alt`*`, `*`mode`*`);`

`CYGHWR_HAL_BCM283X_GPIO_SET` `(`*`desc`*`);`

`desc =` **`CYGHWR_HAL_BCM283X_GPIO_GET`** `(`*`pin`*`);`

`CYGHWR_HAL_BCM283X_GPIO_OUT` `(`*`desc`*`, `*`val`*`);`

`CYGHWR_HAL_BCM283X_GPIO_IN` `(`*`desc`*`, `*`val`*`);`

Description

The BCM283X HAL provides a number of macros to support the encoding of pin multiplexing and GPIO pin modes into a 32 bit descriptor. This is useful to drivers and other packages that need to configure and use different lines for different devices. Pin multiplexing is handled in the GPIO controller, so it is handled by the same interface.

A GPIO descriptor is created with `CYGHWR_HAL_BCM283X_GPIO( pin, alt, mode)` which takes the following arguments:

`pin`
: This gives the GPIO pin number, between 0 and 53.

`alt`
: This gives the pin's function. It may be one of `GPIO_IN`, `GPIO_OUT`, `ALT0`, `ALT1`, `ALT2`, `ALT3`, `ALT4` or `ALT5`. The first two set the pin to be a GPIO input or output respectively, the remainder select one of six alternate functions for the pin, usually assigning it to a particular device signal. The alternate function mappings can be found in the BCM2835 documentation, and may also be seen using the RedBoot **gpio table** command.

`mode`
: This defines any additional properties that this pin should have. These either define the signal input condition on which an interrupt is raised, or the nature of any pull-up or -down to be applied to the pin. The values `RISING` and `FALLING` program the line to interrupt on a rising or falling edge; similarly `HIGH` and `LOW` interrupt on high or low levels. The values `PULL_DOWN` and `PULL_UP` apply a pull resistor in the given direction.

  The value in this argument is the last element of a macro of the form, `CYGHWR_HAL_BCM283X_GPIO_MODE_XXXXX`. It is possible to define additional macros than enable combinations of modes. The HAL defines some such macros: `EDGE` causes and interrupt on any signal edge; `PULL_UP_FALLING` applies a pull up on the line and interrupts on a falling edge, and `PULL_DOWN_RISING` does the inverse.

Additionally, the macro `CYGHWR_HAL_BCM283X_GPIO_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used. It may be passed to any GPIO macro which takes a descriptor and will be treated as a no-op.

The following examples show how this macro may be used:

```
// ACT LED is on GPIO16 on some boards
#define CYGHWR_HAL_PI_LED                       CYGHWR_HAL_BCM283X_GPIO( 16, GPIO_OUT, NONE )

// UART TX and TX pins are on GPIO14 and GPIO15
#define CYGHWR_HAL_BCM283X_UART0_TX             CYGHWR_HAL_BCM283X_GPIO( 14, ALT0, NONE )
```

```
#define CYGHWR_HAL_BCM283X_UART0_RX             CYGHWR_HAL_BCM283X_GPIO( 15, ALT0, NONE )
```

Most of the remaining macros all take a GPIO descriptor as an argument. `CYGHWR_HAL_BCM283X_GPIO_SET` configures the pin according to the descriptor and must be called before any the following macros. `CYGHWR_HAL_BCM283X_GPIO_OUT` sets the pin output to the value of the least significant bit of the *val* argument. The *val* argument of `CYGHWR_HAL_BCM283X_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

The macro `CYGHWR_HAL_BCM283X_GPIO_GET` takes a pin number as an argument and returns a descriptor that encodes the current state of that pin. The `CYGHWR_HAL_BCM283X_GPIO_VAR` performs the same descriptor encoding as `CYGHWR_HAL_BCM283X_GPIO` except that the arguments are not interpreted as macro name fragments. This is useful for generating a descriptor at runtime from variable field values.

Name

DMA Support — Description

Synopsis

#include <cyg/hal/bcm283x_dma.h>

ok = **hal_dma_channel_init**(*hal_dma_channel *chan*, *cyg_uint8 permap*, *cyg_bool fast*, *hal_dma_callback *callback*, *CYG_ADDRWORD data*);

hal_dma_channel_delete(*hal_dma_channel *chan*);

hal_dma_channel_set_polled(*hal_dma_channel *chan*, *cyg_bool polled*);

hal_dma_poll(*void*);

hal_dma_cb_init(*hal_dma_cb *cb*, *cyg_uint32 ti*, *void *source*, *void *dest*, *cyg_uint32 size*);

hal_dma_add_cb(*hal_dma_channel *chan*, *hal_dma_cb *cb*);

hal_dma_channel_start(*hal_dma_channel *chan*);

hal_dma_channel_stop(*hal_dma_channel *chan*);

Description

The HAL provides support for access to the DMA channels. This support is not intended to expose the full functionality of these devices and is mainly limited to supporting peripheral DMA. The API is therefore mainly oriented for use by device drivers rather than applications. The user is referred to the BCM2835 documentation for full details of the DMA channels, and to the SDHOST driver for an example of this API in use.

The DMA hardware consist of sixteen independent channels. DMA is initiated by attaching a chain of control blocks to a channel and starting it running. Each control block contains source and destination addresses, size, transfer direction and a number of other parameters. Of the sixteen channels available, some are reserved for use by the GPU. Also, the channels are divided into full function channels and *lite* channels that lack some functionality and have lower bandwidth. Full details are available in the BCM2835 documentation.

A DMA channel is represented by a hal_dma_channel object that the client must allocate. Control blocks are similarly represented by a hal_dma_cb object, which again must be allocated by the client. DMA control blocks must be aligned on a 32 byte boundary. The type definition in `bcm283x_dma.h` has an alignment attribute so that static allocations should be correctly aligned by default; however care should be taken to align dynamic allocations.

A DMA channel is initialized by calling `hal_dma_channel_init`, the parameters are as follows:

chan
: A pointer to the channel object to be initialized.

permap
: Peripheral map value. This is one of the `CYGHWR_HAL_BCM283X_DMA_DREQ_XXXX` values defined in `bcm238x.h`. It specifies the peripheral to or from which the transfer will be made.

fast
: This specifies whether the DMA channel should be a full featured fast channel or a reduced bandwidth lite channel. If a lite channel is specified and none are available a fast channel will be allocated. However, if a fast channel is specified and none are available then this routine will return 0 to indicate an error.

callback
: A pointer to a function that will be called when the DMA transfer has been completed. This will be called with a pointer to the channel, an event code, nd a copy of the *data* parameter. The event code will be ei-

ther CYGHWR_REG_BCM283X_DMA_CS_END to indicate a successful completion of the transfer or CYGHWR_REG_BCM283X_DMA_CS_ERROR to indicate an error.

data An uninterpreted data value that will be passed to the callback. This would typically be a pointer to a client data structure.

If the initialization is successful the routine will return 1. The current implementation of the DMA API permanently allocates a physical channel when this routine is called. In the future the allocation of physical channels may be more dynamic, so the client should not assume that the channel in use is constant.

The hal_dma_channel_delete function deletes the given channel, releasing any resources and making them available for reuse.

The hal_dma_channel_set_polled function marks a channel for polled operation only. Otherwise the channel will enable interrupts and wait for an interrupt to complete. If a channel is marked polled then it will only be completed and its callback called during calls to hal_dma_poll. Note that channels not marked polled may also be completed during this call if their interrupt has not yet fired.

A transfer control block is initialized by calling hal_dma_cb_init. The parameters are as follows:

cb A pointer to the control block to be initialized.

ti This is an initial value for the TI register field of the control block. This may contain any of the bits and fields specified for this register except the PERMAP field, which will be set from the value set in the channel. For simplicity the standard settings for common operations are defined by the DMA API; HAL_DMA_INFO_DEV2MEM initializes the control block for a single buffer transfer from a device to memory, and HAL_DMA_INFO_MEM2DEV for a transfer in the reverse direction. If a client needs to perform scatter/gather transfers, then it needs to set this argument more explicitly. In particular, the INTEN bit should normally only be set on the last control block of a chain.

source The source address for the transfer, either the start of a memory buffer or the data register of the appropriate device.

dest The destination address for the transfer, either the start of a memory buffer or the data register of the appropriate device.

size Transfer size in bytes.

Once initialized a control block may be added to a channel by calling hal_dma_cb_add. Control blocks will be chained together on the channel in the order in which they are added. The DMA engines operate on addresses in the GPU address space, not the physical address space visible the the ARM CPUs or the virtual address space set up by the MMU. During initialization the source and destination addresses will be translated into GPU addresses, and after it is added, the dma_next field of the control block will be translated to a GPU address. So, care should be taken when inspecting an active control block and it should not be changed.

Once a channel had been initialized and any control blocks have been added the transfers may be started by calling hal_dma_channel_start. For channels not marked polled, interrupts will fire and the callback will be called from a DSR when the control block chain has been completed. For polled channel, it will be necessary to call hal_dma_poll until all channels have completed.

An ongoing transfer may be halted by calling hal_dma_channel_stop. This function should also be called as a matter of course when a transfer has completed normally.

```

Description

The BCM283X GPU provides information about and control over various aspects of the system. A hardware mailbox mechanism is used to exchange messages with the GPU to query or control these aspects. The BCM283X HAL provides some functions to access this interface. The default functions are limited to just those exchanges that are of direct relevance to eCos, although there is scope for expanding these, or for performing a property exchange directly.

`hal_bcm283x_board_model()` and `hal_bcm283x_board_revision()` fetch the board model and revision numbers. The model number is usually zero, but the revision number encodes the board properties as described Raspberry Pi Revision codes page. Normally the eCos HAL reads the revision code at startup and decodes it into a set of variables.

`hal_bcm283x_board_serial()` returns the board's serial number; this is a 64 bit identifier unique to this board. The function `hal_bcm283x_mac_address()` returns a MAC address for this board; this consists of the lower 24 bits of the serial number combined with a vendor ID assigned to the Raspberry Pi Foundation.

`hal_bcm283x_arm_memory()` returns the base and size of the RAM available to the ARM processor. The base will be zero and the size will indicate the top of memory after the GPU memory specified in the `config.txt` file has been allocated.

`hal_bcm283x_clock_rate()` returns the current rate of the given clock in Hz. Clock identifiers can be found in `bcm238x.h`. `hal_bcm283x_clock_rate_max()` and `hal_bcm283x_clock_rate_min()` return the maximum and minimum rates for the clock. `hal_bcm283x_clock_rate_set()` sets the given clock to the supplied rate.

`hal_bcm283x_dma_channels()` returns a mask of the available DMA channels.

`hal_bcm283x_set_gpu_gpio()` sets the value (0 or 1) of a GPIO pin controlled by the GPU through the external GPIO extender. This is mainly used to control the ACT LED on Pi3B and Pi3A boards.

`hal_bcm283x_temperature()` reads the temperature of the SoC in thousandths of a degree C. `hal_bcm283x_temperature_max()` returns the maximum SoC temperature, above which overclocking will be disabled. In both cases the id should be zero.

`hal_bcm283x_property_exchange()` performs a property exchange with the GPU and may be used to implement requests that are not covered above. The protocol used is described on the Raspberry Pi Mailbox properties GitHub page. This function copies the array of property tags pointed to by *`prop`* into a properly aligned buffer after the standard buffer header and terminates it an end tag. It then sends a mailbox message to the GPU and waits for a response. Finally, the updated property buffer is copied back out to *`prop`*. In SMP systems a spinlock is used to control concurrent access from different CPUs.

Name

Frequency Control — control ARM and CORE frequencies

Synopsis

#include <cyg/hal/hal_io.h>

```
void hal_bcm283x_set_freqencies(cyg_uint32 arm, cyg_uint32 core);
```

Description

The BCM283X GPU has control over the frequencies of the various clocks that feed the hardware. Of these the most important are the ARM clock, which feeds the CPUs and the CORE clock which feeds most of the peripherals. On booting, the HAL reads the current, minimum and maximum values of these clocks and stores them in global variables. The UART and EMMC clocks are also read and recorded. The ARM and CORE clocks are then set to either the maximum values, or values set in the HAL configuration (`CYGHWR_HAL_ARM_CORTEXA_BCM283X_ARM_FREQ` and `CYGHWR_HAL_ARM_CORTEXA_BCM283X_CORE_FREQ`).

eCos does not contain any support for dynamic frequency management in the same way that Linux does. The CPUs run at a single frequency throughout. Normally this is the maximum frequency permitted without overclocking. A different frequency may be selected in the configuration, or it may be set at runtime by calling `hal_bcm283x_set_freqencies()`.

The function `hal_bcm283x_set_freqencies()` updates either or both the ARM or CORE clock frequencies. The frequencies are given in Hz, and if zero are not changed. Values that lie below the minimum frequency for the clock are increased to the minimum and those above the maximum are reduced to the maximum. Other clock-related values, such as the mini-UART baud rate divider (which divides the CORE frequency), may also be changed. Finally, the curent values of the main clocks in the system are read back from the GPU to ensure that the correct values are used.

Chapter 274. Broadcom BCM56150 Reference Board Support

Name

eCos Support for the Broadcom BCM56150 Reference Board — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Broadcom BCM956150 SVK reference board. This board is fitted with a BCM56150 CPU and it is referred to in this document and the configuration system as a BCM56150 Reference, or bcm56150_ref, to differentiate it from other Broadcom boards.

In addition to the BCM56150, the board contains 512MiB SDRAM main memory, a 256Mib (32MiB) SPI NOR Flash, a connector for CCA UART1, Ethernet sockets for both the IProc and switch Ethernet interfaces, plus a variety of connectors for other interfaces. The extent of eCos support for the devices and peripherals on the board and the CPU is described below.

For typical eCos development, a RedBoot image is programmed into the SPI NOR flash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug eCos applications via the gdb debugger using the serial line.

This documentation is expected to be read in conjunction with the Broadcom IProc processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The SPI NOR flash consists of 512 blocks of 64KiB each. In a typical setup, the first 13 blocks are reserved for the use of the ROMRAM RedBoot image. One block is reserved to contain DRAM memory parameters. The topmost block is used to manage the flash and also holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

Serial support is through the `CYGPKG_IO_SERIAL_GENERIC_16X5X` generic driver package which is modified by the `CYGPKG_IO_SERIAL_ARM_BROADCOM_IPROC` driver package for the IProc. These packages support both the serial devices on the IProc ChipCommonA device. However, this board only has UART1 connected to an external connector which this HAL indicates by implementing the `CYGINT_HAL_ARM_CORTEXA_BROADCOM_IPROC_UART1` interface. This serial channel is used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. The serial driver package is loaded automatically when configuring for the `bcm56150-ref` target.

The platform HAL provides definitions to enable access to flash devices on the SPI bus. The HAL enables the QSPI driver (`CYGPKG_DEVS_FLASH_QSPI_IPROC`) which in turn provides the underlying implementation for access to the Micron N25Q256 SPI NOR flash. The QSPI support integrates with the `CYGPKG_DEVS_FLASH_SPI_M25PXX` package. These packages are automatically loaded when configuring for the target. This driver is capable of supporting the JFFS2 filesystem, although at greatly reduced performance compared with a parallel flash device.

In general, devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (RTC, QSPI, Ethernet etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate power control and pin multiplexing configuration.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 4.7.3, arm-eabi-gdb version 7.2, and binutils version 2.23.2.

Name

Setup — Preparing the BCM56150 Reference board for eCos Development

Overview

In a typical development environment, the board boots from the SPI NOR Flash and runs the RedBoot bootloader and debug agent from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROMRAM	RedBoot loaded from SPI NOR flash to SDRAM	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`
ROM	RedBoot executed directly from SPI NOR flash	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports flash management.

By default the ROMRAM startup should be used since it relocates itself to RAM after initializing the SDRAM controller. The ROM startup RedBoot is mainly used for debugging board initialization.

Initial Installation

The BCM56150 Reference board comes with U-Boot and Linux installed by default on the SPI NOR flash. For eCos development we need to install RedBoot in the flash. The booting mechanism is that the on-chip firmware interrogates the boot mode pins and jumps to the start of the memory region corresponding to the device selected. For our purposes, this is the start of the memory-mapped SPI NOR flash.

RedBoot must be written to the first few blocks of the SPI NOR flash. Thirteen sectors or 832KiB are reserved for this. There are several ways that this flash may be written. The N25Q256 is removable and may be programmed externally. The SPI CS/SCLK/MOSI/MISO lines are available on a header and may be used to program the flash from an external device. It may also be programmed using software running on the board. The following explains how to program RedBoot using a Lauterbach Power Debug via Trace32.

Programming RedBoot into NOR flash using Trace32

The following gives the steps needed to program RedBoot into the SPI NOR Flash using a Lauterbach Power Debug Interface and Trace32.

1. Install Trace32 onto your host system. Attach the Power Debug module to the JTAG header (JP1801) and to a USB port on the host. Attach the serial adaptor cable from J1801 to a host serial port and run a suitable terminal communications program (e.g. TeraTerm or Putty on Windows, minicom on Linux). The default serial settings are 115200,8,N,1 with no flow control.

2. Locate the boot selection jumper (JP900) and move the jumper from the 5-6 position to 1-2. Power up the board and the Power Debug.

3. Copy the following files from `hal/arm/cortexa/bcm56150_ref/`*`VERSION`*`/misc` in the repository to a working directory: `ecospro.cmm`, `layout.cmm`, `hr2_prog_sflash_trace32`

4. Copy `redboot_ROMRAM.bin` to the same directory, renaming it `app.bin`.

5. With the work directory as your current directory, start Trace32.

6. From the `File` menu, select `Run Script` and run the `ecospro.cmm` script.

7. From the `eCosPro` menu select the `Program APP.BIN to Flash` entry. This should proceed to load `hr2_prog_sflash_trace32` into on-chip SRAM, erase the flash and program the contents of `app.bin` into flash. This will take a while to complete.

8. Once the programming is finished, shut down Trace32. Power off the board. Detach the Power Debug from the board.

8. Move the jumper on JP900 back to the 5-6 position.

9. Power up the board. The DRAM initialization code may spend some time optimizing the memory parameters. This may take several minutes and result in many lines of diagnostic output. This will only need to be done once, in the future these parameters will be loaded from flash.

10. When the DRAM initialization is finished, output similar to the following will be seen on the serial output:

```
+**Warning** FLASH configuration checksum error or invalid key
RedBoot(tm) bootstrap and debug environment [ROMRAM]
Non-certified release, version UNKNOWN - built 18:05:47, Nov 11 2015

Platform: Broadcom BCM56150 Reference Platform (Cortex-A9)
RAM: 0x60000000-0x80000000 [0x6012c680-0x7ffed000 available]
FLASH: 0x1c000000-0x1dffffff, 512 x 0x10000 blocks
RedBoot> fis list
Name              FLASH addr  Mem addr    Length      Entry point
RedBoot           0x1C000000  0x6012C800  0x000E0000  0x6012C800
Memory Params     0x1C0E0000  0x1C0E0000  0x00010000  0x00000000
FIS directory     0x1DFF0000  0x1DFF0000  0x0000F000  0x00000000
RedBoot config    0x1DFFF000  0x1DFFF000  0x00001000  0x00000000
RedBoot>
```

If it proves necessary to install a new version of RedBoot, this may be done from RedBoot itself over the serial line. From RedBoot run the following commands:

```
RedBoot> load -r -m y -b %{freememlo}
C
```

From the terminal program, transmit the new RedBoot binary using Y-Modem protocol. When it is finished, you should see something similar to the following:

```
CRaw file loaded 0x6012c800-0x60154a07, assumed entry at 0x6012c800
xyzModem - CRC mode, 1287(SOH)/0(STX)/0(CAN) packets, 4 retries
```

Now write the loaded binary over the current RedBoot in flash:

```
RedBoot> fis cre RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x1c000000-0x1c0dffff: .............
... Program from 0x6012c800-0x60154a08 to 0x1c000000: ...
... Erase from 0x1dff0000-0x1dffffff: .
... Program from 0x7fff0000-0x80000000 to 0x1dff0000: .
RedBoot>
```

The RedBoot image has now been replaced. Power cycle the board to execute it.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROMRAM version of RedBoot for the BCM56150 Reference are:

```
$ mkdir redboot_bcm56150_ref_romram
$ cd redboot_bcm56150_ref_romram
$ ecosconfig new bcm56150_ref redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/cortexa/bcm56150_ref/VERSION/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This is a binary file that can be programmed directly to the flash.

Name

Configuration — Platform-specific Configuration Options

Overview

The BCM56150 Reference platform HAL package is loaded automatically when eCos is configured for the `bcm56150-ref` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports four separate startup types:

RAM

> This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory via the serial line and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

ROMRAM

> This startup type can be used for finished applications which will be programmed into Flash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. The application starts execution from flash, but relocates itself to RAM during initialization.

ROM

> This startup type can be used for finished applications which will be programmed into Flash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. The application executes from flash. However, since the SPI flash is very slow, it is not recommended for production applications. It is mainly useful for debugging application startup code via a JTAG debugger.

JTAG

> This startup type can be used for finished applications that are to be loaded into RAM via a JTAG debugger. Since DRAM needs to be initialized before loading a JTAG application, it is necessary to allow RedBoot to start and run from flash. After this the JTAG probe may be connected and the application loaded. Once running the application will be self-contained with no dependencies on services provided by other software.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The BCM56150 Reference board contains an 32Mbyte Micron N25Q256 SPI serial NOR flash device attached to the QSPI controller. The `CYGPKG_DEVS_FLASH_SPI_M25PXX` and `CYGPKG_DEVS_FLASH_QSPI_IPROC` packages contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the BCM56150 Reference board. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

This driver is capable of supporting the JFFS2 filesystem. However, note that the SPI interface means that this file system has reduced bandwidth and increased latency compared with other implementations. All that is required to enable the support is to include the filesystem (`CYGPKG_FS_JFFS2`) and any of its package dependencies (including `CYGPKG_IO_FILEIO` and `CYGPKG_LINUX_COMPAT`) together with the flash infrastructure (`CYGPKG_IO_FLASH`).

UART Serial Driver

The board uses the IProc's internal UART serial support as described in the IProc processor HAL documentation. Only one serial connector is available on the board, which is connected to UART1 via the J1801 connector. An adaptor cable is needed to connect to a standard 9-pin serial connector.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. The following flags are specific to this port:

`-mcpu=cortex-a9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=cortex-a9` is the correct option for the CPU in the IProc.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb2 instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mno-unaligned-access`
: The Cortex-A CPU allows unaligned memory accesses and the default for arm-eabi-gcc is to generate instructions that make unaligned accesses. However, for this port, alignment exceptions are enabled, so unaligned accesses should not be made. This option disables unaligned accesses. Note that there is a performance and code size cost in doing this, since all accesses to unaligned data must now be made using individual byte accesses.

`-fno-jump-tables`
: For ROMRAM startup, some code is executed from flash before code is relocated to RAM. As a result, any code or constant data references will use the wrong address. To prevent **switch** statements using tables at the wrong location, this option is enabled for ROMRAM startup builds.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the BCM56150 Reference hardware, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the Cortex-A variant HAL and the Broadcom IProc processor HAL. It provides functionality which is specific to the target board.

Startup

Following a reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROMRAM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x60000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x60000000 with caching enabled. The same memory is also accessible uncached at virtual location 0xA0000000 for use by device drivers. The first 128MiB of SDRAM is also mapped to physical address 0x00000000, which is identity mapped uncached. The exception vectors and VSR table occupy the bottom 64 bytes of this region. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x60010000 to 0x60014000. For ROMRAM startup, the application relocates to 0x60100000 and all remaining SDRAM is available. The virtual vector table is allocated as part of the RedBoot image and occupies 256 bytes from 0x60100050. RAM applications load from 0x60200000, reserving 1MiB for RedBoot. JTAG applications load at 0x60100000, overwriting any ROMRAM application already present.

On-chip SRAM

On-chip SRAM is located at 0x1B000000 and is 16KiB in size. While this memory is used during DRAM initialization, it is not used by eCos for any other purpose and is available for application use.

SPI NOR Flash

SPI NOR flash is supported by a QSPI device that translates read accesses to memory starting at 0x1C000000 into SPI read transactions. Writes to the SPI flash go via a different device which disables this mapping. Because of this, and its poor performance, code should not be executed from SPI flash except during initialization. The Serial flash area at 0x1C000000 is identity mapped uncached, although it should normally be accessed only using the flash API.

Peripheral Registers

These are located at various addresses in the physical memory space. When the MMU is enabled, it contain direct, uncached, identity mappings so that these registers remain accessible at their physical locations.

SPI NOR Flash

eCos supports QSPI access to the NOR flash on the board. The device is typically used to contain RedBoot and flash configuration data.

Accesses to SPI flash are performed via the Flash API, using 0x1C000000 as its base address. Access from RedBoot should be made using **fis** command operations.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM32 mode.

Example 274.1. bcm56150_ref Real-time characterization

```
             Startup, main thrd : stack used   388 size  1792
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    88 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    1.03 microseconds (1 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  64
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32
   Stack Size:             1088

```

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The IProc processor HAL and the ARM architectural HAL documentation should be consulted for further details.

Chapter 275. Altera Cyclone V SX Board Support

Name

eCos Support for the Altera Cyclone V SX Board — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Altera Cyclone V SoC Development kit. This board is fitted with an SX variant of the Cyclone V family of FPGAs and it therefore referred to in this document and the configuration system as a Cyclone V SX, or cyclone5_sx, to differentiate it from other Cyclone V SoC development boards.

In addition to the Cyclone V FPGA, the board contains 1GiB SDRAM main memory, a 1Gib (128GiB) SPI NOR flash, a micro-SD card socket, a USB bridge connected to UART0, Ethernet sockets for both the HPS and FPGA Ethernet interfaces, plus a variety of connectors for other interfaces plus resources devoted to the FPGA. The extent of eCos support for the devices and peripherals on the board and the CPU is described below.

For typical eCos development, a RedBoot image is programmed into the SPI NOR flash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over Ethernet.

Support for SMP operation of the two Cortex-A9 CPUs on the Cyclone V SoC is available, although debugging support is restricted to use of an external JTAG debugger. There is no SMP support in RedBoot.

This documentation is expected to be read in conjunction with the Altera HPS processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The SPI NOR flash consists of 2048 blocks of 64Ki bytes each. In a typical setup, the first 4 blocks are reserved for the second-level bootstrap, the preloader. The 10 blocks from block 6 are reserved for the use of the ROM RedBoot image. The topmost block is used to manage the flash and also holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

Serial support is through the `CYGPKG_IO_SERIAL_GENERIC_16X5X` generic driver package which is modified by the `CYGPKG_IO_SERIAL_ARM_ALTERA_HPS` driver package for the HPS. These packages can support all the serial devices on the HPS. However, this board only has UART0 connected to an external connector which this HAL indicates by implementing the `CYGINT_HAL_ARM_CORTEXA_ALTERA_HPS_UART0` interface. This serial channel is used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as Ethernet should be used instead. The serial driver package is loaded automatically when configuring for the `cyclone5-sx` target.

There is an Ethernet driver `CYGPKG_DEVS_ETH_DWC_GMAC` for the on-chip Ethernet device. A separate package, `CYGPKG_DEVS_ETH_CYCLONE5_SX` configures this generic driver to the hardware. This driver is also loaded automatically when configuring for the `cyclone5-sx` board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_DWWDT`. This driver is also loaded automatically when configuring for the board.

There is a driver for the DS1339C real-time clock (RTC) at `CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1307`, with which it is compatible. This driver is also loaded automatically when configuring for the target and when I²C support is included.

The HPS processor HAL contains a driver for the MultiMedia Card Interface (MMC/SD). This driver is loaded automatically when configuring `CYGPKG_DEVS_DISK_MMCSD_BUS` for this target and allows use of MultiMediaCard (MMC) and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation on the driver may be found in the Altera Hard Processor System Support HAL documentation.

Note

There is no working card-detect (media change) signal available on the Altera Cyclone V SoC Development board for the J3 MicroSD slot.

The platform HAL provides definitions to enable access to flash devices on the SPI bus. The HAL enables the QSPI driver (`CYGPKG_DEVS_FLASH_QSPI`) which in turn provides the underlying implementation for access to the Micron N25Q00AA SPI NOR flash. The QSPI support integrates with the `CYGPKG_DEVS_FLASH_SPI_M25PXX` package. These packages are automatically loaded when configuring for the target. This driver is capable of supporting the JFFS2 filesystem, although at reduced performance compared with a parallel flash device.

In general, devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (RTC, SPI, MMC/SD etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate power control and pin multiplexing configuration.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 4.4.5, arm-eabi-gdb version 7.2, and binutils version 2.20.

Name

Setup — Preparing the Cyclone V SX board for eCos Development

Overview

In a typical development environment, the board boots from the SPI NOR and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from SPI NOR flash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 57600 baud. RedBoot also supports Ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from NOR flash by the preloader. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

The Cyclone V SX board comes with U-Boot and Linux installed by default on a micro-SD card. For eCos development we want to install RedBoot in the SPI NOR flash. The booting mechanism is that the on-chip firmware loads a small preloader from the start of NOR flash which then loads RedBoot from later in the flash.

To write RedBoot to the SPI NOR flash, you must use the command line tools from the Altera QuartusII SoC Embedded Development System.

Programming RedBoot into NOR flash using Altera Tools

The following gives the steps needed to program RedBoot into the SPI NOR Flash using the Altera EDS tools. This uses the **quartus_hps** flash programmer command line utility to do the work.

Note

The examples below are for a Linux host where eCosPro is typically installed in the `/opt/ecospro/ecospro-<version>` sub-directory. On a Windows host eCosPro will typically be installed in the `C:\eCosPro\ecos-<version>` sub-directory.

1. Install QuartusII and the SoC EDS as described by Altera onto your host system. Start an Embedded Command Shell by running either `<SoC EDS Installation Folder>\embedded\Embedded_Command_Shell.bat` in Windows or `<SoC EDS Installation Folder>/embedded/embedded_command_shell.sh` in Linux.
2. Ensure that the BOOTSEL jumpers are set as follows: BOOTSEL0(J28) 2-3, BOOTSEL1(J29) 1-2, BOOTSEL2(J30) 1-2.
3. Connect USB cables between the mini USB socket at J37 (used by the USB-Blaster), and the mini USB socket at J8 (used to provide serial device access) and your host. Power up the board and run a terminal emulator on your host, attaching it to the serial USB channel which should appear on your host, setting the baud rate to 57600.
4. Run the following command on the host to detect the USB-Blaster:

```
# jtagconfig
1) USB-BlasterII [USB 1-1]
  4BA00477   SOCVHPS
  02D020DD   5CS(EBA6ES|XFC6C6ES)/..

#
```

It may be necessary to run this a couple of times before the above result is obtained. If the program failure persists then you should check that your EDS installation is correct.

5. Run the following command to configure the JTAG interface:

   ```
   # jtagconfig --setparam 1 JtagClock 16M
   #
   ```

   This program terminates silently if it is successful.

6. Run the following command to install the preloader, passing it a path to the preloader image from the installed eCos distribution. This preloader was built with the Altera bsp-editor according to the instructions in the "Altera SoC Embedded Design Suite User Guide", chapter "HPS Preloader User Guide". The `BOOT_FROM_QSPI` boot option was used.

   ```
   # quartus_hps -c 1 -o PV /opt/ecospro/ecos-<version>/loaders/cyclone5_sx/preloader-mkpimage.bin

7. Now run the following commands to install RedBoot, passing a path to the RedBoot image from the installed eCos distribution. Note that the **quartus_hps** command can only accept files with a `.bin` extension, so it is necessary to copy the generated RedBoot image to a file with the correct extension before running the command. The RedBoot image file will be located alongside `preloader-mkpimage.bin` in the `loaders/cyclone5_sx` sub-directory of the eCosPro installation as illustrated above. You may ignore the `.bin`, `.elf` and `.srec` files also located in the same sub-directory. Also note that the commands provided are for a Linux host so the `PATH` and copy command will vary.

```
# cp /opt/ecospro/ecos-<version>/loaders/cyclone5_sx/redboot_ROM.img /tmp/redboot.bin
# quartus_hps -c 1 -a 0x60000 -o PV /tmp/redboot.bin

```

8. Detach the USB cable for the USB Blaster from the mini USB socket at J37 and connect an ethernet cable to J2 on the board (located on the opposite side from the ENET1 and ENET2 dual ethernet interfaces) and an ethernet hub that is connected to your host's network.

9. Power cycle the board. You should see the following output on the serial line:

```
+**Warning** FLASH configuration checksum error or invalid key
```

```
Ethernet eth0: MAC address 12:34:aa:bb:cc:ee
IP: 10.0.2.4/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.1

RedBoot(tm) bootstrap and debug environment [ROM]
Non-certified release, version UNKNOWN - built 11:45:41, Jun 26 2013

Copyright (C) 2000-2009 Free Software Foundation, Inc.
Copyright (C) 2003-2012 eCosCentric Limited
RedBoot is free software, covered by the eCos license, derived from the
GNU General Public License. You are welcome to change it and/or distribute
copies of it under certain conditions. Under the license terms, RedBoot's
source code and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: Altera Cyclone V SX Development Kit (Cortex-A9)
RAM: 0x00000000-0x40000000 [0x00259208-0x3ffed000 available]
FLASH: 0x80000000-0x87ffffff, 2048 x 0x10000 blocks
RedBoot>
```

Since the serial USB bridge is also power cycled, you may lose the serial device under Windows or one or two lines from the beginning of this output. If this happens, simply reconnect if necessary and type `version` to see the full output again.

10. Run the following commands to initialize RedBoot's flash file system and flash configuration:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x87ff0000-0x87ffffff: .
... Program from 0x3fff0000-0x40000000 to 0x87ff0000: .
RedBoot>
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 10.0.1.1
Console baud rate: 57600
Network hardware address [MAC] for eth0: 0x12:0x34:0xAA:0xBB:0xCC:0x08
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Default network device: dwc_gmac
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x87ff0000-0x87ffffff: .
... Program from 0x3fff0000-0x40000000 to 0x87ff0000: .
RedBoot>
```

You should substitute your own server IP address for the one shown above. You may also want to change the MAC address if more than one board is present on the network, or use one of the MAC addresses assigned by Altera to this board. If you want to use a static IP address, then choose false for the "Use BOOTP" option and enter the gateway, IP address and netmask that you have assigned.

The RedBoot installation is now complete. This can be tested by power cycling the board again. Output similar to the following should be seen on the serial port.

```
+Ethernet eth0: MAC address 12:34:aa:bb:cc:08
IP: 10.0.2.6/255.0.0.0, Gateway: 10.0.0.3
Default server: 10.0.1.1

RedBoot>
```

If it proves necessary to install a new version of RedBoot, this may be done from RedBoot itself. Place the new image on a TFTP server on the configured server. From RedBoot run the following commands:

```
RedBoot> load -r -b %{freememlo} redboot.img
Using default protocol (TFTP)
Raw file loaded 0x00259400-0x00277c0b, assumed entry at 0x00259400
RedBoot> fis cre RedBoot
An image named 'RedBoot' exists - continue (y/n)? y
... Erase from 0x80060000-0x800fffff: ..........
... Program from 0x00259400-0x00277c0c to 0x80060000: ..
... Erase from 0x87ff0000-0x87ffffff: .
... Program from 0x3fff0000-0x40000000 to 0x87ff0000: .
RedBoot>
```

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the Cyclone V SX are:

```
$ mkdir redboot_cyclone5_sx_rom
$ cd redboot_cyclone5_sx_rom
$ ecosconfig new cyclone5_sx redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/cortexa/cyclone5_sx/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.img`. This is a binary file that includes a header needed by the preloader to load and run RedBoot successfully.

Note

The `flashimg_cv` host executable provided within your eCosPro installation is required on the build host to wrap the RedBoot binary image into an image that can be programmed by the tools from the Altera QuartusII SoC Embedded Development System. This executable must be on your path when you build RedBoot and will normally located in the `/opt/ecospro/ecos-<version>/host/bin-<hostos>` sub-directory of your eCosPro installation. Shells created by future revisions of the eCos GUI configuration tool or `ecosprofileenv` will add this directory to the `PATH` environment variable.

Installing user applications into Flash

If you wish to install a ROM startup application into Flash to be automatically booted instead of RedBoot, you can follow a similar procedure to installing RedBoot into Flash. However before you can do so, you must first prepend a header to your application image in order for the preloader to recognise it as a valid application.

You will need the **flashimg_cv** command, which should be in the host tools binary directory as described above. You will also need to generate a binary image of your program using the **arm-eabi-objcopy** command. The following gives an example simplified command sequence which can be run at a command shell prompt:

```
$ arm-eabi-objcopy -O binary myapp myapp.bin
$ flashimg_cv myapp.bin myapp.img
```

You will need to subsitute your own paths and filenames where applicable.

Once you have the `.img` file, you can follow the same process as above for installing RedBoot via the USB-BlasterII. Once the initial setup has been done once, it is only then necessary to re-install the ROM executable. It is not necessary to reinstall the preloader each time. A typical command sequence might be:

```
$ arm-eabi-objcopy -O binary myapp myapp.bin0
$ flashimg_cv myapp.bin0 myapp.bin
$ quartus_hps -c 1 -a 0x60000 -o PV myapp.bin
```

Name

Configuration — Platform-specific Configuration Options

Overview

The Cyclone V SX platform HAL package is loaded automatically when eCos is configured for the `cyclone5-sx` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports four separate startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into Flash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type can also be used for applications loaded via JTAG.

SRAM
: This startup type can be used for finished applications that are to be loaded into the on-chip SRAM. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type can also be used for applications loaded via JTAG.

SMP
: This startup type can be used for finished applications that can be loaded into RAM via RedBoot. The load address is set to the same as for RAM applications, however, the application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. Once started, this application takes full control of the system and RedBoot will not be called again. This means that debugging via RedBoot will not be possible, only JTAG-based hardware debugging is supported. The intent of this startup type is to allow SMP test programs to be run from RedBoot, most SMP applications should use the ROM startup type. This startup type can also be used for applications loaded directly via JTAG.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The Cyclone V SX board contains an 128Mbyte Micron N25Q00AA SPI serial NOR flash device attached to the QSPI controller. The `CYGPKG_DEVS_FLASH_SPI_M25PXX` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the Cyclone V SX. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

This driver is capable of supporting the JFFS2 filesystem. However, note that the SPI interface means that this file system has reduced bandwidth and increased latency compared with other implementations. All that is required to enable the support is to include the filesystem (CYGPKG_FS_JFFS2) and any of its package dependencies (including CYGPKG_IO_FILEIO and CYGPKG_LINUX_COMPAT) together with the flash infrastructure (CYGPKG_IO_FLASH).

Ethernet Driver

The board uses the HPS's internal GMAC Ethernet device attached to an external Micrel KSZ9021 Gigabit PHY. The CYGPKG_DEVS_ETH_DWC_GMAC package contains all the code necessary to support this device and the CYGPKG_DEVS_ETH_CYCLONE5_SX package contains definitions that customize the driver to the board. This driver is not active until the generic Ethernet support package, CYGPKG_IO_ETH_DRIVERS, is included in the configuration.

Support for PHY events is made available by default when the Kernel (CYGPKG_KERNEL) is available in a configuration.

RTC Driver

The Cyclone V SX board has a Maxim DS1339C I²C based RTC chip installed. For the functionality used by eCos, this device is compatible with the DS1307. Therefore, the CYGPKG_DEVICES_WALLCLOCK_DALLAS_DS1307 package contains all the code necessary to support this device. This driver is not active until the generic wallclock device support package, CYGPKG_IO_WALLCLOCK, is included in the configuration and I²C support is enabled.

Watchdog Driver

The board uses the HPS's internal watchdog support. The CYGPKG_DEVICES_WATCHDOG_DWWDT package contains all the code necessary to support this device. Within that package the CYGNUM_DEVS_WATCHDOG_DWWDT_DESIRED_TIMEOUT_MS configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, CYGPKG_IO_WATCHDOG, is included in the configuration.

UART Serial Driver

The board uses the HPS's internal UART serial support as described in the HPS processor HAL documentation. Only one serial connector is available on the board, which is connected to UART0 via a USB bridge. Only the UART data lines are connected to the bridge, so hardware flow control is not supported.

MMC/SD Driver

As the Cyclone V SX MMC/SD driver is part of the HPS processor HAL, nothing is required to load it. Similarly the MMC/SD bus driver layer (CYGPKG_DEVS_DISK_MMC) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (CYGPKG_IO_DISK), along with the intended filesystem, typically, the FAT filesystem (CYGPKG_FS_FAT) and any of its package dependencies (e.g. for FAT also including CYGPKG_LIBC_STRING and CYGPKG_LINUX_COMPAT packages).

Various options can be used to control specifics of the MMC/SD driver. Consult the HPS processor HAL documentation for information on its configuration.

This board does not have a working MMC/SD card detect for MicroSD socket (J3), thus the disk I/O layer's removeable media support is not available.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. The following flags are specific to this port:

`-mcpu=cortex-a9`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=cortex-a9` is the correct option for the CPU in the HPS.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb2 instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mno-unaligned-access`
: The Cortex-A CPU allows unaligned memory accesses and the default for arm-eabi-gcc is to generate instructions that make unaligned accesses. However, for this port, alignment exceptions are enabled, so unaligned accesses should not be made. This option disables unaligned accesses. Note that there is a performance and code size cost in doing this, since all accesses to unaligned data must now be made using individual byte accesses.

Name

SMP Support — Usage

Overview

Support is available for SMP operation of the two CPUs on this platform. However, debugging support is restricted to using an external SMP-aware JTAG debugger like ARM's DS-5 or a Lauterbach Power Debug probe. RedBoot does not have support for multi-core debugging.

A board intended to be used for SMP operation should be initialized in the same way as a single core board by installing the preloader and RedBoot. If RedBoot is not needed then the preloader must still be installed and a ROM startup application, with headers added by **flashimg_cv**, can be written to flash in place of RedBoot.

SMP support is enabled by setting `CYGPKG_KERNEL_SMP_SUPPORT` to true. SMP applications should only be built using either ROM or SMP startup types. ROM applications can be loaded by the pre-loader in place of RedBoot. The SMP startup is identical to a ROM startup except that the load address is set to allow the application to be loaded into a higher location in RAM from RedBoot. Both application types may also be loaded via a JTAG debugger.

Loading an SMP startup application via RedBoot can be done from the RedBoot command line via serial or Ethernet. It may also be loaded via a GDB connection on serial or Ethernet. However, once started running the SMP application will take full control of the system, including redirecting all interrupt sources, exception vectors and virtual vector table entries. This means that RedBoot will no-longer be active. Any breakpoints planted by GDB will result in an exception to the application, Ctrl-C will not work, any Ethernet connections will be lost and serial output will come from the application in plain ASCII. Any GDB connection will be lost and GDB may start reporting packet errors.

JTAG support has been tested using the ARM DS-5 debugger and the Lauterbach Trace32 debugger. Most of our SMP development has been done using Trace32.

ARM DS-5 Support

Support for this board is included in the Altera QuartusII SoC EDS. Select the Cyclone V dual core option in the debug configuration to debug SMP applications. Otherwise follow the EDS, Eclipse and DS-5 documentation to set up and operate the debugger.

A suitable license file will also be needed.

Trace32 Support

Support for SMP debugging using the Lauterbach **Trace32** debugger using a Power Debug probe is available. You need suitable licenses for the Cortex-A/R families and multicore debugging in order to do this.

The **Trace32** debugger needs a startup script to initialize it for the Cyclone V. Some example scripts are present in the Cyclone V SX platform HAL (i.e. `packages/hal/arm/cortexa/cyclone5_sx/`*`VERSION`*`/misc`). The `ecosprompt.cmm` file provides setup for the standard **Trace32** application, and `ecosprompt-qt.cmm` is for the QT based variant avaliable on some host operating systems. These files are identical except for the layout file they load to define the window arrangement (`layoutmp.cmm` or `layoutmp-qt.cmm`). The expectation in these scripts is that all files are present in the same directory, along with the application being debugged. It is recommended that these files be copied out of the source repository into a working directory to which the application can also be copied and that Trace32 be started from the command line as follows:

```
$ cd /path/to/work/directory
$ t32marm-qt -s ecosprompt-qt.cmm
```

The lack of a clean hardware reset on this board means that the safest approach for debugging any application is to power cycle the board, start Trace32 and then load and run the application. To re-run the application, exit Trace32 before power cycling the board.

In addition to attaching to the target, these startup files define an additional `eCosPro` menu in the **Trace32** GUI. It contains the following entries:

MMU Table List

This entry causes a window showing the curent state of the MMU tables for the current CPU to be displayed. In eCos, all CPUs should be using the same shared table.

Load eCos.t32

This loads the **Trace32** eCos RTOS specialization extenstion. This file should be copied out of the Trace32 installation into the working directory. Note that the eCos RTOS support is not SMP-aware, so some information it displays in SMP application may be a little misleading. See the Lauterbach documentation on the RTOS debugger for eCos for more details of the functionality available.

Display Threads

Displays a list of current threads. Note that in SMP systems only the thread running on CPU 0 will be marked running. Those on other CPUs will be marked ready.

Display Scheduler

Displays state of scheduler. Only those parts of the scheduler state common between single and multi-core systems will be displayed.

Jump to CPU entrypoint

This entry disables the Caches and MMU and sets PC to zero. This may cause the system to restart once it is started running, however, it may also cause a crash since the hardware will not be in its initial state. In particular, if the second CPU is running, it is likely to cause a problem. Under most circumstances the board should be power cycled.

Load APP.ELF

This entry disables the caches and MMU, loads the file `app.elf` from the current directory, and loads any breakpoints from `breakpoints.cmm`. This is the menu entry that should be used to load and run SMP applications for development and testing. The `breakpoints.cmm` file allows a set of current breakpoints to be saved using the Store button on the breakpoint list window and have them reloaded automatically each time the application is reloaded.

Load APP.ELF Syms+Bkpts

This entry loads just the symbol tables and debug information from the application and also loads breakpoints from `breakpoints.cmm`. This is useful if the application is already running when Trace32 is attached. For example if it is a ROM startup application that has been loaded from flash, or an SMP startup application that was loaded by RedBoot.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Cyclone V SX hardware, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the Cortex-A variant HAL and the Altera HPS processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM
: This is located at address 0x00000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x00000000 with caching enabled. The same memory is also accessible uncached and unbuffered at virtual location 0x40000000 for use by device drivers. The first 1MiB of RAM is left unmapped, allowing NULL pointer accesses to be trapped. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x00100000 to 0x00004000. For ROM startup, all remaining SDRAM is available, although ROM applications actually load from 0x00200000. The virtual vector table is allocated as part of the RedBoot image and occupied 256 bytes from 0x00200050. RAM startup applications are loaded from location 0x00300000, reserving 1MiB for RedBoot.

On-chip SRAM
: On-chip SRAM is located at 0xFFFF0000 and occupied all of the remaining 64KiB to the top of the address space. It is identity mapped uncached. This port locates the exception vectors to high memory, at 0xFFFF0000. So, the first 32 bytes of SRAM are used for hardware exception vectors and the next 32 bytes are used for the VSR table. SRAM from 0xFFFF0040 is available for application use.

SPI NOR Flash
: SPI NOR flash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x80000000. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

Peripheral Registers
: These are located at various addresses in the physical memory space above 0xC0000000. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

SPI NOR Flash

eCos supports QSPI access to the NOR flash on the board. The device is typically used to contain RedBoot and flash configuration data.

Accesses to SPI flash are performed via the Flash API, using 0x80000000 or as the nominal address of the device, although it does not truly exist in the processor address space.

Since SPI flash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM32 mode.

Example 275.1. cyclone5_sx Real-time characterization

```
             Startup, main thrd : stack used   380 size  1792
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    88 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    1.12 microseconds (22 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  64
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32
   Stack Size:             1088

```

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The HPS processor HAL and the ARM architectural HAL documentation should be consulted for further details.

Chapter 276. Dream Chip A10 Board Support

Name

eCos Support for the Dream Chip A10 Board — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on the Dream Chip Arria 10 SoM and baseboard Development kit. This board is fitted with avariant of the Arria 10 family of FPGAs and it therefore referred to in this document and the configuration system as the Dream Chip A10, to differentiate it from other Arria 10 development boards.

In addition to the Arria 10 FPGA, the board contains 2GiB SDRAM main memory, a 500Mib (64GiB) SPI NOR flash, a micro-SD card socket, a USB bridge connected to UART1, an Ethernet socket for an HPS Ethernet interface, plus a variety of connectors for other interfaces plus resources devoted to the FPGA. The extent of eCos support for the devices and peripherals on the board and the CPU is described below.

For typical eCos development, a RedBoot image is programmed into the SPI NOR flash memory, and the board will load this image from reset. RedBoot provides gdb stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over Ethernet. Alternatively, RedBoot may be loaded from an SD card.

Support for SMP operation of the two Cortex-A9 CPUs on the SoC is available, although debugging support is restricted to use of an external JTAG debugger. There is no SMP support in RedBoot.

This documentation is expected to be read in conjunction with the Altera HPS processor HAL documentation and further device support and subsystems are described and documented there.

Supported Hardware

The SPI NOR flash consists of 1024 blocks of 64Ki bytes each. In a typical setup, the first 16Mib are reserved for the second-level bootstrap, in this case a port of U-Boot, plus the FPGA bitstreams. The 10 blocks from 1MiB are reserved for the ROM RedBoot image. The topmost block is used to manage the flash and also holds RedBoot **fconfig** values. The remaining blocks can be used by application code.

Serial support is through the `CYGPKG_IO_SERIAL_GENERIC_16X5X` generic driver package which is modified by the `CYGPKG_IO_SERIAL_ARM_ALTERA_HPS` driver package for the HPS. These packages can support all the serial devices on the HPS. However, this board only has UART1 connected to an external connector which this HAL indicates by implementing the `CYGINT_HAL_ARM_CORTEXA_ALTERA_HPS_UART1` interface. This serial channel is used by RedBoot for communication with the host. If this device is needed by the application, either directly or via the serial driver, then it cannot also be used for RedBoot communication. Another communication channel such as Ethernet should be used instead. The serial driver package is loaded automatically when configuring for the `dreamchip-a10` target.

There is an Ethernet driver `CYGPKG_DEVS_ETH_DWC_GMAC` for the on-chip Ethernet device. A separate package, `CYGPKG_DEVS_ETH_DREAMCHIP_A10` configures this generic driver to the hardware. This driver is also loaded automatically when configuring for the `dreamchip-a10` board.

There is a watchdog driver `CYGPKG_DEVICES_WATCHDOG_DWWDT`. This driver is also loaded automatically when configuring for the board.

The HPS processor HAL contains a driver for the MultiMedia Card Interface (MMC/SD). This driver is loaded automatically when configuring `CYGPKG_DEVS_DISK_MMCSD_BUS` for this target and allows use of MultiMediaCard (MMC) and Secure Digital (SD) flash storage cards within eCos, exported as block devices. Further documentation on the driver may be found in the Altera Hard Processor System Support HAL documentation.

Note

There is no working card-detect (media change) signal available on the board for the J3 MicroSD slot.

The platform HAL provides definitions to enable access to flash devices on the SPI bus. The HAL enables the QSPI driver (CYGPKG_DEVS_FLASH_QSPI) which in turn provides the underlying implementation for access to the Micron N25Q512A SPI NOR flash. The QSPI support integrates with the CYGPKG_DEVS_FLASH_SPI_M25PXX package. These packages are automatically loaded when configuring for the target. This driver is capable of supporting the JFFS2 filesystem, although at reduced performance compared with a parallel flash device.

In general, devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (RTC, SPI, MMC/SD etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence will set up the appropriate power control and pin multiplexing configuration.

All development and testing was undertaken using the DCT10A22L20G2T4C3ES variant of the Dream Chip Arria 10 SoM and DCT10ABASE Evaluation Baseboard.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 7.3.0, arm-eabi-gdb version 8.1, and binutils version 2.30.

Name

Setup — Preparing the Dream Chip A10 board for eCos Development

Overview

In a typical development environment, the board boots from the SPI NOR and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into flash memory.

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROM	RedBoot loaded from SPI NOR flash to SDRAM	`redboot_ROM.ecm`	`redboot_ROM.bin`

For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 115200 baud. RedBoot also supports Ethernet communication and flash management.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from NOR flash by U-Boot. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to the RAM configuration which assumes that this has already been done.

Initial Installation

For eCos development we want to install RedBoot in the SPI NOR flash. The booting mechanism is that the on-chip firmware loads U-Boot from the start of NOR flash which then loads RedBoot from later in the flash.

To write RedBoot to the SPI NOR flash, you must use the command line tools from the Intel Quartus FPGA Development Tools and the SoC FPGA Embedded Development Suite. Any of the Prime, Standard or Lite versions of these tools may be used.

Programming RedBoot into NOR flash using Altera Tools

The following gives the steps needed to program RedBoot into the SPI NOR Flash using the Altera tools. This uses the **quartus_hps** flash programmer command line utility to do the work.

Note

The examples below are for a Linux host where eCosPro is typically installed in the `/opt/ecospro/ecospro-<version>` sub-directory. On a Windows host eCosPro will typically be installed in the `C:\eCosPro\ecos-<version>` sub-directory.

1. Install Quartus and the SoC EDS as described by Intel onto your host system. Quartus and EDS should be installed into the same directory if the following script is to work. Start an Embedded Command Shell by running either `<SoC EDS Installation Folder>\embedded\Embedded_Command_Shell.bat` in Windows or `<SoC EDS Installation Folder>/embedded/embedded_command_shell.sh` in Linux.

2. Ensure that there is no SD card installed.

3. Connect USB cables between the mini USB socket at J14 (used by the USB-Blaster), and the mini USB socket at J13 (used to provide serial device access) and your host. Power up the board and run a terminal emulator on your host, attaching it to the serial USB channel which should appear on your host, setting the baud rate to 115200. Attach an Ethernet cable to the RJ45 connector.

4. Run the following command on the host to detect the USB-Blaster:

```
   # jtagconfig
   1) DCT10ABASE [1-5]
     02E020DD   10AS022C(3|4)/10AS022E(3|4)
     4BA00477   SOCVHPS

   #
   ```

   It may be necessary to run this a couple of times before the above result is obtained. If the program failure persists then you should check that your EDS installation is correct.

5. If installing the prebuilt RedBoot image provided with the eCosPro release:
   change directory to `loaders/dreamchip_a10/etc/qspi_boot` within the `ecos-x.y.z` installation sub-directory.

   If installing the RedBoot image you built:
   change directory to `etc/qspi_boot` in the `install` directory.

6. Run the script `qspi_prog`. If you are running on a Windows host, you will need to run the script using the **bash** command. This will use the **quartus_hps** to program U-Boot, the FPGA bit streams and RedBoot into the QSPU flash. This script will produce a lot of output, which is not reproduced here. Monitor the output to ensure each component is written to the flash correctly.

7. Power cycle the board. Output similar to the following should be seen on the serial line:

   ```
   U-Boot 2014.10-dirty (Feb 20 2023 - 12:40:11)

   CPU   : Altera SOCFPGA Arria 10 Platform

and eCos Public License. You are welcome to change it and/or distribute copies
of it under certain conditions. Under the license terms, RedBoot's source code
and full license terms must have been made available to you.
Redboot comes with ABSOLUTELY NO WARRANTY.

Platform: Dreamchip Arria 10 SoM Development Kit (Cortex-A9)
RAM: 0x00000000-0x40000000 [0x0017be78-0x3fd2d000 available]
  Arena: base 0x3fe00000, size 0x200000, 99% free, maxfree 0x1fffec
FLASH: 0x80000000-0x83ffffff, 1024 x 0x10000 blocks
RedBoot>
```

8. Run the following commands to initialize RedBoot's flash file system and flash configuration:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
... Erase from 0x83ff0000-0x83ffffff: .
... Program from 0x3fdf0000-0x3fe00000 to 0x83ff0000: .
RedBoot>
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address: 10.0.1.1
Console baud rate: 115200
DNS domain name: calivar.com
DNS server IP address: 10.0.0.5
Network hardware address [MAC] for eth0: 0x12:0x34:0xAA:0xBB:0xCC:0xEE
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Default network device: dwc_gmac
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x83ff0000-0x83ffffff: .
... Program from 0x3fdf0000-0x3fe00000 to 0x83ff0000: .
RedBoot>
```

   You should substitute your own server IP address for the one shown above. You may also want to change the MAC address if more than one board is present on the network. If you want to use a static IP address, then choose false for the "Use BOOTP" option and enter the gateway, IP address and netmask that you have assigned.

The RedBoot installation is now complete. Power cycling the board should show

```

Booting RedBoot from an SD card

The following gives the steps needed to run RedBoot from an SD card. This does not need any tools from Quartus.

Notes:

1. These instructions are only applicable to developers running on a Linux host.
2. eCosPro is typically installed in the `/opt/ecospro/ecospro-<version>` sub-directory.

1. Insert a blank SD card into an SD card drive on your host machine and identify the device name by either monitoring the system messages or using **lsblk**.

2. Connect USB cables between the mini USB socket at J14 (used by the USB-Blaster), and the mini USB socket at J13 (used to provide serial device access) and your host. Run a terminal emulator on your host, attaching it to the serial USB channel which should appear on your host, setting the baud rate to 115200. Attach an Ethernet cable to the RJ45 connector.

3. If installing the prebuilt RedBoot image provided with the eCosPro release:
   change directory to `loaders/dreamchip_a10/etc/sd_boot` within the `ecos-x.y.z` installation sub-directory.

   If installing the RedBoot image you built:
   change directory to `etc/sd_boot` in the `install` directory.

4. Run the script `sd_prog` as root giving it the name of the SD device as an argument. For example **sudo ./sdcard_build /dev/sdx**. This will format the SD card and copy U-Boot, the FPGA bit streams and RedBoot on to it. flash. The script should produce output similar to the following:

```
$ sudo ./sdcard_build /dev/sdh
1024+0 records in
1024+0 records out
1048576 bytes (1.0 MB, 1.0 MiB) copied, 0.261784 s, 4.0 MB/s
Checking that no-one is using this disk right now ... OK

Disk /dev/sdh: 14.84 GiB, 15931539456 bytes, 31116288 sectors
Disk model: MassStorageClass
Units: sectors of 1 * 512 = 512 bytes
Sector size (logical/physical): 512 bytes / 512 bytes
I/O size (minimum/optimal): 512 bytes / 512 bytes

RedBoot>
```

7. Due to the different FPGA bitstreams, The SD card version of RedBoot cannot access the QSPI flash. Consequently any configuration such as Ethernet MAC address or IP address must be configured in to the RedBoot executable.

If it proves necessary te reinstall RedBoot then rerunning the above script is the simplest approach. Alterntively the first partition on the SD card can be mounted on the host and the new RedBoot executable copied over.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the Dream Chip A10 are:

```
$ mkdir redboot_dreamchip_a10_rom
$ cd redboot_dreamchip_a10_rom
$ ecosconfig new dreamchip_a10 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/cortexa/dreamchip_a10/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This is a binary file that includes a header needed by the preloader to load and run RedBoot successfully.

These instructions build a RedBoot that can be booted from the QSPI flash. To build a RedBoot to boot from SD, use `redboot_ROM_SD.ecm` in the above import command.

Name

Configuration — Platform-specific Configuration Options

Overview

The Dream Chip A10 platform HAL package is loaded automatically when eCos is configured for the `dreamchip-a10` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three startup types:

RAM
: This is the startup type which is normally used during application development. The board has RedBoot programmed into flash and boots into that initially. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into Flash. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type can also be used for applications loaded via JTAG.

SMP
: This startup type can be used for finished applications that can be loaded into RAM via RedBoot. The load address is set to the same as for RAM applications, however, the application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. Once started, this application takes full control of the system and RedBoot will not be called again. This means that debugging via RedBoot will not be possible, only JTAG-based hardware debugging is supported. The intent of this startup type is to allow SMP test programs to be run from RedBoot, most SMP applications should use the ROM startup type. This startup type can also be used for applications loaded directly via JTAG.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

Flash Driver

The Dream Chip A10 board contains a 64Mbyte Micron SPI serial NOR flash device attached to the QSPI controller. The `CYGPKG_DEVS_FLASH_SPI_M25PXX` package contains all the code necessary to support this part and the platform HAL package contains definitions that customize the driver to the Dream Chip A10. This driver is not active until the generic Flash support package, `CYGPKG_IO_FLASH`, is included in the configuration.

This driver is capable of supporting the JFFS2 filesystem. However, note that the SPI interface means that this file system has reduced bandwidth and increased latency compared with other implementations. All that is required to enable the support is to include the filesystem (`CYGPKG_FS_JFFS2`) and any of its package dependencies (including `CYGPKG_IO_FILEIO` and `CYGPKG_LINUX_COMPAT`) together with the flash infrastructure (`CYGPKG_IO_FLASH`).

Ethernet Driver

The board uses the HPS's internal GMAC Ethernet device attached to an external Micrel KSZ9021 Gigabit PHY. The `CYGPKG_DEVS_ETH_DWC_GMAC` package contains all the code necessary to support this device and the `CYGPKG_DEVS_ETH_DREAMCHIP_A10` package contains definitions that customize the driver to the board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

Support for PHY events is made available by default when the Kernel (`CYGPKG_KERNEL`) is available in a configuration.

Watchdog Driver

The board uses the HPS's internal watchdog support. The `CYGPKG_DEVICES_WATCHDOG_DWWDT` package contains all the code necessary to support this device. Within that package the `CYGNUM_DEVS_WATCHDOG_DWWDT_DESIRED_TIMEOUT_MS` configuration option controls the watchdog timeout, and by default will force a reset of the board upon timeout. This driver is not active until the generic watchdog device support package, `CYGPKG_IO_WATCHDOG`, is included in the configuration.

UART Serial Driver

The board uses the HPS's internal UART serial support as described in the HPS processor HAL documentation. Only one serial connector is available on the board, which is connected to UART1 via a USB bridge. Only the UART data lines are connected to the bridge, so hardware flow control is not supported.

MMC/SD Driver

As the Dream Chip A10 MMC/SD driver is part of the HPS processor HAL, nothing is required to load it. Similarly the MMC/SD bus driver layer (`CYGPKG_DEVS_DISK_MMC`) is automatically included as part of the hardware-specific configuration for this target. All that is required to enable the support is to include the generic disk I/O infrastructure package (`CYGPKG_IO_DISK`), along with the intended filesystem, typically, the FAT filesystem (`CYGPKG_FS_FAT`) and any of its package dependencies (e.g. for FAT also including `CYGPKG_LIBC_STRING` and `CYGPKG_LINUX_COMPAT` packages).

Various options can be used to control specifics of the MMC/SD driver. Consult the HPS processor HAL documentation for information on its configuration.

This board does not have a working MMC/SD card detect for MicroSD socket (J3), thus the disk I/O layer's removeable media support is not available.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. The following flags are specific to this port:

`-mcpu=cortex-a9`
The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use, and with current tools `-mcpu=cortex-a9` is the correct option for the CPU in the HPS.

`-mthumb`
The arm-eabi-gcc compiler will compile C and C++ files into the Thumb2 instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

`-mno-unaligned-access`
The Cortex-A CPU allows unaligned memory accesses and the default for arm-eabi-gcc is to generate instructions that make unaligned accesses. However, for this port, alignment exceptions are enabled, so unaligned accesses should not be made. This option disables un-

aligned accesses. Note that there is a performance and code size cost in doing this, since all accesses to unaligned data must now be made using individual byte accesses.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, including RedBoot. Only ROM configuration applications should be debugged using JTAG, RAM applications assume the presence of RedBoot.

OpenOCD notes

OpenOCD support is available for loading and running ROM or SMP startup applications. Single CPU applications can be debugged via OpenOCD but SMP support is not currently available.

An OpenOCD configuration file, `openocd.dreamchip_a10.cfg`, is available in the `misc` subdirectory of the platform hal subdirectory. This will be installed as `etc/openocd.cfg` in the `install` subdirectory when building the eCos libarary for use by the eCos GUI Configuration Tool or Eclipse when running tests or debugging your application respectively. This openocd configuration file should be used with a recent release of OpenOCD.

Name

SMP Support — Usage

Overview

Support is available for SMP operation of the two CPUs on this platform. However, debugging support is restricted to using an external SMP-aware JTAG debugger like ARM's DS-5 or a Lauterbach Power Debug probe. RedBoot does not have support for multi-core debugging.

A board intended to be used for SMP operation should be initialized in the same way as a single core board by installing the preloader and RedBoot. If RedBoot is not needed then the preloader must still be installed and a ROM startup application, with headers added by **flashimg**, can be written to flash in place of RedBoot.

SMP support is enabled by setting `CYGPKG_KERNEL_SMP_SUPPORT` to true. SMP applications should only be built using either ROM or SMP startup types. ROM applications can be loaded by U-Boot in place of RedBoot. The SMP startup is identical to a ROM startup except that the load address is set to allow the application to be loaded into a higher location in RAM from RedBoot. Both application types may also be loaded via a JTAG debugger.

Loading an SMP startup application via RedBoot can be done from the RedBoot command line via serial or Ethernet. It may also be loaded via a GDB connection on serial or Ethernet. However, once started running the SMP application will take full control of the system, including redirecting all interrupt sources, exception vectors and virtual vector table entries. This means that RedBoot will no-longer be active. Any breakpoints planted by GDB will result in an exception to the application, Ctrl-C will not work, any Ethernet connections will be lost and serial output will come from the application in plain ASCII. Any GDB connection will be lost and GDB may start reporting packet errors.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Dream Chip A10 hardware, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the Cortex-A variant HAL and the Altera HPS processor HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM startup, the HAL will perform additional initialization. This is all done in the `PLATFORM_SETUP1` macro in the assembler header file `hal_platform_setup.h`.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM
: This is located at address 0x00000000 of the physical memory space. The SDRAM is 2GiB in size, although only the first 1GiB is used by eCos. The HAL configures the MMU to retain the SDRAM at virtual address 0x00000000 with caching enabled. The same memory is also accessible uncached and unbuffered at virtual location 0x40000000 for use by device drivers. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x00010000 to 0x00014000. For ROM startup, all remaining SDRAM is available, although ROM applications actually load from 0x00100000. The virtual vector table is allocated as part of the RedBoot image and occupied 256 bytes from 0x00000050. RAM startup applications are loaded from location 0x00200000, reserving 1MiB for RedBoot.

SPI NOR Flash
: SPI NOR flash media can only be accessed with the Flash API. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is 0x80000000. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

Peripheral Registers
: These are located at various addresses in the physical memory space above 0xC0000000. When the MMU is enabled, it sets up a direct, uncached, unbuffered mapping so that these registers remain accessible at their physical locations.

SPI NOR Flash

eCos supports QSPI access to the NOR flash on the board. The device is typically used to contain RedBoot and flash configuration data.

Accesses to SPI flash are performed via the Flash API, using 0x80000000 or as the nominal address of the device, although it does not truly exist in the processor address space.

Since SPI flash is not directly addressable, access from RedBoot is only possible using **fis** command operations.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM32 mode.

Example 276.1. dreamchip_a10 Real-time characterization

```
             Startup, main thrd : stack used   404 size  2304
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    96 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    1.00 microseconds (1 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  64
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32
   Stack Size:             1088

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The HPS processor HAL and the ARM architectural HAL documentation should be consulted for further details.

Chapter 277. Atmel ATSAMA5D3 Variant HAL

Name

`CYGPKG_HAL_ARM_CORTEXA_SAMA5D3` — eCos Support for the Atmel SAMA5D3 Microprocessor Family

Description

This document covers the configuration and usage of the Hardware Abstraction Layer (HAL) for the Atmel SAMA5D3 series of Cortex-A5 microcontrollers. It is expected to be read in conjunction with platform HAL-specific documentation, as well as the eCos HAL specification. This processor package complements the ARM architectural HAL, Cortex-A variant HAL and the platform HAL. It provides functionality common to all SAMA5D3-based implementations.

This support is found in the eCos package located at `packages/hal/arm/cortexa/sama5d3/var` within the eCos source repository.

The SAMA5D3 HAL package is loaded automatically when eCos is configured for a SAMA5D3-based platform. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

The Cortex-A5 CPU uses the common ARM Cortex-A package which provides run-time support for cache, MMU, etc. The Cortex-A5 has full application compatability with Cortex-A8, Cortex-A9, and Cortex-A15 processors, but in a smaller, lower power, package.

In addition to the core CPU support, the SAMA5D3 processor variant package provides common functionality and definitions that SAMA5D3 based platforms may require, as well as definitions useful to application developers.

The platform HAL documentation Setup section gives an overview of hardware debugging support, e.g. PEEDI, J-Link, etc.

Name

SAMA5D3 hardware definitions — Details on obtaining hardware definitions for SAMA5D3

Register definitions

The file `<cyg/hal/sama5d3.h>` can be included from application and eCos package sources to provide definitions related to SAMA5D3 subsystems. These include register definitions for the interrupt controller, power management controller, clock generator, memory controller, external bus interface, GPIO, USART, and other subsystems.

Initialization helper macros

The file `<cyg/hal/sama5d3_init.inc>` contains definitions of helper macros which may be used by SAMA5D3 platform HALs in order to initialise common subsystems without excessive duplication between the platform HALs. Typically this file will be included by the `hal_platform_setup.h` header in the platform HAL, in turn included from the architectural HAL file `vectors.S`.

This file is solely intended to be used by platform HALs. At the same time, it is only present to assist initialization, and platform HALs are not obliged to use it if their startup requirements vary.

Name

Bootstrap — System startup

Overview

The BMS signal to the CPU controls the initial system bootstrap selection. This is used in conjunction with the OTP (FUSE) on-chip configuration, and reset “input” pin state, to select the boot source for the CPU.

Table 277.1. BMS signal

BMS signal	Description
BMS_BIT=0	The embedded (on-chip) `RomBOOT` first-level bootloader is used. The actual boot source used will depend on the presence of suitable binaries on the sources scanned by the `RomBOOT` code. The first acceptable binary is loaded into SRAM and executed. If no valid non-volatile-memory (NVM) binary is found then the `RomBOOT` will enter the Atmel SAM-BA monitor.
BMS_BIT=1	The application installed on the EBI_CS0 device is executed in-situ. The on-chip `RomBOOT` configures the chip-select for 12MHz RC access prior to executing the code mapped from address 0x00000000.

The “Standard Boot Strategies” section of the SAMA5D3 Series Datasheet provides details about the boot sequence configuration, and should be read in conjunction with this documentation.

The hardware platform documentation should be read in conjunction with this generic SAMA5D3 CPU documentation with regards to specific jumper settings that may affect the bootstrap code executed.

For some designs directly booting from an `EBI_CS0` memory-mapped device is the simplest option. However, making use of the SAMA5D3 `RomBOOT` world to load a small second-level boot loader allows the easier possibility of providing support for in-field upgrades and selection of multiple application images.

Note

When `BMS_BIT=1` and code is started from the `EBI_CS0` device then the Atmel Secure Boot functionality is not available.

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

On-chip Memory

The Atmel SAMA5D3 parts include 128K of on-chip SRAM for general application use. Other SRAM memory exists as part of specific on-chip I/O controllers and may be available for general purpose use if the corresponding I/O is not being used (e.g. NFC SRAM), though eCos by default does not provide explicit support for such use.

The SAMA5D3 parts also provide I/O controllers which allow access to various external memory types, which eCos may use where supported by the relevant platform HAL. Application execution is normally based on such external memory due to the limited size of the on-chip SRAM available.

Interrupts

The SAMA5D3 HAL provides interrupt support via the on-chip Advanced Interrupt Controller.

Interrupt controller definitions

The file `<cyg/hal/sama5d3_ints.h>` (located at `hal/arm/cortexa/sama5d3/var/`*`VERSION`*`/include/sama5d3_ints.h` in the eCos source repository) contains interrupt vector number definitions for use with the eCos kernel and driver interrupt APIs.

It should be noted that further decoding is performed on the multiplexed system `CYGNUM_HAL_INTERRUPT_SYS` interrupt to identify the cause more specifically. Note that as a result, placing an interrupt handler on the `CYGNUM_HAL_INTERRUPT_SYS` interrupt will not work as expected. Conversely, masking a decoded derivative of the `CYGNUM_HAL_INTERRUPT_SYS` interrupt will not work as this would mask other `CYGNUM_HAL_INTERRUPT_SYS` interrupts, but masking the `CYGNUM_HAL_INTERRUPT_SYS` interrupt itself will work. On the other hand, unmasking a decoded `CYGNUM_HAL_INTERRUPT_SYS` interrupt *will* unmask the `CYGNUM_HAL_INTERRUPT_SYS` interrupt as a whole, thus unmasking interrupts for the other units on this shared interrupt.

If the CDL option `CYGHWR_HAL_ARM_CORTEXA_SAMA5D3_PIO_DEMUX` is configured then the variant HAL also provides support for de-multiplexing PIO interrupt sources, allowing the standard eCos interrupt system to be used to control the use of individual PIO pin interrupt handlers. This support avoids the need for the developer to manually handle multiple active interrupt PIO pins on a single controller vector ISR function, and as such the feature is normally recommended. However for very small memory footprint systems the RAM overhead of maintaining a significantly increased set of ISR descriptor vectors may be deemed inappropriate, and so the developer is free to disable the extension and manually support the base per-controller `CYGNUM_HAL_INTERRUPT_PIO#` shared interrupt source as required for their PIO interrupt requirements.

Note

If the variant demultiplexing support is disabled then certain standard drivers may have restricted functionality on specific platforms if they depend on using the per-pin interrupt support for certain features.

The list of interrupt vectors may be augmented on a per-platform basis. Consult the platform HAL documentation for your platform for whether this is the case.

Interrupt controller Functions

The source file `src/sama5d3_misc.c` within this package provides most of the support functions to manipulate the interrupt controller. The `hal_IRQ_handler` queries the IRQ status register to determine the interrupt cause. Functions `hal_interrupt_mask` and `hal_interrupt_unmask` enable or disable interrupts within the interrupt controller.

Interrupts are configured in the hal_interrupt_configure function, where the level and up arguments are interpreted as follows:

level	up	interrupt on
0	0	Falling Edge
0	1	Rising Edge
1	0	Low Level
1	1	High Level

To fit into the eCos interrupt model, interrupts essentially must be acknowledged immediately once decoded. The hal_interrupt_acknowledge function explicitly acknowledges the PIO controller interrupt sources.

The hal_interrupt_set_level is used to set the priority level of the supplied interrupt within the Advanced Interrupt Controller.

Note that in all the above, it is not recommended to call the described functions directly. Instead either the HAL macros (HAL_INTERRUPT_MASK et al) or preferably the kernel or driver APIs should be used to control interrupts.

Using the Advanced Interrupt Controller for VSRs

The SAMA5D3 HAL has been designed to exploit benefits of the on-chip Advanced Interrupt Controller (AIC) on the SAMA5D3. Support has been included for exploiting its ability to provide hardware vectoring for VSR interrupt handlers.

The interrupt decoding path has been optimised by allowing the AIC to be interrogated for the interrupt handler VSR to use. These vectored interrupts are by default still configured to point to the default ARM architecture HAL IRQ and FIQ VSRs. However applications may set their own VSRs to override this default behaviour to allow optimised interrupt handling.

The VSR vector numbers to use when overriding are also defined in the <cyg/hal/sama5d3_ints.h> header. Consult the kernel and generic HAL documentation for more information on VSRs and how to set them.

Interrupt handling withing standalone applications

For non-eCos standalone applications running under RedBoot, it is possible to install an interrupt handler into the interrupt vector table manually. Memory mappings are platform-dependent and so the platform documentation should be consulted, but in general the address of the interrupt table can be determined by analyzing RedBoot's symbol table, and searching for the address of the symbol name hal_interrupt_handlers. Table slots correspond to the interrupt numbers as detailed above. Pointers inserted in this table should be pointers to a C/C++ function with the following prototype:

```
extern unsigned int isr( unsigned int vector, unsigned int data );
```

For non-eCos applications run from RedBoot, the return value can be ignored. The vector argument will also be the interrupt vector number. The data argument is extracted from a corresponding table named hal_interrupt_data which immediately follows the interrupt vector table. It is still the responsibility of the application to enable and configure the interrupt source appropriately if needed.

Periodic Interval Timer

The eCos kernel system clock is implemented using the Periodic Interval Timer (PIT) controller. By default, the system clock interrupts once every 10ms, corresponding to a 100Hz clock. This can be changed by the configuration option CYGNUM_HAL_RTC_DENOMINATOR which corresponds to the clock frequency. Other clock-related settings are recalculated automatically if the denominator is changed. If the desired frequency cannot be expressed accurately solely with changes to CYGNUM_HAL_RTC_DENOMINATOR, then the configuration option CYGNUM_HAL_RTC_NUMERATOR may also be adjusted, and again clock-related settings will automatically be recalculated.

The PIT is also used to implement the HAL microsecond delay function, HAL_DELAY_US. This is used by some device drivers, and in non-kernel configurations such as with RedBoot where this timer is needed for loading program images via X/Y-modem protocols and debugging via TCP/IP. Standalone applications which require RedBoot services, such as debugging, should avoid use of this timer.

GPIO

The variant HAL provides support for packaging the configuration of a GPIO line into a single 32-bit descriptor that can then be used with macros to configure the pin and set and read its value. Details are supplied later.

RTC/Wallclock

eCos includes RTC (known in eCos as a wallclock) device drivers for the on-chip RTC in the SAMA5D3 family. This support is located in the package `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91` ("AT91 wallclock driver"). Normally this package is included automatically by the relevant platform HAL.

Profiling Support

The SAMA5D3 HAL contains support for **gprof**-based profiling using a sampling timer. The default timer used is channel 0 of Timer 0 (`CYGHWR_HAL_SAMA5D3_TC0`). This timer is only enabled when the gprof profiling package (`CYGPKG_PROFILE_GPROF`) is included and enabled in the eCos configuration, otherwise it remains available for application use.

Not all SAMA5D3 variants have multiple timer blocks. For example, when targetting the SAMA5D31 variant, only `TC0` is available and so profiling support may not be possible if the application requires the use of that timer block.

Serial I/O

The SAMA5D3 variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_ARM_AT91` which provides all support for the SAMA5D3 on-chip serial devices. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor or RedBoot for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

The HAL defines CDL interfaces for each of the available UARTs, `CYGINT_HAL_ARM_CORTEXA_SAMA5D3_DBGU`. `CYGINT_HAL_ARM_CORTEXA_SAMA5D3_USART0` to `CYGINT_HAL_ARM_CORTEXA_SAMA5D3_USART3`, and (if available for the target CPU) `CYGINT_HAL_ARM_CORTEXA_SAMA5D3_UART0` and `CYGINT_HAL_ARM_CORTEXA_SAMA5D3_UART1`. The platform HAL CDL should contain an **implements** directive for each such UART that is available for use on the board. This will enable use of the UART for diagnostic use.

The SAMA5D3 UARTs provide TX and RX data lines plus hardware flow control using RTS/CTS for those UARTs that have them available and connected.

SPI

The platform HAL provides definitions to allow access to devices on the SPI buses. The HAL provides information to the general AT91 SPI driver (`CYGPKG_DEVS_SPI_ARM_AT91`) which in turn provides the underlying implementation for the SPI API layer in the `CYGPKG_IO_SPI` package. All these packages are automatically loaded when configuring for the board.

The SAMA5D3 variant implements the SPI buses as configured for the platform:

- `cyg_spi_at91_bus0`
- `cyg_spi_at91_bus1`

The platform specific HAL may implement specific SPI device instances as relevant for the underlying hardware. e.g. SPI Dataflash devices.

Two-Wire Interface (TWI)

The CYGPKG_DEVS_I2C_ATMEL_TWI package implements a Two-Wire Interface (TWI) driver for the TWI controllers present on the SAMA5D3 family of devices. This type of bus is also known as I²C®. The generic API for this driver may be found within the CYGPKG_IO_I2C package, along with the API documentation. The CYGPKG_DEVS_I2C_ATMEL_TWI hardware package is normally included by default when configuring a SAMA5D3 platfornm, and so does not need to be manually added to a configuration.

Support for TWI functionality is controlled within the SAMA5D3 variant HAL via the CYGPKG_HAL_ARM_CORTEXA_SAMA5D3_I2C CDL component. The component controls, via sub-options, whether TWI driver support is enabled for the different on-chip TWI buses available.

For each individual bus that is available the driver package itself provides the CYGNUM_DEVS_I2C_ATMEL_TWI*x*_CLOCK option to configure the TWI bus clock speed, where *x* is replaced by the relevant bus number.

The driver package implements the necessary I²C bus instances as appropriate:

- hal_atmel_i2c_bus0
- hal_atmel_i2c_bus1
- hal_atmel_i2c_bus2

The platform or application code can then register devices attached tospecific buses as needed.

MCI (MMC/SD card controller)

If a suitable socket or sockets exist, the platform HAL may provide definitions to allow use of MMC or SD cards accessed using the on-chip Multimedia Card Interface (MCI) peripheral block. The SAMA5D3 processor has support for up to three independent high speed MCI (HSMCI) controllers; although at present in eCos, only one may be configured for use, fixed at configuration time.

The device driver itself is found in the separate package CYGPKG_DEVS_MMCSD_ATMEL_SAM_MCI, which is loaded automatically when selecting any platform supporting it, and further documentation can be found in that package. Typically, disk support (CYGPKG_IO_DISK), generic filesystem support (CYGPKG_IO_FILEIO) and a filesystem such as FAT (CYGPKG_FS_FAT along with its prerequisite CYGPKG_LINUX_COMPAT) are then added to allow application use.

Features such as card insertion/removal detection, SDIO or write protection detection are hardware and platform specific, and platform documentation should be consulted for more information on those features.

USB

The platform HAL provides definitions to the general USB controller driver (CYGPKG_DEVS_USB_AT91) which in turn provides the underlying implementation for the USB API layer (CYGPKG_IO_USB).

The driver layer supports both OHCI host functionality via the CYGPKG_DEVS_USB_OHCI package, allowing peripheral devices to be attached to an eCos “host”, and for device functionality via the CYGPKG_DEVS_USB_PCD_UDPHS package, where the eCos application implements the peripheral device support for attaching to an external host.

All the necessary hardware packages are automatically loaded when configuring for the board. However, the top-level CYGPKG_IO_USB package needs to be included and configured when USB functionality is required.

OHCI

The CYGPKG_DEVS_USB_OHCI package implements the generic parts of the OHCI (host controller) support, and in conjunction with the platform specific driver and the CYGPKG_IO_USB package allows eCos to act as a “host” for attached USB devices.

The eCos USB host stack includes a number of class drivers and the ability for users to write additional ones using the eCos USB host API. See the USB chapter for further details, including a complete listing of supported classes.

Device

The CYGPKG_DEVS_USB_PCD_UDPHS package implements the generic parts of the Atmel UDPHS (USB High Speed Device Port) peripheral controller support, and in conjunction with the CYGPKG_IO_USB package provides support for implementing USB device/peripheral class drivers.

The USB chapter provides target mode stack details including a list of supported device/peripheral class drivers and information related to adding new class drivers.

Clock Control

Depending on how an eCos SAMA5D3 application is started will influence the CPU and peripheral clock frequencies used for application execution. For ROM startup, or SRAM when started by the on-chip RomBOOT, the eCos configuration supplied CYGHWR_HAL_ARM_CORTEXA_SAMA5D3_CLOCK_PLL_DIVA and CYGHWR_HAL_ARM_CORTEXA_SAMA5D3_CLOCK_PLL_MULA options, in conjunction with the platform supplied CYGHWR_HAL_ARM_CORTEXA_SAMA5D3_OSC_MAIN value, will be used to set the CPU and I/O clock frequencies. For the ROMRAM and RAM startup types the clock frequenies in effect when the application is loaded (either via another application, debug monitor of hardware debugger) are used. As such, the SAMA5D3 variant HAL provides access to variables that hold the currently configured clock frequencies:

```
cyg_uint32 hal_sama5d3_slck;   // SLCK
cyg_uint32 hal_sama5d3_mainck; // MAINCK
cyg_uint32 hal_sama5d3_pllack; // PLLA frequency
cyg_uint32 hal_sama5d3_upllck; // UPLL frequency
cyg_uint32 hal_sama5d3_pclk;   // Processor clock
cyg_uint32 hal_sama5d3_mclk;   // Main peripheral clock
```

It is not expected that applications will need to interpret or use the values, but the HAL makes use of the values to ensure valid clock configurations are used.

Name

GPIO Support on SAMA5D3 processors — Details

Synopsis

#include <cyg/hal/hal_io.h>

cyg_uint32 pin = **CYGHWR_HAL_SAMA5D3_PIN**(*port*, *bit*, *mode*, *md*, *pupd*, *if*, *int*, *conf*);

cyg_uint32 pin = **CYGHWR_HAL_SAMA5D3_PIN_OUT**(*port*, *bit*, *md*, *pupd*);

cyg_uint32 pin = **CYGHWR_HAL_SAMA5D3_PIN_IN**(*port*, *bit*, *md*, *pupd*, *if*, *int*);

CYGHWR_HAL_SAMA5D3_PIN_SET (*pin*);

CYGHWR_HAL_SAMA5D3_GPIO_OUT (*pin*, *val*);

CYGHWR_HAL_SAMA5D3_GPIO_IN (*pin*, *val*);

Description

The SAMA5D3 HAL provides a number of macros to support the encoding of the GPIO pin identity and I/O configuration into a single 32-bit descriptor. This is useful to drivers and other packages that need to configure and use different lines for different devices.

A descriptor is created with one of the 3 variants depending on how the pin is to be used. The support is implemented by the CYGHWR_HAL_SAMA5D3_PIN macro, with CYGHWR_HAL_SAMA5D3_PIN_IN and CYGHWR_HAL_SAMA5D3_PIN_OUT being shorthand helpers when direct control of a pin is required: CYGHWR_HAL_SAMA5D3_PIN_IN defines the pin as an input whose value can be accessed by the user using the macro CYGHWR_HAL_SAMA5D3_GPIO_IN (see later), CYGHWR_HAL_SAMA5D3_PIN_OUT defines the pin as an output where the user can set the pin output value with the macro CYGHWR_HAL_SAMA5D3_GPIO_OUT (see later).

The CYGHWR_HAL_SAMA5D3_PIN macro can be used when defining a pin that will be controlled by an on-chip peripheral.

Note

The HAL supplied header file sama5d3.h provides existing configuration definitions for the majority of the on-chip peripherals supported by eCos, thus obviating the need for the developer to provide their own pin definitions.

The macro variants take a subset of arguments from the following list:

port
: This identifies the PIO controller to which the pin is attached. Ports are identified by letters from A to E.

bit
: This gives the bit, or pin number, within the controller port. These are numbered from 0 to 31.

mode
: This parameter indicates whether the pin is controlled by an on-chip peripheral, or is to be used as a GPIO pin under application control.

Table 277.2. Pin Mode

mode	Details
GPIOIN	The pin is to be configured as an INPUT, and after configuration the CYGHWR_HAL_SAMA5D3_GPIO_IN macro can be used to ascertain the pin state.

mode	Details
GPIOOUT	The pin is to be configured as an OUTPUT, and after configuration the CYGHWR_HAL_SAMA5D3_GPIO_OUT macro can be used to drive the pin level.
PER_A, PER_B, PER_C, PER_D	The required peripheral mapping when the pin is to be assigned to an on-chip peripheral. The multiplexing of peripheral signals is defined by the CPU variant being targetted, and is beyond the scope of this documentation. When creating pin configurations for on-chip peripherals the relevant Atmel datasheet or technical reference manual should be consulted.

md
: This setting indicates whether the pin should be driven in open-drain mode (OPENDRAIN). If the pin is not to be configured as OPENDRAIN this value is unused, but for clarity can be given the setting NA.

pupd
: If this is an input pin, or an output pin configured in open-drain mode (whether controlled by GPIO or a peripheral), this setting can be used to indicate whether a weak pull-up resistor (PU) is used, or a weak pull-down resistor (PD) is used. If neither are to be used, then a value of NONE can be given.

if
: For input pins (GPIO or peripheral) a glitch (GLITCH) or debouncing (DEBOUNCE) filter can be configured for the pin. When no input filtering is required, or when the field is not relevant due to the other pin configuration fields, the value NONE can be specified.

int
: This parameter indicates whether the pin should have an interrupt configuration defined.

Table 277.3. Interrupt Type

int	Details
EDGE_ANY	When an interrupt event should be raised on a pin edge event (rising or falling).
EDGE_RISE	An interrupt should only be raised on rising (LOW->HIGH) edge transitions.
EDGE_FALL	An interrupt should only be raised on falling (HIGH->LOW) edge transitions.
LEVEL_HIGH	Interrupts should be asserted when the pin is at a HIGH level.
LEVEL_LOW	Interrupts should be asserted when the pin is at a LOW level.
NA	This value can be used when an interrupt configuration is not required, or not applicable due to the other pin configuration parameters.

conf
: This parameter provides a simple “extension” mechanism; and is treated as a 32-bit binary value that is OR-ed into the pin descriptor. Care must be taken to ensure that existing bitfields within the binary descriptor are not corrupted.

The following examples show how these macros may be used:

```
// Define port B pin 28 as being controlled by peripheral multiplex A,
// which for this pin on SAMA5D3 devices is USART1, without any
// pull-ups/pull-downs:
#define CYGHWR_HAL_SAMA5D3_USART1_RXD CYGHWR_HAL_SAMA5D3_PIN(B,28,PER_A,OPENDRAIN,NONE,NONE,NA,(0))

// Define port E pin 24 as a GPIO output with a pull-down, for an
// active-low LED:
#define CYGHWR_HAL_SAMA5D3_LED_RED CYGHWR_HAL_SAMA5D3_PIN_OUT(E,24,NA,PD)
```

Additionally, the manifest CYGHWR_HAL_SAMA5D3_PIN_NONE may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used. This can be useful when defining pin configurations for a series of instances of a peripheral (e.g. USART ports), but where not all instances support all the same pins (e.g. hardware flow control lines).

The remaining macros all take a suitably constructed GPIO pin descriptor as an argument. The CYGHWR_HAL_SAMA5D3_PIN_SET macro configures the pin according to the descriptor and must be called before any other macros. CYGHWR_HAL_SAMA5D3_GPIO_OUT sets the output to the value of the least significant bit of the *val* argument. The *val* argument of CYGHWR_HAL_SAMA5D3_GPIO_IN should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

Further helper macros are available, and it is recommended to consult the header file <cyg/hal/sama5d3.h> (also present in the include subdirectory of the SAMA5D3 variant HAL package within the eCos source repository), for the complete list if needed.

The Interrupt controller definitions section provides an overview of variant support for demultiplexing PIO interrupts.

Name

Peripheral clock control — Details

Synopsis

#include <cyg/hal/hal_io.h>

`cyg_uint32` **`CYGHWR_HAL_ATMEL_CLOCK_ENABLE`**`(`*`pid`*`);`

`CYGHWR_HAL_ATMEL_CLOCK_DISABLE` `(`*`pid`*`);`

Description

The HAL provides macros which may be used to enable or disable peripheral clocks. Effectively this indicates whether the peripheral is powered on (enabled) or powered down (disabled), and so may be used to ensure unused peripherals are turned off to save power. The `CYGHWR_HAL_ATMEL_CLOCK_ENABLE` macro will enforce the maximum frequency limitations for particular peripheral blocks, and will return the frequency of the clock used for the enabled periperhal. Such frequency information may be useful to device drivers if clock divider configuration is required.

It is important to remember that before a peripheral can be used, it must be enabled. It is safe to re-enable a peripheral that is already enabled, although usually a device driver will only do so once in its initialisation. eCos will automatically initialise some peripheral blocks where it needs to use the associated peripherals (such as memory controllers and some (but usually not all) PIO banks), and in eCos-supplied device drivers which are included in the eCos configuration. However this should not be relied on - it is always safest to enable the peripheral clocks anyway just in case. Finally, remember that each PIO bank must be enabled separately.

Each peripheral has a unique ID defined by the HAL, and these values are used as the *`pid`* parameter to the enable and disable macros.

Name

DMA Support — Details

Description

The package `CYGPKG_DEVS_DMA_ATMEL_DMAC` implements the DMA support for the eCos run-time, and the documentation for that package should be referenced as appropriate.

The DMAC package is automatically loaded when eCos is configured for a SAMA5D3-based platform. It should never be necessary to load this package explicitly.

Name

Configuration — Common SAMA5D3 configuration options

Overview

Startup

The SAMA5D3 variant HAL package supports four separate startup types for application configuration:

ROMRAM

> This startup type is for *stand-alone* applications that are loaded into external DDR2-SDRAM via a second-level boot loader (e.g. the default SAMA5D3x-CM based AT91BootLoader, or the eCosPro `BootUp` loader), or via a JTAG/SWD hardware debugger. The data and BSS areas will be put into suitable memory locations as defined by the relevant platform HAL linker script. The application will be self-contained with no dependencies on services provided by other software. The eCos startup code will perform all necessary hardware initialization.
>
> ### Note
>
> The application is copied from its persistent location by the second-level application bootloader, or is directly loaded to RAM via a JTAG/SWD hardware debugger. The `ROMRAM` startup code does not perform the copy to RAM itself.

SRAM

> This startup type is used for *stand-alone* applications. The application will be loaded from a suitable supported “bootable” device by the on-chip first-level (`RomBOOT`) bootloader, or directly via a hardware (JTAG/SWD) debugger. The application will be self-contained with no dependencies on services provided by other software. It is not envisaged that the `SRAM` startup type will normally be used for full applications, primarily being used for developing `RomBOOT` loaded second-level bootloaders. However, it can be useful for small platform verification tests loaded via JTAG.

ROM

> This startup type is used for *stand-alone* applications which will be programmed into bootable memory located in the EBI_CS0 space from 0x10000000. The data and BSS areas will be put into suitable memory as defined by the relevant platform HAL linker script. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with the EBI_CS0 space mapped from location zero. It will then transfer control to the 0x10000000 region. The eCos startup code will perform all necessary hardware initialization.

RAM

> This startup type is used for RAM based applications that are dependent on a “debug” monitor (e.g. RedBoot or GDB stubs) for some run-time services. By default the application will use the eCos virtual vectors mechanism to obtain services from the monitor, including diagnostic output. Normally arm-eabi-gdb is used to load a `RAM` startup application into memory, and then to debug it. It is assumed that the hardware has already been initialized by the relevant debug monitor.
>
> This startup type can be useful during development, since it allows debugging applications where a hardware debug solution is not available.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when Building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option CYGSEM_HAL_USE_ROM_MONITOR should be set. By default this option is enabled when building for a RAM startup, and disabled otherwise.

If the application does not rely on a ROM monitor for diagnostic services then, by default, the on-chip DBGU serial port will be used for HAL diagnostic output.

RedBoot Location

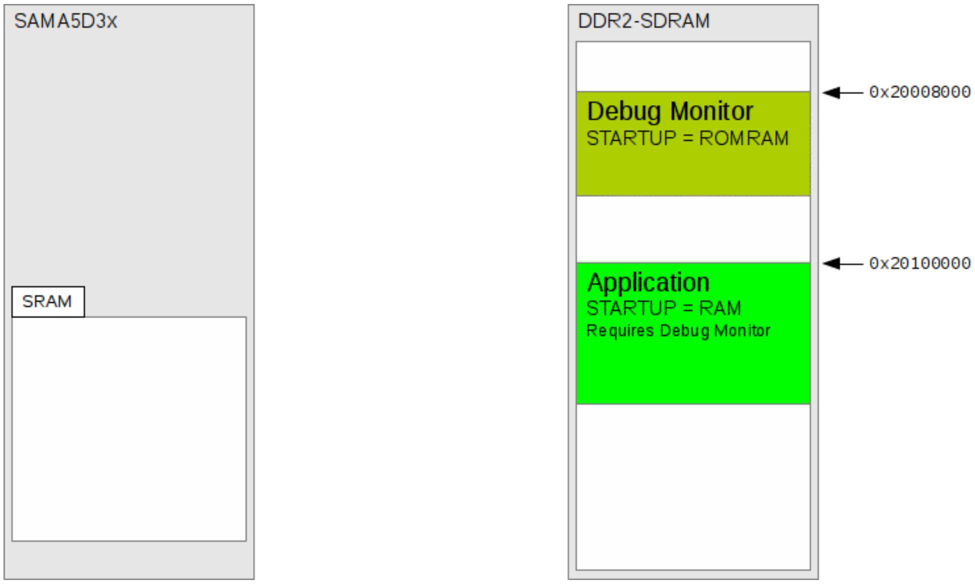
RedBoot can be used in conjunction with the host debugger arm-eabi-gdb to load and debug applications configured for the RAM startup type. Depending on the product requirements the RedBoot binary can either be executed in-situ from the NOR flash, or loaded dynamically into the DDR2-SDRAM for execution.

The ROMRAM RedBoot diagram shows the memory layout for a RAM resident RedBoot. The RedBoot binary is loaded into its final DDR2-SDRAM location either via a second-level boot loader (e.g. BootUp) or directly using a hardware debugger.

Note

The addresses shown in the following diagrams are based on the default linker script values.

Figure 277.1. ROMRAM RedBoot

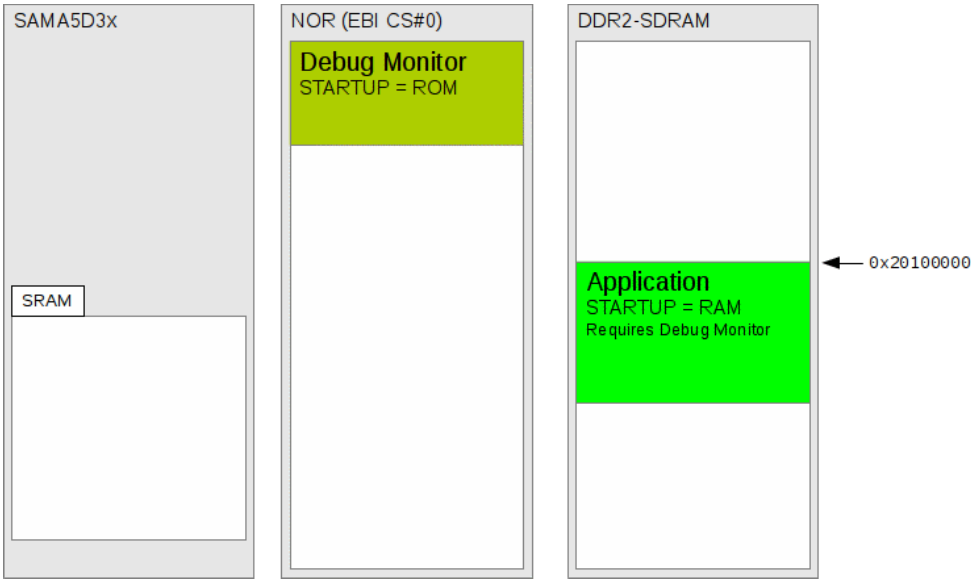


An illustration of a ROMRAM RedBoot executing from DDR2-SDRAM

Any application can be configured for the ROM startup type, and when stored from offset 0 in the NOR flash (mapped to address 0x10000000) the CPU can be configured (via BMS_BIT=1) to execute the code upon reset. The application does not need to be a debug monitor, but can be the final application if required.

The ROM RedBoot diagram shows the memory layout for a NOR flash resident RedBoot.

Figure 277.2. ROM RedBoot



An illustration of a ROM RedBoot executing from NOR flash

Name

Test Programs — Details

Test Programs

The SAMA5D3 variant HAL contains a test program which allows various aspects of the microcontroller to be tested.

varinfo

The simple `varinfo` test provides some output identifying the CPU, and the system configuration. It is designed as a very basic “Hello World” test to validate an eCos run-time build.

Chapter 278. Atmel SAMA5D3x-MB (MotherBoard) Platform HAL

Name

CYGPKG_HAL_ARM_CORTEXA_SAMA5D3X_MB — eCos Support for the SAMA5D3x-MB Board

Description

This document covers the configuration and usage of eCos and RedBoot on the Atmel SAMA53x-MB based evaluation kits. This motherboard is fitted with a SAMA5D3x-CM CPU module containing a variant of the SAMA5D3 family of microcontrollers. The board is referred to in this document using SAMA5D3x-MB. The eCos configuration system uses explicit target names to identify the available CPU evaluation kits based on this board, e.g. atsama5d31_ek, atsama5d33_ek, etc.

The CPU Module contains the available memories, as well as some I/O functionality to extend the features available on the base SAMA5D3x-MB motherboard. The CPU Module is connected to the J12 SODIMM 200 connector.

For typical eCos development it is expected that programs will be downloaded and debugged via the on-board J-Link USB interface (J14), or via a hardware debugger (JTAG/SWD) attached to the standard ARM 20-pin JTAG (J9) connector. Use of a hardware debugging interface avoids the requirement for a debug monitor application to be present on the platform.

Note

Hardware modification of the board may be required to add support to allow use of the 20-pin J9 connector.

See the CPU Module documentation regarding the use of flash for holding a RedBoot or GDB Stubs image if a debug monitor is required for development.

Supported Hardware

The SAMA5D3x-MB motherboard is common to different "EK" systems, but depending on the actual CPU installed some differences exist as to motherboard peripherals/connections that may be useable.

The motherboard provides the 10/100 Ethernet (MII/RMII) KSZ8051RNL PHY providing support via the J24 (labelled "ETH1") connector. For CPU Module systems where the Gigabit GMAC interface is available the PHY and support logic is provided by the CPU Module. The base motherboard provides the J17 GETH connector.

The Multimedia Card Interface (MCI) on the CPU provides support for the two card sockets on the motherboard. The MCI0 peripheral is connected to the full size SD/MMCplus card socket at J7. While the socket supports 8-bit mode, at present in eCos, only 1- or 4-bit modes are supported. MCI1 is connected to the MicroSD card socket at J6. Both sockets support card insertion/removal detection, but neither support write protect tab detection. Support for MCI use of these sockets is provided by definitions in the platform HAL along with the main SAM MCI device driver in CYGPKG_DEVS_MMCSD_ATMEL_SAM_MCI.

The motherboard supports dual CAN bus interfaces CAN0/CAN1, via the RJ12 connectors at J18/J27. Note that the pin assignments on these RJ12 sockets differ from some previous Atmel boards, so care needs to be taken to ensure that CAN cables are wired correctly. Support for the CAN interfaces is provided by the Atmel SAM CAN Driver.

The BMS signal to the CPU controls how the system is booted. The CPU variant bootstrap overview should be read in conjunction with this documentation. For example, when used with the SAMA5D3x-CM daughterboards the JP9 jumper controls the CPU bootstrap source:

Table 278.1. JP9 BMS

BMS signal (JP9)	Description
JP9 OPEN	Embedded (on-chip) RomBOOT first-level bootloader is used. Actual boot source used will depend on a combination of the CPU Module I/O configuration and the presence of suitable binaries.

BMS signal (JP9)	Description
JP9 CLOSED	Application installed on the EBI_CS0 parallel NOR flash on the CPU Module daughterboard is executed in-situ.

Note

On the SAMA5D3x-MB the BMS signal is connected to GND through JP9 (shipped “open” by default).

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3e, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.23.2. All development work and testing was undertaken using SAMA5D3x-MB REV.C hardware.

Name

Setup — Preparing the SAMA5D3x-MB Board for eCos Development

Overview

In a typical development environment the SAMA5D3x-MB board is programmed via a JTAG/SWD interface. This will either be by loading smaller applications into the on-chip SRAM, or into suitably initialised DDR2-SDRAM memory. Alternatively applications may be loaded into bootable memory-mapped devices, e.g. EBI_CS0 NOR flash, or loaded via the on-chip `RomBOOT` code via a second-level SRAM boot scheme. The following sections initially deal with JTAG/SWD hardware based debugging approaches.

For debugging applications are loaded and then executed on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE.

The SAMA5D3x-MB motherboard provides a built-in J-Link hardware debug solution, as well as optionally providing the J9 JTAG connector for attaching 3rd-party hardware debuggers (e.g. Ronetix PEEDI).

J-Link

By default the motherboard provides access to both the SAMA5's DBGU (debug UART) and the J-Link adapter through the J14 USB connector. Output on the DBGU channel is accessible via USB on a connected host as a USB CDC-ACM serial class device. Additionally, debugging support is accessible through the proprietary J-Link adaptor via the Segger J-Link GDB server.

The motherboard can be modified (by adding and removing resistors) to route DBGU to the J8 USART1 connector. However, if diagnostics via that connector are desired, it is simpler to re-configure eCos to directly send diagnostics to the J8 port. This can be achieved by setting the HAL diagnostic console channel (and if using RedBoot, GDB channel) to port 1 (the default setting of 0 indicates routing to the DBGU). However, if it is necessary after all to modify the hardware and route DBGU to J8, then support for the SAMA5's USART1 device must be manually disabled by the user as it will no longer be physically connected (removing the "`implements CYGINT_HAL_ARM_CORTEXA_SAMA5D3_USART1`" line from `hal_arm_cortexa_sama5d3x_mb.cdl`).

JLinkGDBServer

Segger's JLinkGDBServer application provides a network-based GDB server connection to J-Link hardware debuggers, including on-board J-Link hardware as used on the SAMA5D3x-MB. The Segger webpage http://www.segger.com/jlink-software.html provides a J-Link software package download that incorporates the J-link GDB Server.

Note

When downloading the software you may need to click on a link “I do not have a serial number because I own an eval board with J-Link on-board. How can I download J-Link software for it?”. This will allow you to download the J-Link software without prior knowledge of a serial number.

Experience has also shown that a reboot of the PC may be required after installation of the jlink software.

To ensure compatibility between the on-board J-Link firmware and software, agree to any prompt you may encounter to update the firmware during the first run of the J-Link software.

A helper script `sama5d3xek-ddram.jlink` is provided in the `misc` directory of the `sama5d3x_mb` package. This should be specified when executing the `JLinkGDBServer` application, and implements a set of commands that are executed when a GDB connection is established to the server. For example, under Linux:

```
$ JLinkGDBServer -device ATSAMA5D31 -xc $ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3x_mb/current/misc/sam
```

Under Windows:

```
C:\eCosPro> "C:\Program Files (x86)\SEGGER\JLink_V612j\JLinkGDBServerCL.exe" -device ATSAMA5D31 -xc $ECOS_REPOSITORY\p
```

Note that in the above examples the -device argument should reference the relevant processor installed on the SAMA5D3x-MB motherboard. The eCos <vsn> and JLink_Vxxxx version names will change over time; you will need to use the path specific to the actual versions installed.

Other JLinkGDBServer options may be used as required, for example the `-silent` option reduces the output generated by the server.

A normal GDB debug session can then be started by connecting to the relevant JLinkGDBServer port (default 2331), for example:

```
(gdb) target remote localhost:2331
(gdb) load
```

A simpler `sama5d3xek.jlink` script is provided that does *NOT* initialise the clocks or DDR2-SDRAM, and can be used if explictly debugging `ROM` or `SRAM` startup types where execution of the relevant run-time initialization is desired.

From the GDB command-line when connected to JLinkGDBServer the “monitor regs” command can be used to see all of the non-VFP register state.

Note

Currently, as-of JLinkGDBServer version `V484`, there is *no* support for accessing the Cortex-A5 VFPv4-D16 (VFP) registers when using JLinkGDBServer. e.g. from the GDB “info all-reg” or “info float” commands.

If low-level debugging of floating point operations is required then n alternative debugger should be used. The PEEDI hardware JTAG debugger provides support for displaying the VFP register state, as does the GDB stubs present in the software based RedBoot monitor.

OpenOCD

Using the OpenOCD debug server via the J-Link (J14) interface, is not yet possible. For the moment it is recommended to use the JLinkGDBServer on the host if hardware debug via the J-Link interface is required.

PEEDI

For the Ronetix PEEDI, the `sama5d31ek.peedi.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLLs and SDRAM controller. You can also check the Ronetix website http://download.ronetix.info/peedi/cfg_examples/cortex-a for updated versions.

Note

Use of a PEEDI debugger requires hardware modification of the standard SAMA5D3x-MB board, which will provide a 20-pin ARM JTAG connector at J9. The required modifications are detailed in the board's user manual.

The `sama5d31ek.peedi.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_CortexA8]` section (NOTE: The PEEDI firmware identifies not just A8 CPUs with the `CortexA8` tag). Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `sama5d31ek.peedi.cfg` file, and halts the target. This behaviour is repeated with the PEEDI **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal. Depending on how the platform jumper state is configured this could run either a second-level bootstrap, or a `ROM` RedBoot resident in flash.

By default the arm-eabi-gdb connection to the PEEDI will default to displaying the obsolete `FPA` registers. To enable access to the `VFP` registers a suitable target description file should be configured prior to connecting to the target system. This can either be done manually every time a GDB session is started, or more sensibly embedded in the users `.gdbinit` used to configure GDB.

The `sama5d3x-tdesc.xml` file can be used to define the target description using the GDB **set tdesc filename *<file>*** command. For example the `.gdbinit` could contain something similar to:

```
set tdesc filename $ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3x_mb/current/misc/sama5d3x-tdesc.xml
```

So that it has the relevent target description available prior to the remote debug connection being established. This will allow access to the VFP registers via the PEEDI, for example via the GDB **info all-reg** command.

Consult the PEEDI documentation for information on other features.

Name

Configuration — Platform-specific Configuration Options

Overview

The SAMA5D3x-MB motherboard platform HAL package is loaded automatically when eCos is configured for a suitable target, e.g. `atsama5d31_ek`. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Name

HAL Port — Implementation Details

Overview

The platform consists of the pairing of the MotherBoard and a CPU Module. The only motherboard specific support is the EMAC PHY. The majority of the port is covered by the CPU Module package.

The CPU Module startup documentation provides an overview of the system startup.

Name

BootUp Integration — Detail

BootUp

BootUp is a lightweight BootROM package that can support features such as in-field upgrades and in the case of the SAMA5 in particular, a secure boot capability.

The BootUp support for the SAMA5D3 targets is primarily implemented in the `sama5d3_mb_misc.c` file. The functions are only included when the `CYGPKG_BOOTUP` package is being used to construct the actual BootUp loader binary.

The BootUp code is designed to be very simple, and it is envisaged that once an implementation has been defined the binary will only need to be installed onto a device once. Its only purpose is to allow the startup of the main `ROMRAM` application.

This platform specific documentation should be read in conjunction with the generic BootUp package documentation.

The BootUp package provides a basic but fully functional implementation for the platform. It is envisaged that the developer will customize and further extend the platform side support to meet their specific application identification and update requirements.

The BootUp binary can be installed on *any* SAMA5D3x bootable media, and is not restricted to being placed into SPI Dataflash.

Note

The NOR flash mapped to EBI_CS#0 is *NOT* an acceptable boot source for the on-chip first-level `RomBOOT` code.

On execution BootUp will copy the `ROMRAM` configured final application from its Non-Volatile-Memory (NVM) location, which currently can either be the SPI Dataflash (default) or the memory-mapped NOR flash. The configuration option `CYGIMP_BOOTUP_SAMA5D3_SOURCE` selects whether the second-level BootUp code will look for the final application image in `SPI` or `NOR`.

Warning

When selecting `SPI` then the relevant CPU Module hardware configuration to allow the on-chip `RomBOOT` to boot from SPI should be used. This requires that jumper `JP1` on the Embest/Flextronics “SAMA5D3x-CM_rev.E” be fitted, and for the Ronetix “SAMA5D3x-CM v2.0” daughterboard jumper `J2` should be fitted.

The following diagrams give an overview of the first-level (on-chip `RomBOOT`) and second-level (`SRAM`) boot sequence:

Figure 278.1. On-chip `RomBOOT` executes

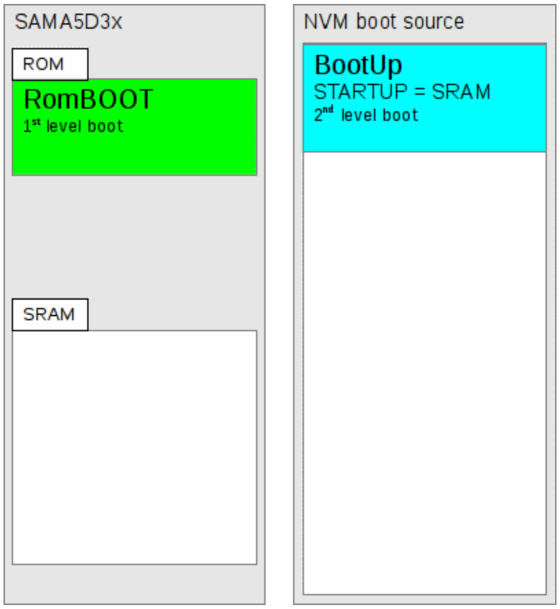


Figure 278.2. On-chip `RomBOOT` copies second-level boot code from NVM to on-chip SRAM

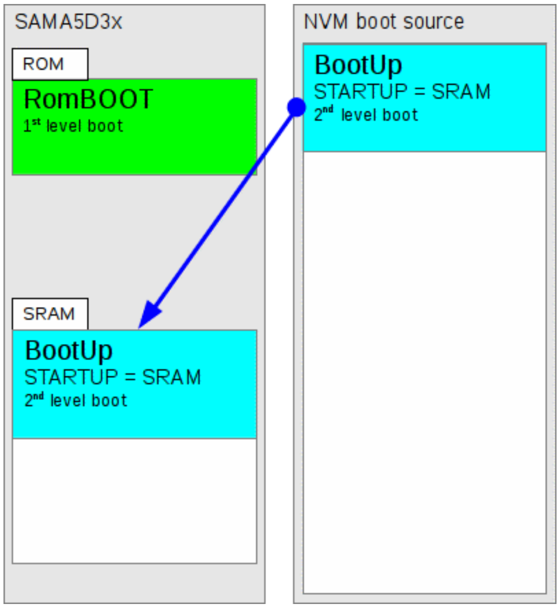

Figure 278.3. SRAM loaded second-level boot code is executed

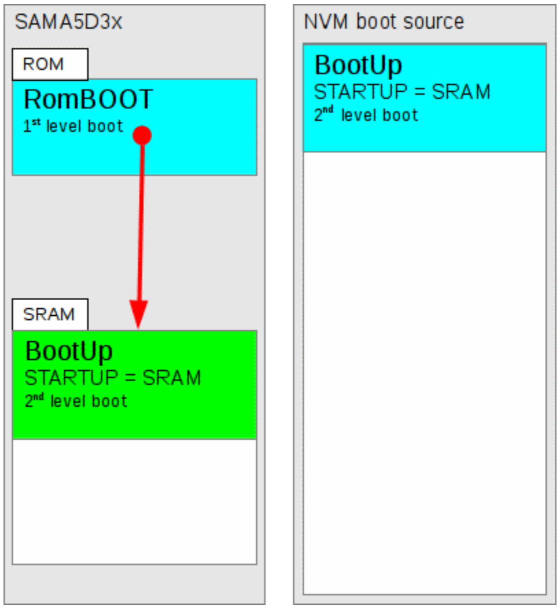

Figure 278.4. Final application `ROMRAM` is located in SPI or NOR NVM

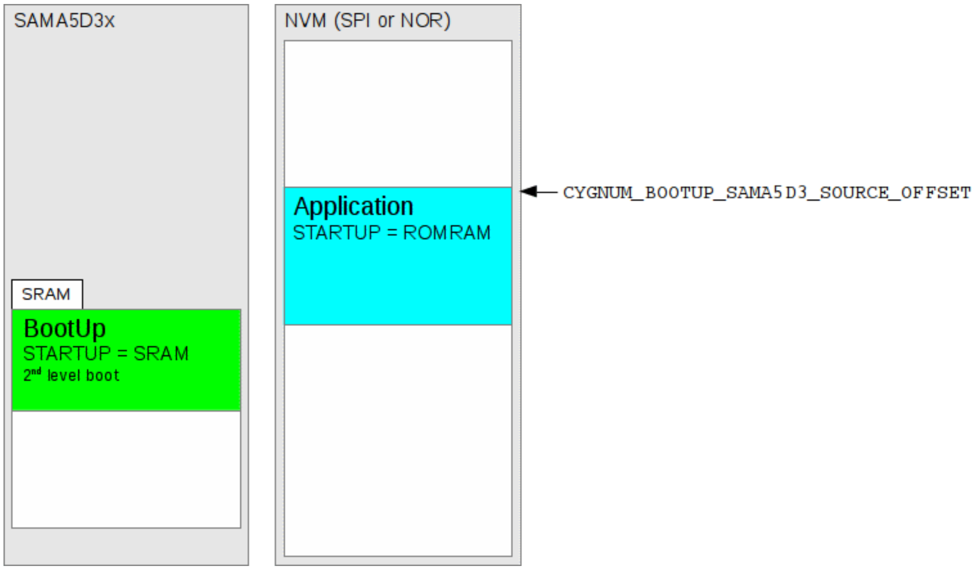

Figure 278.5. Second-level boot copies `ROMRAM` from NVM to DDR2-SDRAM

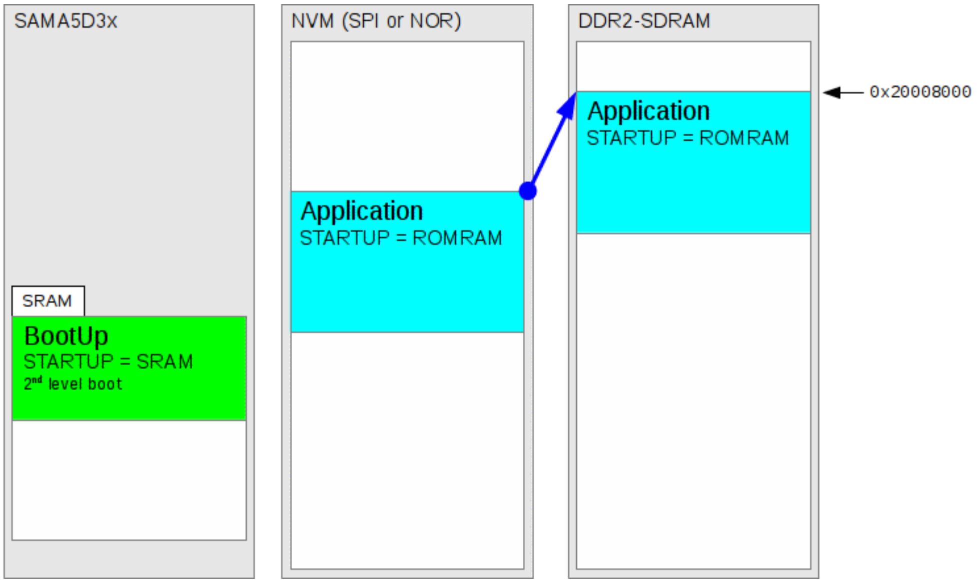

Figure 278.6. Application is started

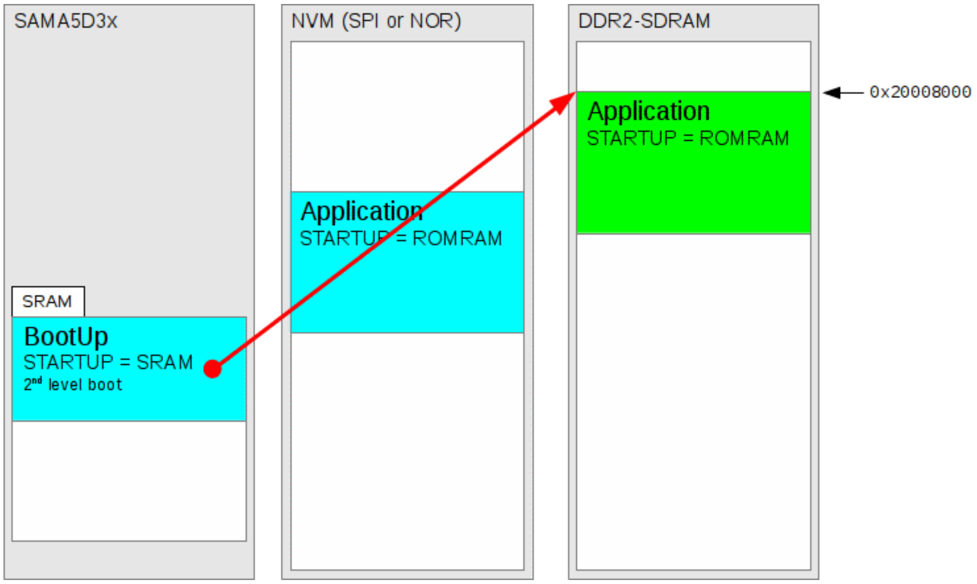

Encrypted Application

The BootUp SRAM application can be configured with a built-in AES-256 key which can be used to decrypt the final `ROMRAM` application image (as stored on the NVM) prior to execution from its final RAM location. For ease of use during development, the BootUp binary can load both encrypted and plaintext (unencrypted) application images. This allows testing of the boot sequence prior to finalising the application key, or the final application build encryption process.

Note

This feature is really only relevant (and useful) as part of a secure boot process. When secure boot is *NOT* being used then by itself encrypting the final `ROMRAM` application provides no security since the SRAM second-level boot loader can be examined to extract the AES-256 key used to decrypt the application. Using the BootUp decryption support only makes sense when it is part of a complete reset->application security implementation.

As with the normal SRAM based second-level bootstrap world, the on-chip `RomBOOT` code loads and executes the second-level boot code from any suitable boot source. When BootUp is used as the second-level bootstrap it is configured to look at either the `SPI` or `NOR` memories for the encrypted final `ROMRAM` application image.

Figure 278.7. Second-level boot code built with AES-256 key

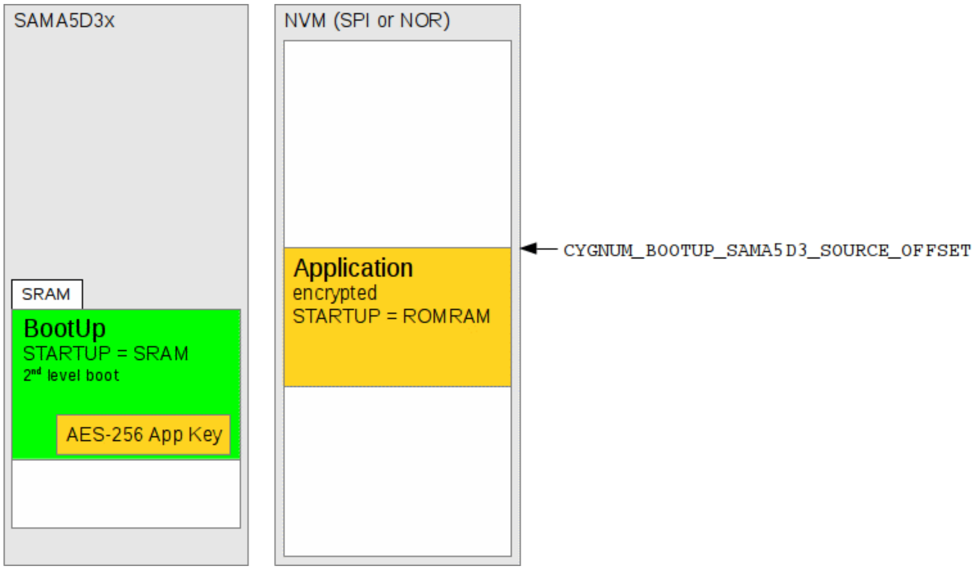

Figure 278.8. Stored key is used to decrypt NVM application into RAM

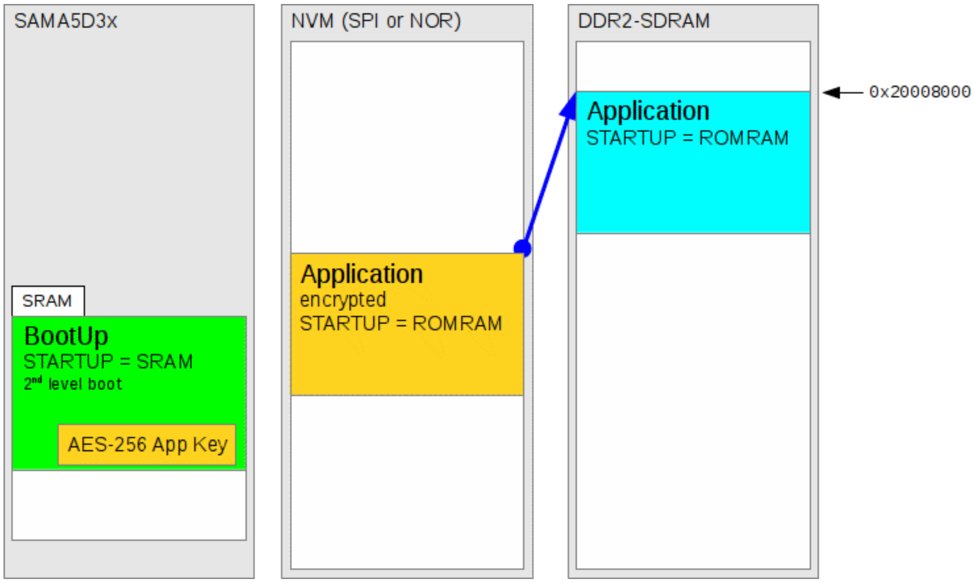

Figure 278.9. Decrypted application is started

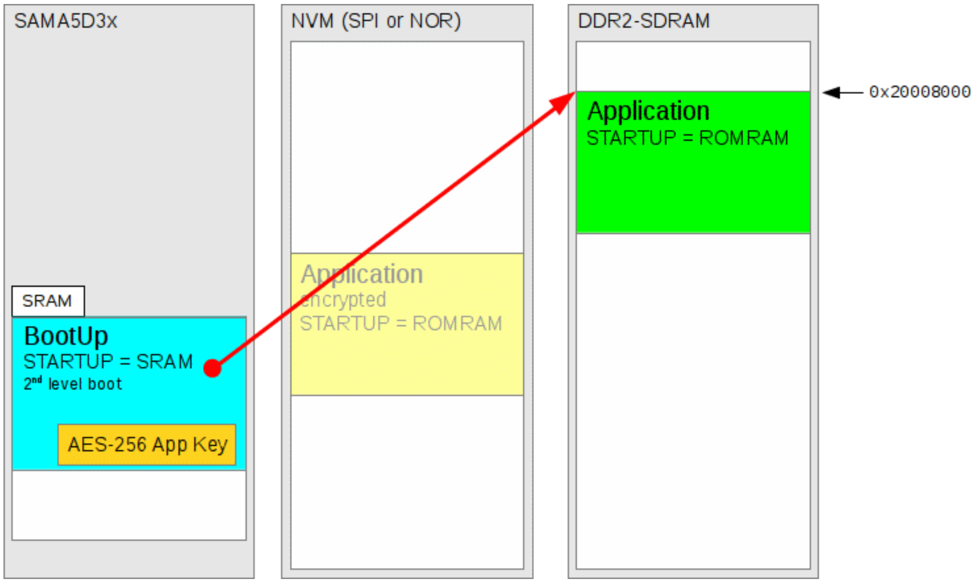

Encrypting The “Final” Application

An example host tool to encrypt the final `ROMRAM` application using a AES-256 key is provided. A pre-built executable is provided, and available from the installed tools path as for the other build related tools. The source for the tool is available in the `$ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3x_mb/current/host/claes.c` file. If required, a `Makefile` (for GNU make) is provided in the `host` directory to allow the command to be built locally.

The AES-256 key used to encrypt the application binary *MUST* be the same key that is *built-into* the second-level boot loader used to copy the application from its NVM location into RAM for execution.

An example key file is provided in `$ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3x_mb/current/misc/example256.key`, but as always for a production environment the developer is responsible for managing the actual key values used, and for ensuring that embedded keys are not distributed publicly.

Assuming that the application binary is available in the file `finalapp.bin`, the following example shows how the `claes` tool can be used to create the encrypted image.

```
$ claes -k example256.key finalapp.bin -o encrypted.bin
```

The encrypted image `encrypted.bin` would then be stored at the relevant NVM offset using whatever production methodology is in use. If required, for example, the default SAMA5D3 RedBoot application provides the necessary network and flash operations to allow it to be used to initialise the NVM contents from supplied binary images.

The claes command provides a brief description of its options, which can be viewed by requesting `--help` (or the shorthand `-h`) on the command-line:

```
$ claes --help
```

Atmel Secure Boot

Details of the Atmel Secure Boot process are beyond the scope of this document, since a customer specific Non-Disclosure-Agreement (NDA) with Atmel needs to be in place. The reader is referred to the Atmel website www.atmel.com with regards to the “Secure Boot on SAMAD3 Series” (Atmel literature number `11165A`) documentation.

Building BootUp

Building a BootUp loader image is most conveniently done at the command line. The steps needed to rebuild the SRAM version of BootUp are:

```
$ mkdir bootup_SRAM
$ cd bootup_SRAM
$ ecosconfig new sama5d31_ek minimal
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3_mb/current/misc/bootup_SRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The resulting install/bin/bootup.bin binary can then be programmed into a suitable non-volatile memory as supported by the SAMA5D3 on-chip RomBOOT.

The example bootup_SRAM.ecm is configured to expect to find the ROMRAM application stored in the SPI Dataflash at offset CYGNUM_BOOTUP_SAMA5D3_SOURCE_OFFSET. It also is configured with application encryption support (CYGFUN_BOOTUP_SAMA5D3_SOURCE_SECURE option) to allow decryption of the SPI Dataflash stored application to its final RAM destination.

Note

The application image to be loaded does *not* need to be encrypted. The BootUp code checks the embedded application binary identity markers to check for a plaintext (unencrypted) image to be started, prior to attempting to decrypt the data and check for a valid encrypted image at offset CYGNUM_BOOTUP_SAMA5D3_SOURCE_OFFSET in the source NVM.

Chapter 279. Atmel SAMA5D3x-CM (CPU Module) Platform HAL

Name

CYGPKG_HAL_ARM_CORTEXA_SAMA5D3X_CM — eCos Support for the SAMA5D3x-CM CPU Module

Description

There are currently two supported variants of CPU Module (CM). The Embest/Flextronics “SAMA5D3x-CM_rev.E” and the Ronetix “SAMA5D3x-CM v2.0” daughterboards. The boards can be identified by the silk screened names on the respective PCBs.

The currently supported CM variants are identical in functionality, with the exception of the type of NOR flash installed on EBI_CS0. However, the eCos port is configured to allow a single binary to execute irrespective of the installed CPU Module.

The common CM features include 512MiB of DDR2-SDRAM, 16MiB NOR flash, routing for the 10/100 EMAC and 10/100/1000 GMAC, and blue and red LEDs. Some common CM features are not yet supported by the eCos port, e.g. NAND.

For typical eCos development it is expected that hardware debugging will be used, as detailed in the SAMA5D3x-MB MotherBoard documentation.

However, RedBoot can be used to provide development support. RedBoot provides gdb stub functionality. so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger. This can happen over either a serial line or over Ethernet. The RedBoot image can be a ROM application programmed into the parallel NOR flash, or a ROMRAM application loaded via the second-level bootloader. See RedBoot Location for an overview.

The bootstrap options for the SAMA5D3x parts are documented in the CPU variant documentation. How the CPU boots depends on the BMS signal (supplied by the motherboard via the CPU Module main connector pin 184). The CM has a Pull-Up on the CPU BMS pin so will default to BMS_BIT=0.

Note

The Embest/Flextronics CM is pre-installed with example application software. The software execute depends on the setting of CM jumper JP1. When JP1 is open then the NAND based AT91Bootstrap second-level boot loader is loaded into SRAM and used to start a NAND stored application world. When JP1 is closed then a system “test” application is loaded into SRAM from the SPI Dataflash and executed.

Warning

When JP1 is closed, if the example Atmel code is present and the NOR test (single test 05) is executed then it will erase the first 384K of the NOR flash (0x10000000..0x1005FFFF). This could erase any ROM application (e.g. RedBoot) that the user may have installed into the parallel NOR flash.

Name

HAL Port — Implementation Details

Overview

The SAMA5D3x-CM daughterboard platform HAL package is loaded automatically when eCos is configured for a suitable target, e.g. `atsama5d31_ek`. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

In the release view of the world (depending on the state of the `BMS` signal) the SAMA5D3x-CM daughterboard either boots into the BootUp “application loader” from a suitable on-chip `RomBOOT` supported memory, or alternatively from the EBI-CS0 parallel NOR flash based `ROM` startup type application.

When using the second-stage BootUp loader the main (`ROMRAM` startup type) application is then loaded from the configured non-volatile storage (e.g. parallel NOR flash) into the DDR2-SDRAM for execution.

The CPU variant bootstrap overview should be read in conjunction with this documentation.

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services, and so will not attempt to re-initialize the underlying peripheral.

For `ROM`, `ROMRAM` and `SRAM` startups the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins as required. The details of the early platform hardware startup may be found in the `plf_hardware_init()` function within the source file `src/sama5d3x_mb_misc.c`.

Memory Map

The SAMA5D3X_CM HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External RAM

This is located at address 0x20000000 of the memory space, and is 512MiB long. For `ROM`, `ROMRAM` and `SRAM` applications the initial 32KiB is set aside, primarily for the first level MMU table and (depending on the startup type) the eCos VSR table. The rest of the RAM is then available for application use. For `RAM` startup applications the first 1MiB of RAM is reserved for the “debug” monitor (e.g. RedBoot), and the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder is then available for the `RAM` application.

Internal RAM

This is located at address 0x00300000 of the memory space, and is 128KiB in size.

NOR FLASH

This is located at address 0x10000000 of the memory space and *MAY* be mapped to 0x00000000 at reset if the SAMA5D3 is so configured. This region is 16MiB in size. `ROM` applications are by default configured to run from this memory. When RedBoot is being used then this memory is managed by RedBoot's FIS system, otherwise it is the applications responsibility to manage the NOR flash space.

On-chip Peripherals

The I/O is primarily accessible from location 0xF0000000 upwards, though some I/O is mapped into the initial 10MiB of the address space. Descriptions of the contents can be found in the Atmel SAMA5D3 Series Datasheet.

Linker Scripts

The platform linker script defines the following symbol:

hal_mmu_page_directory_base — This symbol defines where the initialization code will place the level-1 table when initialising the MMU.

Diagnostic LEDs

Two LEDs are fitted onto the CPU Module for diagnostic purposes, one red and one blue.

The platform HAL header file at `<cyg/hal/sama5d3x_cm_io.h>` defines the following convenience function to allow the LEDs to be controlled:

```
extern void hal_sama5d3x_cm_led(cyg_uint32 bitmask);
```

The low-order 2-bits of the argument *`bitmask`* correspond to each of the 2 LEDs. The red LED is logically mapped to bit 0, with the blue LED mapped to bit 1.

Note

The blue LED on GPIO line PE25 is also used as the 1-wire bus, so accesses to 1-wire devices will cause that LED to flicker.

SPI Dataflash

The variant HAL SPI support provides the necessary underlying SPI bus definition. The CM platform layer defines the `spi_dataflash_dev0` device instance describing the SPI Dataflash hardware.

The SPI Dataflash media can only be accessed with the Flash API using the flash device `m25pxx_flash_device`. For the purposes of this API a placeholder address range has been allocated as if the Flash is present at this address. The base of this address range is `0xE0000000`. This reserved range is not real memory and any attempt to access it directly by the processor other than via the Flash API will result in a memory address exception.

A test application at25df321 is provided within the `tests` subdirectory of the `CYGPKG_HAL_ARM_CORTEXA_SAMA5D3X_CM` package. This test communicates with the SPI Dataflash on the CM to perform read and write operations using the flash API.

Ethernet Driver

Depending on the processor specific SAMA5D3x-CM module used, either or both EMAC and GMAC Ethernet devices are available to use. The `CYGPKG_DEVS_ETH_ARM_AT91` package supports both of these devices. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

Both the standard (BSD and lwIP compatible) and direct (lwIP only) device drivers are supported. The standard driver is enabled by default; the direct driver can be enabled by setting `CYGOPT_IO_ETH_DRIVERS_LWIP_DRIVER_DIRECT` option. At the time of writing, the direct driver only supports the EMAC (ETH1), and not the GMAC (ETH0).

RedBoot Installation

Note

Unless you explicitly need network based debugging, or are interested in other aspects of the RedBoot functionality, it is generally the case that development and debugging using a direct hardware JTAG/SWD approach is generally superior and obviates the need to install RedBoot on the target.

RedBoot, by default, is configured to use the EBI_CS0 NOR flash as storage for its FIS and config information, regardless of whether it is executing from RAM or in place as a `ROM` application.

Building RedBoot

RedBoot will normally be a ROMRAM startup, since it will be loaded via the second-level bootloader, or loaded directly using a hardware JTAG debugger, into the DDR2-SDRAM memory for execution.

Note

Pre-built RedBoot binary images are supplied with the eCos release in the loaders sub-directory.

The following example illustrates the command-line steps needed to configure and build a ROMRAM RedBoot:

```
$ mkdir redboot_ROMRAM
$ cd redboot_ROMRAM
$ ecosconfig new atsama5d31_ek redboot
$ ecosconfig import $ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3x_mb/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

However, if required, a ROM based RedBoot can be executed directly from the EBI_CS0 NOR flash when JP9 on the SAMA5D3x-MB motherboard is closed.

```
$ mkdir redboot_ROM
$ cd redboot_ROM
$ ecosconfig new atsama5d31_ek redboot
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3x_mb/current/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The RedBoot Location section of the generic SAMA5D3 variant documentation provides a graphical representation of both these ROMRAM and ROM models.

Programming RedBoot

Some hardware debuggers will allow direct programming of the EBI_CS0 NOR flash, but for those that do not provide such support a JTAG loaded ROMRAM executable can be used to load and write the ROM image to its NOR flash destination. For example, if the ROMRAM RedBoot as built above is loaded using a hardware debugger and executed, then the following shows that RAM based RedBoot being used to load a 0x16020 byte long redboot.bin image from a TFTP server and written to the RedBoot FIS section in the NOR.

```
RedBoot> load -r -h 192.168.7.39 -b 0x30000000 redboot.bin
Using default protocol (TFTP)
Raw file loaded 0x30000000-0x30016020, assumed entry at 0x30000000
RedBoot> fis unlock RedBoot
... Unlocking from 0x10000000-0x100fffff: ........
RedBoot> fis write -f 0x10000000 -b 0x30000000 -l 0x16020
* CAUTION * about to program FLASH
            at 0x10000000..0x1001ffff from 0x30000000 - continue (y/n)? y
... Erase from 0x10000000-0x1001ffff: .
... Program from 0x30000000-0x30020000 to 0x10000000: .
RedBoot> mcmp -s 0x30000000 -d 0x10000000 -l 0x16020
```

With the binary image written to the start of the NOR flash, and the motherboard BMS signal suitably configured, then after a power-on reset the board will boot using the ROM RedBoot application. Such a RedBoot world allows for GDB debugging of RAM startup applications loaded via the J8 USART1 serial connection, the 10/100 (EMAC) Ethernet connection, or the 10/10/1000 (GMAC) Ethernet connection. Selection of which Ethernet interface to use is set with the RedBoot **fconfig** command and its Default network device: entry. Entering at91_eth0 selects the Gigabit Ethernet (J17/GETH) interface, whereas at91_eth1 selects the 10/100 Ethernet (J24/ETH1) interface.

This method of using a RAM based RedBoot, and loading a binary into RAM (or SRAM) before writing to the NOR flash, can be used for any `ROM` application that needs to be executed from startup with a BMS closed configured platform. Alternatively, Atmel provides tools to work in conjunction with the on-chip SAM-BA monitor that can also be used to program the various CPU Module memories.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for ROMRAM startup, where both code and data are using the external DDR2-SDRAM.

Example 279.1. sama5d3x_cm Real-time characterization

```
            Startup, main thrd : stack used   444 size  1792
            Startup :  Interrupt stack used  4096 size  4096
            Startup : Idlethread stack used    88 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead

Chapter 280. Atmel SAMA5D3 Xplained Platform HAL

Name

`CYGPKG_HAL_ARM_CORTEXA_SAMA5D3XPLD` — eCos Support for the SAMA5D3 Xplained platform

Description

The SAMA5D3-XPLD board consists of an ATSAMA5D36 Cortex-A5 microcontroller, 128kiB of SRAM, 256MiB of RAM and 256MiB of NAND flash. It has connectors for Ethernet, LCD, USB and other expansion boards as well as an SD card slot.

For typical eCos development it is expected that `ROMRAM` startup type applications will be downloaded and debugged via a hardware debugger (JTAG) attached to connector `J24`. Use of a hardware debugging interface avoids the requirement for a debug monitor application to be present on the platform. However, if required, a RedBoot image can be programmed into the onboard NAND flash to provide an interactive bootloader environment. When using a GDB stubs monitor it is then possible to download and debug eCos `RAM` startup applications via the gdb debugger over USB (using the TTL debug channel) or Ethernet.

The bootstrap options for the SAMA5D3x parts are documented in the CPU variant documentation. How the CPU boots depends on the BMS signal. The SAMA5D3 Xplained has a Pull-Up on the CPU BMS pin so will default to `BMS_BIT=0`, resulting in the RomBOOT, on-chip, first-level boot loader being executed.

Note

The Atmel SAMA5D3 Xplained is pre-installed with example application software. The board is supplied with jumper `JP5` ("NAND CS") closed, which causes the board to boot using its factory-programmed NAND-based boot loader and then to the sample application image. It is necessary to overwrite these images in order to place RedBoot or any other application on the NAND flash.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3e, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.23.2.

Name

Setup — Preparing the SAMA5D3-XPLD Board for eCos Development

Overview

In a typical development environment, a direct hardware JTAG connection is used to load and execute the eCos application. For hardware debugging, eCos applications would normally be configured for `ROMRAM` startup. The same application binary can be executed via a hardware debugger environment, or programmed into the onboard NAND flash for loading via a second-level boot loader.

Alternatively, the SAMA5D3-XPLD board can boot from NAND flash into a `ROMRAM` RedBoot. eCos applications are then configured for `RAM` startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**.

Note

Unless you explicitly need network based debugging, are interested in other aspects of the RedBoot functionality, or you lack the requisite hardware support, it is generally the case that development and debugging using a direct hardware JTAG/SWD approach is generally superior and obviates the need to install RedBoot on the target.

Atmel Secure Boot code and the normal `RomBOOT` code will disable JTAG over certain startups.

For JTAG debugging the `RomBOOT` code may need to be started with *NO* bootable source (e.g. JP5 `NAND CS` open and no bootable SD card) to enable JTAG access. After reset, a CDC-ACM tty connection (to the on-chip ROM provided SAM-BA terminal) via the J6 USB-A interface can be used to enter a # key to enable JTAG.

Bootstrap process

The typical bootstrap process for this board has several steps:

1. RomBOOT (on-chip, cannot be modified).
2. eCosPro BootUp or AT91Bootstrap
3. Your choice of `ROMRAM` eCos application (such as RedBoot).

For more information about the bootstrap process, refer to the CPU variant bootstrap overview.

RedBoot Installation

The following RedBoot configurations are supported:

Configuration	Description	Use	File
ROMRAM	RedBoot running from external RAM. Loaded from NAND by second-level boot loader, or directly via JTAG hardware debugger.	`redboot_ROMRAM.ecm`	`redboot_ROMRAM.bin`

Note

The DBGU diagnostic (serial) debug channel is only exposed as TTL on J23 pins. A RS232 TTL to USB adapter can be used to allow serial diagnostic output. The serial terminal connection is not required for normal Ethernet based

GDB debugging, but for initial board bring-up where no valid flash configuration is available it can be easier to see what network address has been supplied to the board.

If the standard serial diagnostic/terminal is not available, then it is worth considering configuring the local DHCPD to present a known (fixed) IP address. The current fixed RedBoot MAC address is `12:34:56:78:9a:bc`. RedBoot defaults to using port `9000`.

Programming RedBoot

There are several ways to program the target flash:

1. Some hardware debuggers will allow direct programming of the target NAND flash.
2. If a hardware debugger is available but does not support NAND flash, it is possible to load and run a `ROMRAM` executable that does know how to write the image to its flash destination.
3. Atmel provides tools to work in conjunction with the on-chip SAM-BA monitor that can also be used to program the various memories. Detailed instructions for this process are provided in the Installing binaries with SAM-BA section.

Note

RedBoot is configured by default with both network interfaces active, and waits for both of them to come up before allowing user interaction. This may take up to a minute if either are not connected to a network. It is recommended to connect both interfaces.

Initializing RedBoot Flash Configuration

When RedBoot is loaded into the on-chip flash, it maintains a number of persistent settings in the configuration store on the NAND flash. The flash configuration area needs to be initialized with the following commands.

```
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Use BOOTP for network configuration: true
Default server IP address:
DNS domain name:
DNS server IP address:
Network hardware address [MAC] for eth0: 0x0E:0x00:0x00:0xEA:0x18:0xF0
Network hardware address [MAC] for eth1: 0x0E:0x00:0x00:0xEA:0x18:0xF0
GDB connection port: 9000
Force console for special debug messages: false
Network debug at boot time: false
Default network device: at91_eth1
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x00000000-0x00000fff: .
... Program from 0x2fdff000-0x2fe00000 to 0x00000000: .
RedBoot>
```

Rebuilding RedBoot

Note

Pre-built RedBoot binary images are supplied with the eCos release in the `loaders` sub-directory.

RedBoot will normally be a `ROMRAM` startup, since it will be loaded via the second-level bootloader, or loaded directly using a hardware JTAG debugger, into the DDR2-SDRAM memory for execution.

The following example illustrates the command-line steps needed to configure and build a `ROMRAM` RedBoot:

```
$ mkdir redboot_ROMRAM
$ cd redboot_ROMRAM
$ ecosconfig new sama5d3xpld redboot
$ ecosconfig import $ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3xpld/current/misc/redboot_ROMRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The RedBoot Location section of the generic SAMA5D3 variant documentation provides a graphical representation of the `ROMRAM` model.

Building BootUp

Full details are provided in the BootUp Integration section.

Building AT91Bootstrap

As an alternative to the eCosPro BootUp second-level loader, the Atmel AT91Bootstrap second-level loader can be used to load a `ROMRAM` startup type application from the NVM boot memory into RAM for execution.

A version of the AT91Bootstrap source, modified by eCosCentric, is available in the directory `$ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/var/current/misc/at91bootstrap`. The original (as of writing) is v3.6.2 obtained by:

```
git clone https://github.com/linux4sam/at91bootstrap
```

The modifications provide example configurations to allow RedBoot to be loaded by the SAMA5D3X-EK and SAMA5D3 Xplained platforms, and to allow compilation using the eCosCentric cross-compilation tools (e.g. 4.7.3e release).

The AT91Bootstrap binary can be built from the provided source with the following steps:

```
cd at91bootstrap
make mrproper
make sama5d3_xplainednf_redboot_defconfig
export CROSS_COMPILE=arm-eabi-
make
```

The result of this process is a second-level boot loader binary `binaries/sama5d3_xplained-nandflash-boot-uboot-3.6.2.bin` that can be installed into NAND using SAM-BA as described below.

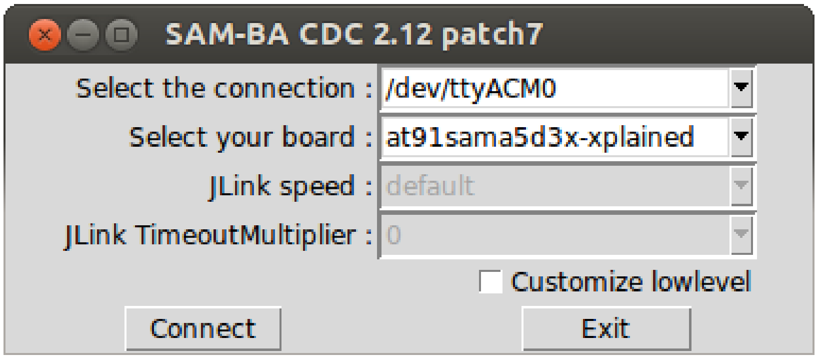
Installing binaries with SAM-BA

A version of the Atmel SAM-BA tool which supports the `at91sama5d3x-xplained` target (e.g. v2-12 patch level 7) can be used to install your choice of BootUp, AT91Bootstrap, RedBoot or any other `ROMRAM` eCos application.

1. Download and install the SAM-BA tool, plus any required patches, from http://www.atmel.com/tools/atmelsam-bain-system-programmer.aspx
2. Disconnect JP5 (`NAND CS`) and ensure no bootable SD card is installed
3. Connect host to J6 USB-A
4. Launch the SAM-BA application
   - Select the relevant COM or /dev/ttyACM port
   - Select board type “at91sama5d3x-xplained”

- Hit “Connect”

Figure 280.1. SAM-BA Board Connection



Select the connection : /dev/ttyACM0

Select your board : at91sama5d3x-xplained

JLink speed : default

JLink TimeoutMultiplier : 0

□ Customize lowlevel

5. Re-connect (close) JP5 `NAND CS`
6. Select `DDRAM` tab

- In “Scripts” select `Enable DDRAM` and hit `Execute`

```

/dev/ttyACM0   Board : at91sama5d3x-xplained

8. Program your choice of second stage bootstrap (BootUp or AT91Bootstrap):

- Still within the `NandFlash` tab, in “Scripts” select `Send Boot File` and hit `Execute`

  - A file selection dialog opens. Find and select the relevant binary (e.g. `bootup.bin`) and hit `Open`.

  - HEADER value  is 0xC0902405
-I- Pmecc header configration successful
-I- PMECC configure c0902405
(sam-ba_cdc_cdc_linux-P7) 1 %
```

/dev/ttyACM0   Board : at91sama5d3x-xplained

9. Program RedBoot (or other application)

   - Still within the `NandFlash` tab, in the “Download/Upload File” area, select the file selection icon 📂 beside the `Send File Name:` field.

     - A file selection dialog opens. Find and select the binary (e.g. `redboot.bin`).

Tip

The `objcopy` tool may be used to convert a built `ROMRAM` eCos application to the binary format required for programming.

```
arm-eabi-objcopy -O binary application.elf application.bin
```

   - In the “Address” field change the address to `0x40000`.

Note

If you are using BootUp with a non-default setting of `CYGNUM_BOOTUP_SAMA5D3_SOURCE_OFFSET`, use that value instead of `0x40000`.

   - Hit the `Send File` button.

Figure 280.5. Programming the Application

  - HEADER value  is 0xC0902405
-I- Pmecc header configration successful
-I- PMECC configure c0902405
(sam-ba_cdc_cdc_linux-P7) 1 %
```

/dev/ttyACM0 Board : at91sama5d3x-xplained

10.The SAM-BA application can now be quit

11.Reset the board. The new images will be booted.

Note

With RedBoot, the board will typically take several seconds to become ready as it waits for the network interfaces to initialise. (This may take up to a minute if either or both network interfaces are not connected to a network.) During this time RedBoot will not respond, either to telnet on the configured gdb port (usually 9000), or to input on the TTL debug channel. However the TTL debug channel will emit diagnostic output along these lines:

```
RomBOOT
+NAND: onboard: 1 partition  configured
NAND: Read partition geometry from config store
NAND: onboard: 2 partitions configured
Ethernet eth1: MAC address 0e:00:00:ea:18:f0

Configuration — Platform-specific configuration options

Overview

The SAMA5D3 Xplained platform HAL package is loaded automatically when eCos is configured for a suitable target, e.g. `at-sama5d3xpld`. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The SAMA5D3-XPLD board platform HAL package supports three separate startup types, as documented in the variant Startup documentation. The `ROM` startup type is *not* supported on this platform since the BMS signal configuration does not allow for `EBI_CS#0` memory-mapped execution support.

Note

Normally the board has BootUp or AT91Bootstrap programmed into internal NAND flash within the first two non-factory-bad blocks. When using RedBoot as the loaded application then a `ROMRAM` build of RedBoot is programmed into the next four non-factory-bad blocks. On boot, RedBoot is copied to location 0x20008000 in external RAM. arm-eabi-gdb is then used to load a `RAM` startup application into memory from 0x20100000 and debug it. For such `RAM` applications it is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB stub ROM (or RedBoot).

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The SAMA5D3-XPLD board provides a two-pin UART within the on-chip debug unit. This UART is configured as virtual vector communications channel 0 and is typically claimed by RedBoot for use as a console and/or GDB communication.

If this UART is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support.

The UART manifests on the board as the TTL-level TXD and RXD pins on J23. Hardware flow control (RTS/CTS) is not supported.

SPI Driver

An SPI bus driver is available for the SAMA5D3 in the package "Atmel AT91 SPI device driver" (`CYGPKG_DEVS_SPI_ARM_AT91`).

There are no on-board SPI devices, so no SPI devices are instantiated by default.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the AT91 SPI device driver.

I²C Driver

Support for SAM I²C (TWI) busses is provided by the "Atmel TWI (I2C) device driver" package (`CYGPKG_DEVS_I2C_ATMEL_TWI`). The SAM variant HAL causes the two buses to be instantiated. These have been tested using external I²C devices.

Onboard NAND

The HAL port includes a low-level driver to access the on-board Micron MT29F2G08 NAND flash memory chip. To enable the driver, add the CYGPKG_IO_NAND package to your eCos configuration.

If using the NAND library direct, see also the NAND port implementation details.

Note

The onboard NAND chip is usually the boot device on this board.

Warning

Before writing to the NAND device from an application, be sure you understand the partition scheme in use and how it relates to the system bootstrap code. Failure to do so risks overwriting the second stage boot loader and/or RedBoot, leaving your board unbootable until you reprogram it.

There are several ways to partition the NAND chip. The eCos configuration setting `CYGSEM_HAL_SAMA5D3_NAND_PARTITION_SCHEME` specifies which one to use. The default NAND configuration, which eCosCentric recommend for development, is "`Config_store`" which uses the eCos on-NAND partition table.

eCos on-NAND partition table

The eCos native partition scheme ("`Config_store`") for this board has the following contents:

- The first 6 non-factory-bad blocks (384k) are reserved for the system bootstrap, and normally contain AT91Bootstrap or BootUp, followed by RedBoot (or an application running in place of it). This number appears in the eCos configuration as `CYGNUM_HAL_SAMA5D3_NAND_RESERVE_BLOCKS_FOR_SYSTEM`.
- NAND partition 0 comprises the next 10 blocks. This is used for the NAND configuration store which records the geometry of the remaining NAND partitions and hosts the RedBoot flash config area. The size of the configuration store may be reconfigured as `CYGNUM_HAL_SAMA5D3_NAND_PARTITION_CONFIG_STORE_SIZE`.
- The remainder of the chip, and the remainder of the partition slots, are available for arbitrary partitioning and use by applications, with their geometry stored dynamically in the configuration store (see below). It is automatically set up as a single partition, numbered 1; up to three partitions are available in a default configuration, but moremay be provisioned if required by reconfiguring `CYGNUM_NAND_MAX_PARTITIONS`.

Warning

If you change `CYGNUM_HAL_SAMA5D3_NAND_RESERVE_BLOCKS_FOR_SYSTEM` or `CYGNUM_HAL_SAMA5D3_NAND_PARTITION_CONFIG_STORE_SIZE`, you must rebuild all images (including RedBoot) that use the changed value and reprogram them at the same time. You should consider erasing and reprogramming the entire NAND array in order to guard against configuration skew situations which are likely to cause data corruption.

The geometry of the remaining partitions is stored as integer entries in the config store, with config store keys named `nand.partition1.base`, `nand.partition1.size`, `nand.partition2.base`, `nand.partition2.size` and so on.

These may be changed from within RedBoot using the `nconfig` command. For example:

```
RedBoot> nand info
NAND device `onboard':
  2048 bytes/page, 64 pages/block, capacity 2048 blocks x 128 kB = 256 MB
  Partition Start Blocks
       0       6     10
       1      16   2036
RedBoot> nconfig put nand.partition1.size uint 200
Written OK
RedBoot> nconfig put nand.partition2.base uint 216
Written OK
RedBoot> nconfig put nand.partition2.size uint 1836
Written OK
RedBoot> reset
... Resetting. RomBOOT

. . . full boot-up messages omitted for brevity . . .

+NAND: onboard: 1 partition  configured
NAND: Read partition geometry from config store
NAND: onboard: 3 partitions configured

. . . full boot-up messages omitted for brevity . . .

NAND: onboard
RedBoot> nand info
NAND device `onboard':
  2048 bytes/page, 64 pages/block, capacity 2048 blocks x 128 kB = 256 MB
  Partition Start Blocks
       0       6     10
       1      16    200
       2     216   1836
RedBoot>
```

Applications may change these via the config store call `cyg_configstore_write_int`; refer to the configuration store documentation for details.

Note

After changing the partition geometry in the config store, it is necessary to reset the board for the changes to take effect - hence the reset command above.

Caution

When changing partition geometry, eCos makes no attempt to preserve any data on the affected partition(s); it is up to you to arrange this if it is important to you. If you do not need to keep the data, consider erasing the affected partition(s) before editing them. RedBoot provides a `nand erase` command for just this purpose.

Manual partitioning

A CDL script which allows the chip to be manually partitioned is provided (see `CYGSEM_HAL_SAMA5D3_NAND_PARTITION_MANUAL`); if you choose to use this, by setting `CYGSEM_HAL_SAMA5D3_NAND_PARTITION_SCHEME` to "`Manual`", the relevant data structures will automatically be set up for you when the device is initialised. By default, the manual config CDL script does not set up any partitions.

Note

The configuration store always uses partition 0 on this board. If you wish to use the configuration store (such as in RedBoot) you must leave a suitable space for it. Do not write any other data to partition 0; it is automatically managed by the config store and will likely be erased.

Warning

The manual partitioning scheme does NOT take account of the space required for system bootstrap. If you choose this option, be sure to allow sufficient space for these in your partition layout.

Other partitioning schemes

It is possible to configure the partitions in some other way, should it be appropriate for your setup, for example to read a Linux-style partition table from the chip. To do so you will have to add appropriate code to `sama5d3xpld_nand.c`, and a new option to `CYGSEM_HAL_SAMA5D3_NAND_PARTITION_SCHEME`.

Ethernet Driver

The SAMA5D3-XPLD board uses the SAMA5D3's internal EMAC and GMAC Ethernet devices attached to external Micrel KSZ8081RNB and KSZ9031RN PHYs respectively. The `CYGPKG_DEVS_ETH_ARM_AT91` package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the board. This driver is not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

Both the standard and direct (lwIP only) device drivers are supported. The standard driver is enabled by default; the direct driver can be enabled by setting `CYGOPT_IO_ETH_DRIVERS_LWIP_DRIVER_DIRECT` option. At the time of writing, the direct driver only supports the EMAC (ETH1), and not the GMAC (ETH0).

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the SAMA5D3-XPLD board hardware, and should be read in conjunction with that specification. The SAMA5D3-XPLD platform HAL package complements the ARM architectural HAL and the SAMA5D3 variant HAL. It provides functionality which is specific to the target board.

Startup

In the release view of the world the SAMA5D3 Xplained board boots into the BootUp “application loader” from a suitable on-chip `RomBOOT` supported memory.

When using the second-stage BootUp loader the main (`ROMRAM` startup type) application is then loaded from the configured non-volatile storage (e.g. NAND, SD card) into the DDR2-SDRAM for execution.

The CPU variant bootstrap overview should be read in conjunction with this documentation.

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for `RAM` startup applications which depend on a ROM monitor for certain services, and so will not attempt to re-initialize the underlying peripheral.

For `ROM`, `ROMRAM` and `SRAM` startups the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins as required. The details of the early platform hardware startup may be found in the `plf_hardware_init()` function within the source file `src/sama5d3xpld_misc.c`.

Memory Map

The SAMA5D3 Xplained HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

External RAM
: This is located at address 0x20000000 of the memory space, and is 256MiB long. For `ROM`, `ROMRAM` and `SRAM` applications the initial 32KiB is set aside, primarily for the first level MMU table and (depending on the startup type) the eCos VSR table. The rest of the RAM is then available for application use. For `RAM` startup applications the first 1MiB of RAM is reserved for the “debug” monitor (e.g. RedBoot), and the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder is then available for the `RAM` application.

Internal RAM
: This is located at address 0x00300000 of the memory space, and is 128KiB in size.

On-chip Peripherals
: The I/O is primarily accessible from location 0xF0000000 upwards, though some I/O is mapped into the initial 10MiB of the address space. Descriptions of the contents can be found in the Atmel SAMA5D3 Series Datasheet.

Linker Scripts

The platform linker script defines the following symbol:

hal_mmu_page_directory_base
: This symbol defines where the initialization code will place the level-1 table when initialising the MMU.

Diagnostic LEDs

Two LEDs are fitted onto the CPU Module for diagnostic purposes, one red and one blue.

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow the LEDs to be controlled:

```
extern void hal_sama5d3xpld_led(cyg_uint32 bitmask);
```

The low-order 2-bits of the argument *`bitmask`* correspond to each of the 2 LEDs. The red LED is logically mapped to bit 0, with the blue LED mapped to bit 1.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for RAM startup, where both code and data are using the external DDR2-SDRAM.

Example 280.1. sama5d3xpld Real-time characterization

```
             Startup, main thrd : stack used   388 size  1792
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    96 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    2.97 microseconds (24 raw clock ticks)

Testing parameters:
   Clock samples:            32

Data integrity on the on-board NAND

The HAL port only provides ECC protection for the *main area* of the on-board MT29F2G08 NAND array. (This is achieved using the SAMA5D3 CPU's internal PMECC unit.)

Applications using the NAND library to store data in the *spare area* of the array should consider whether they ought to employ ECC or comparable protection for the data stored there. The recommended correction capacity for this part is 4 bits per quarter-page; refer to the MT29F2G08 datasheet for full details.

Caution

The consequences of insufficient ECC protection are difficult to predict but are likely to include data corruption, undetected by the driver, at a higher rate than expected.

Name

BootUp Integration — Detail

BootUp

The BootUp support for this platform is primarily implemented in the `sama5d3xpld_misc.c` file. The functions are only included when the `CYGPKG_BOOTUP` package is being used to construct the actual BootUp loader binary.

The BootUp code is designed to be very simple, and it is envisaged that once an implementation has been defined the binary will only need to be installed onto a device once. Its only purpose is to allow the startup of the main `ROMRAM` application.

This platform specific documentation should be read in conjunction with the generic BootUp package documentation.

The BootUp package provides a basic but fully functional implementation for the platform. It is envisaged that the developer will customize and further extend the platform side support to meet their specific application identification and update requirements.

The BootUp binary can be installed on *any* SAMA5D3x bootable media, and is not restricted to being placed into NAND flash.

On execution BootUp will copy the `ROMRAM` configured final application from its Non-Volatile-Memory (NVM) location. The configuration option `CYGIMP_BOOTUP_SAMA5D3_SOURCE` selects where the second-level BootUp code will look for the final application image. At present only NAND Flash is supported.

The SAMA5D3x-MB (MotherBoard) documentation provides more detail about the SAMA5D3 BootUp world, including secure boot functionality.

Building BootUp

Building a BootUp loader image is most conveniently done at the command line. The steps needed to rebuild the `SRAM` version of BootUp are:

```
$ mkdir bootup_SRAM
$ cd bootup_SRAM
$ ecosconfig new sama5d3xpld minimal
$ ecosconfig import $ECOS_REPOSITORY/packages/hal/arm/cortexa/sama5d3/sama5d3xpld/current/misc/bootup_SRAM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

The resulting `install/bin/bootup.bin` binary can then be programmed into a suitable non-volatile memory as supported by the SAMA5D3 on-chip `RomBOOT`. e.g. NAND Flash.

The example `bootup_SRAM.ecm` is configured to expect to find the `ROMRAM` application stored in the NAND Flash at offset `CYGNUM_BOOTUP_SAMA5D3_SOURCE_OFFSET`. It is also configured with application encryption support (`CYGFUN_BOOTUP_SAMA5D3_SOURCE_SECURE` option) to allow decryption of the stored application to its final RAM destination.

Note

The application image to be loaded does *not* need to be encrypted. The BootUp code uses binary identity markers to check for the presence of a plaintext (unencrypted) image; if not present, a check for encrypted markers is made.

Whether or not encryption is in use, the application image must be installed to offset `CYGNUM_BOOTUP_SAMA5D3_SOURCE_OFFSET` in the source NVM.

Installing BootUp

How the second-level BootUp loader is placed into bootable memory in a production environment is beyond the scope of this document. However, for the `sama5d3xpld` target platform, several solutions are available.

The simplest may be to use the on-chip SAM-BA support via a USB CDC-ACM host connnection to `J6`. This procedure is documented in the Setup section, which may also be used to install your choice of `ROMRAM` eCos application onto the target hardware.

Alternatively, a suitable hardware debugger (JTAG) configuration could directly update the relevant memories via suitable host-based debugger software features, or configuration script sequence. At its simplest the JTAG interface could be used to load a `ROMRAM` application that performs the necessary update of the boot NVM memory, either from embedding the required binaries in the application image, or (ideally) loading data from a suitable network location via the Ethernet interfaces `J12`/`J13`.

Chapter 281. Raspberry Pi Board Support

Name

eCos Support for the Raspberry Pi Board Family — Overview

Description

The eCosPro release for the Raspberry Pi family is free to use for non-commercial, educational and evaluation purposes. If you wish to use it within a commercial product then a license from eCosCentric is required. Please see the eCosPro license page for details.

This document covers the configuration and usage of eCos and RedBoot on the Raspberry Pi Family of Boards. eCos should be functional on all current members of the family and has been tested on the following variants: Pi Zero, Pi Zero W, Pi 1 Model B, Pi 2 Model B, Pi 3 Model B, Pi 3 Model B+, Pi 3 Model A+, Pi Compute Module 1 and Pi Compute Module 3 (standard, lite and plus versions). These boards are fitted with one of three variants of the Broadcom BCM283X System-on-Chip devices.

In addition to the BCM283X, the board contains 256MiB to 1GiB of SDRAM main memory, an SD card socket, and an optional LAN951X or LAN7515 USB hub/Ethernet device. Variants of the RPi may have a CYW43438 WiFi/Bluetooth device, and may have an eMMC device in place of the SD socket. All have a GPIO header giving access to various IO pins, including GPIO, UART, SPI and I^{2}C. For details of which devices are available on which board variants, see the Raspberry Pi Foundation website, or the Raspberry Pi Wikipedia page.

eCos applications can be developed either using a JTAG-based hardware debugger or by use of the RedBoot ROM monitor. eCos applications are deployed booting directly from the Raspberry Pi SD card, or in the case of the compute modules, from the eMMC.

For RedBoot-based development, the RedBoot image is programmed onto an SD card, or into eMMC, and the board boots directly into RedBoot from reset. RedBoot incorporates a gdb stub that enables eCos applications to be downloaded and debugged via the host-based gdb debugger. You can connect gdb to the board either via a serial line or over Ethernet. Note that applications that make use of USB-based peripherals (including Ethernet) are limited to the serial connection as the eCos USB functionality cannot be shared with RedBoot.

Support for SMP operation of the four CPUs in the RPi2 and RPi3 variants is available, although debugging support is restricted to use of an external JTAG debugger, such as the Lauterbach TRACE32. There is no SMP debug support in RedBoot.

This documentation is expected to be read in conjunction with the BCM283X variant HAL documentation and further device support and subsystems are described and documented there.

Note that the Raspberry Pi may be also be referred to using the abbreviation "RPi" within the documentation.

Supported Hardware

The following devices are currently supported by the Raspberry Pi port. These apply to all RPi boards unless stated otherwise.

UART
: Auxiliary mini UART only, RX and TX lines only connected to GPIO14 and GPIO15 on the GPIO header. Used by RedBoot for communication with the user and GDB. The PL011 UART1 is not currently supported and is reserved for future use with Bluetooth on those boards that are so equipped.

SPI
: SPI0 device only. The auxiliary SPI1 and SPI2 devices are not supported. SPI0 is mapped to GPIO7 to GPIO11 on the GPIO header.

I^{2}C
: I2C1 using the BSC1 controller only. I2C1 uses the GPIO2 and GPIO3 pins on the GPIO header. BSC0 is reserved for use by the GPU, and BSC2 is dedicated to the HDMI interface.

PWM
: Support for simple use of the PWM device is available via the PWM API package. The PWM device ("pwm0") has two channels. Channel 0 is connected to GPIO pins 12 and 18, pins 12 and 32 on the GPIO header. Channel 1 is connected to GPIO pins 13 and 19, pins 33 and 35 on the GPIO header.

USB
USB host support is provided by the USB protocol stack and the Synopsys DWC host controller driver. The stack also provides support for the hub component of the LAN951X/LAN7515 device. The stack currently only provides Control and Bulk endpoint support, at High, Fast and Low speeds.

Ethernet
For those boards equipped with a LAN951X/LAN7515, the Ethernet driver provides support for both the BSD and LWIP protocol stacks.

WiFi
For those RPi boards equipped with a suitable 802.11 chipset the hardware specific `CYGPKG_NET_WIFI_BROADCOM_WWD` driver package, in conjunction with the generic `CYGPKG_NET_WLAN` package, provides support for the LWIP protocol stack.

The wireless network support has been tested against the RPi3B (Raspberry Pi 3 Model B V1.2), RPi3B+ (Raspberry Pi 3 Model B+ 2017) and RPi0W (Raspberry Pi Zero W V1.1) platforms.

The majority of testing involves the standard `CYGPKG_NET_NETTEST` package network tests using the lwIP (`CYGPKG_NET_LWIP`) TCP/IP stack. The eCosPro WLAN (`CYGPKG_NET_WLAN`) provides the settings for the default wireless network connection settings used, as well as some wireless specific tests.

MMC/SD
A driver for the Broadcom SDHOST MMC/SD controller provides access to either cards in the SD socket or, in the compute modules, the eMMC device. The FAT filesystem package provides access to files on these devices.

GPIO
A set of macros in the BCM283X variant HAL provide support for controlling all GPIO pins, including setting pin modes and selecting alternate functions. GPIO interrupts are decoded to provide a separate vector for each pin.

JTAG
On booting RedBoot, and ROM startup eCos applications, the HAL sets a group of GPIO pins to their JTAG alternate functions. This allows an external JTAG debugger to connect and load an application for development. RedBoot also contains a JTAG command that allows the JTAG pin mappings to be changed at runtime.

In general, devices (Caches, GPIO, UARTs) are initialized only as far as is necessary for eCos to run. Other devices (I^{2}C, SPI, MMC/SD etc.) are not touched unless the appropriate driver is loaded, although in some cases, the HAL boot sequence may set up the appropriate pin alternate configuration.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 4.7.3, arm-eabi-gdb version 7.2, and binutils version 2.23.

Name

Setup — Preparing the Raspberry Pi for eCos Development

Overview

In a typical development environment, the board boots from the SD/eMMC and runs the RedBoot ROM monitor from SDRAM. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the board therefore usually involves programming a suitable RedBoot image into an SD card.

Initial Installation

A Raspberry Pi boots initially to the GPU which then reads and executes a second-level GPU bootstrap image from the SD card. This then reads an ARM executable image from the card into SDRAM and executes it. For eCos development we want RedBoot to be the ARM image loaded from the SD card.

The SD card used to boot RedBoot is prepared in exactly the same way as a card is prepared to boot Raspian or any other operating system for the RPi. A complete disk image must be written to the card, typically from a host system running either Windows or Linux. You will need a 2GB, or larger, SD card for this purpose.

A prebuilt bootable SD card image is supplied as part of the eCosPro release. This image is universal and will boot RedBoot on all Raspberry Pi variants. The `eCosPro_RedBoot_RPi_2Mb.img` image is located within your eCosPro installation in the `eCosPro/ecos-`*`VERSION`*`/loaders/rpi` directory. This RedBoot uses 2Mb/s as its default serial speed.

A few non-FTDI based USB to serial converters have been found to be incapable of reliably handling the high-speed 2Mb/s default baud rate used by the standard RedBoot image. For these systems an alternative `eCosPro_RedBoot_RPi_115k.img` image has been provided in the same location. This defaults to a baud rate of 115200, but is otherwise identical. This may also be useful if you encounter any communications issues with slow host machines, or with specific operations such as x/ymodem transfers. Alternatively you could dynamically change the communications speed used by RedBoot with its **baudrate** command.

Installation from Windows to an SD card

The following steps describe how to create a bootable RedBoot SD card for your Raspberry Pi. The best Windows-based tool for this purpose is the freely available **balenaEtcher** SD card image burning utility (previously and often still referred to as Etcher). This is also the recommended utility for writing Raspian and other RPi Linux images.

Visit www.balena.io/etcher to download and install the **balenaEtcher** SD Burner utility.

1. Insert the SD card to be programmed into the PC's card reader.
2. Start the **balenaEtcher** utility and click *Select image*, then browse to and select the RedBoot Raspberry Pi image from within the `loaders/rpi` directory.
3. Click *Select drive* and select your SD card drive. Note that **balenaEtcher** may have already pre-selected the SD drive. You can click on *Change* if this is not the correct drive.
4. Click *Flash!* to write the image to the SD card. You'll see a progress bar that tells you how much is left to do. Once complete, the utility will automatically unmount the SD card so it's safe to immediately remove it from the computer.

Installation from Linux to an SD card

Installation on Linux should be done using the **dd** command.

1. Locate a Linux PC with an SD card reader and insert the SD card to be programmed into the reader.

2. Identify the device name that Linux has assigned to the SD card. This can be done either by monitoring the system log, or by using lsblk before and after inserting the card. In this example we will use `/dev/sdX` as a placeholder.

3. Execute the following command in a shell:

   ```
   $ dd status=progress if=/path/to/eCosPro_RedBoot_RPi_2Mb.img of=/dev/sdX
   ```

   Depending on permissions and user group membership, it may be necessary to prefix this command with **sudo** or run it in a root shell.

4. Execute the **sync** command. This may not be strictly necessary, but it will ensure that all data is safely written to the card.

5. The card is now ready and may be removed.

Installation from Windows to Compute Module eMMC

Installation to the compute module eMMC requires the installation of a driver and a boot utility tool.

1. Download and run the Windows Installer to install the drivers and boot tool.

2. Follow the instructions on the Raspberry Pi website for installing the driver. Make sure the J4 jumper is in the EN position.

3. Run the **RPiBoot.exe** tool. The compute module will then appear as a USB mass storage disk drive under Windows.

4. You can now use the **balenaEtcher** tool to write the RedBoot image to the drive as described above for an SD card.

5. Once complete, the USB cable can be detached. Power off the CMIO board and move J4 back to its original position. On re-applying power, RedBoot will start.

Installation from Linux to Compute Module eMMC

To program an image from Linux it is necessary to download and compile the **rpiboot** utility program.

1. The utility program is in a github repository, so ensure that git is installed. The program also needs libusb-1, so ensure that this is also installed.

2. Clone the git repository into a convenient directory.

   ```
   $ git clone --depth=1 https://github.com/raspberrypi/usbboot
   Cloning into 'usbboot'...
   remote: Counting objects: 21, done.
   remote: Compressing objects: 100% (19/19), done.
   remote: Total 21 (delta 1), reused 14 (delta 0), pack-reused 0
   Unpacking objects: 100% (21/21), done.
   $
   ```

3. Build the tool:

   ```
   $ cd usbboot
   $ make
   cc -Wall -Wextra -g -o rpiboot main.c -lusb-1.0
   $
   ```

4. Move J4 on the compute module IO board to the EN position. Connect a USB cable between the USB SLAVE port and the host and power up the board.

5. Run the rpiboot just built from the build directory:

   ```
   $ sudo ./rpiboot
   Waiting for BCM2835/6/7
   ```

```
Sending bootcode.bin
Successful read 4 bytes
Waiting for BCM2835/6/7
Second stage boot server
File read: start.elf
Second stage boot server done
$
```

6. The CM board will now be visible to Linux as a new USB mass storage device. Identify the device name that Linux has assigned to the SD card. This can be done either by monitoring the system log, or by using lsblk before and after inserting the card. In this example we will use `/dev/sdx` as a placeholder.

7. Execute the following command in a shell:

   ```
   $ dd status=progress if=/path/to/eCosPro_RedBoot_RPi_2Mb.img of=/dev/sdx
   ```

   Depending on permissions and user group membership, it may be necessary to prefix this command with **sudo** or run it in a root shell.

8. Execute the **sync** command. This may not be strictly necessary, but it will ensure that all data is safely written to the eMMC.

9. Remove power from the compute module, move J4 back to its original position and detach the USB cable from the USB SLAVE port.

10. Restore power to the compute module and RedBoot should boot.

RedBoot Startup

Once the RedBoot image has been flashed, insert the SD card into your RPi board's SD socket. If the board has an Ethernet socket insert an Ethernet cable. Connect an RS232 TTL transceiver to the Raspberry Pi's UART pins. On the host run a terminal emulator and connect to the transceiver's serial port, setting it to 2Mb/s (2000000 baud), 8 data bits, no parity, one stop bit (8N1).

Note

Suitable low cost USB RS232 TTL transceivers include the FTDI Raspberry Pi Cable: TTL-232R-RPI or FTDI LC234X module. The FTDI cable can be connected directly to the Raspberry Pi, whereas connecting the module will reqire set of additional jumper cables. These FTDI products are fully supported by drivers on both Windows and Linux hosts. Whatever transceiver is used, it will need connecting to the Raspberry Pi's GND, GPIO14 TXD (transceiver RXD) and GPIO15 RXD (transceiver TXD) pins on the GPIO header. For the 40 way expansion header on standard RPi's these are pins 6, 8 and 10 respectively. We do NOT recommend connecting any other signals that the transceiver might provide, in particular 3V3 or 5V lines.

Note

There are a wide range of freely available terminal emulation programs to choose from - we can recommend Minicom on Linux and PuTTY on Windows.

When the above connections have been made, apply power to the board and similar output to the following should be seen on the terminal:

```
+USB LOG: HCD register DWC ports 1
USB LOG: hub 01 attach on port 1
USB LOG: hub attach 03
USB LOG: hub 03 attach on port 1
USB LOG: hub attach 04
USB LOG: hub 04 attach on port 1
USB LOG: device attach 05 [ff:00] [0424:7800]
... waiting for BOOTP information
Ethernet eth0: MAC address b8:27:eb:30:d0:7b
```

```

RedBoot> fs exec
RedBoot>
```

Before loading RedBoot, the GPU configures the board according to the contents of the `config.txt` file in the boot partition. eCosPro currently makes minimal use of the settings in this file, the default `config.txt` for eCosPro just sets the GPU reserved memory to its minimum of 16MiB. No other configuration settings have been tested, so change them at your peril. Full details of the file contents can be found in the Raspberry Pi Foundation documentation.

Note

If a RPi board supports Ethernet and you do not connect an Ethernet cable, or the network does not provide a dhcp server, then you will experience a delay before the full RedBoot banner and prompt are displayed.

Resizing the Second SD Partition

The standard eCosPro disk image is sized to fit into a 2GB SD card with two partitions. The first partition is located 4MB from the beginning of the SD card and contains RedBoot and other system files necessary to boot the Raspberry Pi. The second partition follows the first and contains an initially empty VFAT filesystem of 1.23GB in size. If you have a larger card, and wish to utilise all the available storage capacity from eCos, you will need to expand the second partition to incorporate the unused capacity. As an embedded system eCosPro does not have the ability to repartition the disk itself. This needs to be done from a host system running either Windows or Linux.

Resizing from Windows

In Windows you need to run the Windows Disk Management tool to remove the second partition and create the new partition sized as required:

1. To start the tool you can click on the Start Menu and type "disk management", click on the "Create and format hard disk partitions control panel" entry that appears.

2. Remove the second partition (1.23GB FAT32) by right clicking on second partition and selecting "Delete Volume...". Click "Yes" to confirm.

3. Create a new volume of the required size (typically the remaining space on the SD) by right clicking on the "Unallocated" space and selecting "New Simple Volume...".

4. In the New Simple Volume Wizard's initial dialog click "Next >" to move to the "Specify Volume Size" dialog, then choose the disk size required (default is the remaining space on the SD) and click "Next >" again.

5. In the "Assign Drive Letter or Path" dialog choose the drive letter of your choice, typically the default provided and click "Next >".

6. In the final "Format Partition" dialog, choose the file system type - this should be the default "FAT32", then select the allocation size - choose "Default" or 4096 and then enter the "Volume label" of your choice. Leaving the "Perform a quick format" checkbox ticked, click "Next >". Review the settings and then click "Finish".

Your SD card should now contain two partitions. The first is the original boot partition containing RedBoot (or your own application, named as kernel*.img) and the second is a new partition expanded to incorporate the remaining SD card capacity.

Resizing from Linux

There are a variety of Linux tools in different distributions for resizing a partition, many are GUI based and similar to the Windows tool. The following example uses just command line tools and should work on all Linux distributions.

1. Depending on permissions, it may be best to perform the following actions as root. Either start a root shell, or prefix all commands with **sudo**.

2. Insert the SD card into the card reader and identify the device name assigned to it. This can be done either by monitoring the system log, or by using lsblk before and after inserting the card. In this example we will use `/dev/sdX` as a placeholder.

3. Run fdisk on the device and type `p` to print the partition table:

```
# fdisk /dev/sdX

Welcome to fdisk (util-linux 2.28).
Changes will remain in memory only, until you decide to write them.
Be careful before using the write command.

Command (m for help): p
Disk /dev/sdX: 14.9 GiB, 15931539456 bytes, 31116288 sectors
Units: sectors of 1 * 512 = 512 bytes
Sector size (logical/physical): 512 bytes / 512 bytes
I/O size (minimum/optimal): 512 bytes / 512 bytes
Disklabel type: dos
Disk identifier: 0xec05ec05

Device     Boot  Start     End Sectors  Size Id Type
/dev/sdX1         8192  137215  129024   63M  c W95 FAT32 (LBA)
/dev/sdX2       137216 2715647 2578432  1.2G  c W95 FAT32 (LBA)

Command (m for help):
```

   Check that things like the disk identifier and the partition parameters match the above to ensure you have the right device.

4. Use the `d` command to delete partition 2:

```
Command (m for help): d
Partition number (1,2, default 2): 2

Partition 2 has been deleted.
```

```
Command (m for help):
```

5. Ensuring you set the first sector to 137216, since there is 3MB of free space before the first partition which should NOT be used, use the `n` command to create a new partition. Check that the new partition fills the remaining card space with the `p` command.

```
Command (m for help): n
Partition type
   p   primary (1 primary, 0 extended, 3 free)
   e   extended (container for logical partitions)
Select (default p): p
Partition number (2-4, default 2): 2
First sector (2048-31116287, default 2048): 137216
Last sector, +sectors or +size{K,M,G,T,P} (137216-31116287, default 31116287):

Created a new partition 2 of type 'Linux' and of size 14.8 GiB.

Command (m for help): p
Disk /dev/sdX: 14.9 GiB, 15931539456 bytes, 31116288 sectors
Units: sectors of 1 * 512 = 512 bytes

Disk identifier: 0xec05ec05

Device     Boot  Start      End  Sectors  Size Id Type
/dev/sdX1         8192   137215   129024   63M  c W95 FAT32 (LBA)
/dev/sdX2       137216 31116287 30979072 14.8G 83 Linux

Command (m for help):
```

6. Fdisk has set the new partition's type to `Linux`, use the `t` command to change the type to FAT32:

```
Command (m for help): t
Partition number (1,2, default 2): 2
Partition type (type L to list all types): c

Changed type of partition 'Linux' to 'W95 FAT32 (LBA)'.

Command (m for help):
```

7. Finally use the `w` command to write the partition table back and exit fdisk.

8. The new partition now needs to be formatted with a FAT32 filesystem. This can be done using the **mkfs.fat** command:

```
# mkfs.fat -v -F 32 /dev/sdX2
mkfs.fat 3.0.26 (2014-03-07)
/dev/sdX2 has 64 heads and 32 sectors per track,
hidden sectors 0x21800;
logical sector size is 512,
using 0xf8 media descriptor, with 30979072 sectors;
drive number 0x80;
filesystem has 2 32-bit FATs and 16 sectors per cluster.
FAT size is 15112 sectors, and provides 1934301 clusters.
There are 32 reserved sectors.
Volume ID is e2a0eca8, no volume label.
#
```

9. Execute the **sync** command. This may not be strictly necessary, but it will ensure that all data is safely written to the card.

10. The card is now ready and may be removed.

Installing user applications onto an SD card

If you wish to install a ROM startup application onto an SD to be automatically booted instead of RedBoot, then you can do this by replacing the appropriate kernel image file in the SD card boot partition.

First prepare an SD card as per the Initial Installation section above. The card should then be remounted and your application copied over, replacing the relevant kernel image file(s) within the boot partition. Applications are compiled and linked to ELF format, and need to be converted to binary before copying to the the SD card. This can be done as follows using **objcopy**:

```
$ arm-eabi-objcopy -O binary app.elf kernel.img
```

If you have built the application for the BCM2835 (Pi1/Pi0) based boards, replace `kernel.img`, and for the BCM2836 (Pi2) or BCM2837 (Pi3) based boards, replace `kernel7.img`. Replacing the wrong file may result in the board failing to boot. For widest compatibility you can replace both `kernel.img` and `kernel7.img` with suitably built versions of your application.

Rebuilding RedBoot

Typical users should never need to rebuild RedBoot. If you do intend to modify RedBoot then please note that rebuilding it is currently only supported from the Linux command line.

The following RedBoot configurations are supported:

Configuration	**Description**	**Use**	**File**
ROM_2Mb	RedBoot loaded from SD card to SDRAM, Standard version with default baud rate of 2Mb/s	`redboot_ROM_2Mb.ecm`	`redboot_ROM_2Mb.bin`
ROM_115k	RedBoot loaded from SD card to SDRAM, alternative version with default baud rate of 115200	`redboot_ROM_115k.ecm`	`redboot_ROM_115k.bin`
JTAG	RedBoot loaded via a JTAG debugger, for RedBoot developers only	`redboot_JTAG.ecm`	`redboot_JTAG.bin`

The JTAG configuration is only required if you wish to build a version of RedBoot to load and debug over JTAG, before ultimately creating a final ROM version to be booted from SD.

Note that the use of the term ROM for the initial RedBoot configuration is a historical accident. RedBoot actually runs from SDRAM after being loaded there from the SD card by the GPU bootstrap. The use of ROM for this configuration is intended to indicate that it initializes the microprocessor and board peripherals, as opposed to a RAM configuration which assumes that this has already been done.

The ROM_115k configuration is provided as an alternative to the ROM_2Mb configuration, for compatibility with low performance USB to serial converters. It simply lowers the default baud rate to 115200 and is otherwise identical.

The final stage of the RedBoot build process will create a bootable RedBoot SD image. This is handled within the `eCosPro/ecos-`*`VERSION`*`/packages/hal/arm/cortexa/pi/current/host/buildimg.sh` script. In order for the script to complete successfully, the user must either have sudo privileges to **mount** and **cp**, or the user must be able to **mount** `/tmp/sd_pi` on `/tmp/sd`. For the latter case, the following entry in `/etc/fstab` is advised:

```
/tmp/sd_pi   /tmp/sd   vfat   user,noauto,rw,loop,offset=4194304  0   0
```

The steps needed to rebuild the ROM version of RedBoot are:

```
$ mkdir redboot_rpi2_rom
$ cd redboot_rpi2_rom
$ ecosconfig new raspberry_pi2 redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/cortexa/pi/VERSION/misc/redboot_ROM_2Mb.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `sd_pi.img`. This file is the SD card image and is suitable at this point for booting Pi2 and Pi3 boards, including the CM3, since it only contains a `kernel7.img` file. To make it also capable of booting a Pi1 or Pi0 board repeat the above command sequence with the following changes:

```
$ mkdir redboot_rpi1b_rom
$ cd redboot_rpi1b_rom
$ ecosconfig new raspberry_pi1b redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/cortexa/pi/VERSION/misc/redboot_ROM_2Mb.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of this build the `install/bin` subdirectory will contain a new `sd_pi.img` file. This should be a copy of the previous image with the addition of `kernel.img`. This image should then be written to an SD card as per the above Linux hosted setup instructions. e.g:

```
sudo dd status=progress if=install/bin/sd_pi.img of=/dev/sdX
```

The SD created should now be able to boot all RPi variants.

To build a RedBoot that uses a different default UART baud rate to the standard 2Mb/s, then edit the `ecos.ecc` file after each **ecosconfig import** stage as described above. Set user_value for both `cdl_option CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD` and `cdl_option CYGNUM_HAL_VIRTUAL_VECTOR_CONSOLE_CHANNEL_BAUD` to your desired baud rate. For example:

```
cdl_option CYGNUM_HAL_VIRTUAL_VECTOR_DEBUG_CHANNEL_BAUD {
    # Flavor: data
    # No user value, uncomment the following line to provide one.
    user_value 115200
    # value_source default
    # Default value: 2000000
    # Legal values: 9600 19200 38400 57600 115200 230400 460800 500000 576000 921600 1000000 1152000 1500000 2000000 2
};
```

You will then need to use this baud rate when connecting to the new RedBoot via a terminal or gdb debug session. The highest attainable reliable baud rate can depend upon the specific model Raspberry Pi, transceiver and/or host PC/OS used. The default 2MB/s has been found to work reliably across the Pi family members, using FTDI transceivers, connected to either Linux or Windows hosts. Use of other transceivers may require you to reduce the baud rate.

Name

JTAG-based Debugging — Usage

JTAG Hardware Connection

JTAG-based debugging requires direct wiring of the JTAG probe lines to the external GPIO pins of a Raspberry Pi board. The eCosCentric TAP-HAT provides a simple way of doing this. The GPIO pins are not enabled for JTAG operation by default and need to be initialised by RedBoot when the board is booted. See the RedBoot JTAG Command section below for details of how to select and enable the set of pins to be used.

Lauterbach TRACE32

eCosPro includes support for JTAG-based debugging using the Lauterbach **TRACE32** debugger with a Lauterbach Power Debug probe. This is currently the best solution for debugging of eCos SMP applications on the Raspberry Pi. You will need suitable licenses for ARM Architecture-v7, Architecture-v8 and multicore debugging in order to debug an SMP application, or an ARM11 license to debug the single core in an Raspberry Pi0 or Pi1.

The **TRACE32** debugger needs a startup script to initialize it for the Raspberry Pi. Some example scripts are present in the Raspberry Pi platform HAL (i.e. `packages/hal/arm/cortexa/pi/`*`VERSION`*`/misc/trace32`). The file `ecospropi2-qt.cmm` initializes TRACE32 to debug a Raspberry Pi2 using the QT based variant avaliable on some host operating systems. Similarly the file `ecospropi3-qt.cmm` initializes TRACE32 to debug a Raspberry Pi3, Pi2 v1.2, or CM3. Finally, `ecospropi1-qt.cmm` initializes TRACE32 to debug a Raspberry Pi1, Pi0, or CM1. Each of these files additionally loads `layout1s-qt.cmm` to define the initial window layout and `ecospromenu.cmm` to define an eCosPro menu.

The expectation in these scripts is that all files are present in the same directory, along with the application being debugged. It is recommended that these files be copied out of the source repository into a working directory to which the application can also be copied and that TRACE32 be started from the command line as follows:

```
$ cd /path/to/work/directory
$ t32marm64-qt -s ecospropi3-qt.cmm
```

Raspberry Pi boards cannot be reset from TRACE32, so the safest approach to debugging is to power cycle the board between runs. It is not necessary to exit TRACE32, so long as the eCosPro menu entries to re-attach or load a new application are used, TRACE32 can be re-attach to a reset board.

In addition to attaching to the target, these startup files define an additional `eCosPro` menu in the **TRACE32** GUI. It contains the following entries:

MMU Table List
: This entry causes a window showing the current state of the MMU tables for the current CPU to be displayed. In eCos, all CPUs should be using the same shared table.

Load eCos.t32
: This loads the **TRACE32** eCos RTOS specialization extension. This file should be copied out of the TRACE32 installation into the working directory. Note that depending on the version of TRACE32 in use, the eCos RTOS support may not be fully SMP-aware, so some information it displays in SMP application may be a little misleading. See the Lauterbach documentation on the RTOS debugger for eCos for more details of the functionality available.

Display Threads
: Displays a list of current threads. In recent versions of TRACE32 the current thread on each CPU will be marked RUNNING with the CPU number beside it in parentheses. However, CPU affinity is not currently displayed.

Display Scheduler
: Displays state of scheduler. Only those parts of the scheduler state common between single and multi-core systems will be displayed.

Display Thread Stacks

Displays a summary of stack usage for all threads. This includes the stack limits, current SP, and the maximum amount of stack each thread has used.

Reset Board

Reset the board. This requires an attachment between the SRST pin of the JTAG cable and the RUN pin on the Raspberry Pi board. If you are using an eCosCentric TAP-HAT adaptor, then the two pin header needs to be soldered in to the RUN-PEN holes on the Raspberry Pi board and the micro-probe lead connected between the centre SRST pin and the RUN pin.

(Re-)Attach

After the RPi has been reset, this entry will re-attach TRACE32 to the board. Typically it will be executing in RedBoot.

Disable MMU

This will disable the MMU and Caches, which may be useful during development if an unmapped view of memory is required. Any halted program cannot be restarted once this has been done.

Save Breakpoints

This entry saves the current set of breakpoints to `breakpoints.cmm`. The contents of this file is saved amd reloaded whenever an application file is loaded and allows breakpoint settings to be preserved across restarts of TRACE32. This menu entry provides an alternative way to save the current breakpoints. prior to exiting TRACE32 for example.

Load APP.ELF

This entry disables the caches and MMU, loads the file `app.elf` from the current directory, and loads any breakpoints from `breakpoints.cmm`. This is the menu entry that should be used to load and run SMP applications for development and testing. The `breakpoints.cmm` file allows a set of current breakpoints to be saved using the Store button on the breakpoint list window and have them reloaded automatically each time the application is reloaded.

Load APP.ELF Syms+Bkpts

This entry loads just the symbol tables and debug information from the application and also loads breakpoints from `breakpoints.cmm`. This is useful if the application is already running when TRACE32 is attached. For example if it is a ROM startup application that has been loaded from the SD card, or an SMP startup application that was loaded by RedBoot.

Load REDBOOT.ELF

This does exactly the same thing as the *Load APP.ELF* menu entry except that it loads `redboot.elf`. This has been useful in debugging RedBoot.

Load REDBOOT.ELF Syms +Bkpts

This does exactly the same thing as the *Load APP.ELF Syms+Bkpts* menu entry except that it loads symbold from `redboot.elf`.

Name

Configuration — Platform-specific Configuration Options

Overview

The Raspberry Pi platform HAL package is loaded automatically when eCos is configured for any RPi target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports four separate startup types:

RAM
: This startup type is normally used during application development when using the RedBoot ROM monitor. arm-eabi-gdb is used to load the RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be booted direct from the SD card. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type can also be used for applications loaded via JTAG for testing prior to committing to an SD card.

JTAG
: This startup type can be used for finished applications that are to be loaded by a JTAG debugger. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. This startup type can also be used for applications loaded via JTAG.

SMP
: This startup type can be used for finished applications that can be loaded into RAM via RedBoot or via a JTAG debugger. The load address is set to the same as for RAM applications, however, the application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. Once started, this application takes full control of the system and RedBoot will not be called again. This means that debugging via RedBoot will not be possible, only JTAG-based hardware debugging is supported. The intent of this startup type is to allow SMP test programs to be run from RedBoot, most SMP applications should use the ROM startup type.

The main difference between ROM, JTAG and SMP startup types is the address at which they are loaded. ROM applications load at 0x00008000, which is the default address used by the GPU boot loader. JTAG applications load at 0x00100000, leaving the lower 1MiB free for a ROM RedBoot. This is necessary because in multi-core systems, the secondary cores will be looping in code in the RedBoot executable, and we don't want to overwrite that, since it may cause these cores to run wild. SMP applications load at 0x00200000, leaving the lower 2MiB free. This allows either a ROM or JTAG RedBoot to be used to load it without affecting the secondary cores. For the same reasons, RAM applications also load at the 0x00200000 boundary.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

UART Serial Driver

The auxiliary mini UART is 16550 compatible and is supported by the CYGPKG_IO_SERIAL_GENERIC_16X5X generic driver package which is modified by the CYGPKG_IO_SERIAL_ARM_BCM283X driver package for the Raspberry Pi family. By default the UART used only the TXD0 and RXD0 pins connected to GPIO14 and GPIO15 on the GPIO header. While RTS and CTS could be made available on GPIO16 and GPIO17, this is not currently supported since these pins are better left for other purposes. The mini UART is also lacking some 16550 functionality, it is only capable of 7 or 8 bit characters, and only supports one stop bit and no parity; attempts to select other settings will be accepted, but will have no effect. Since the TXD0 and RXD0 pins are not at RS232 levels it is necessary to either connect an RS232 transceiver to them or, more usually, an FTDI USB serial convertor module.

SPI Driver

SPI0 is supported by the CYGPKG_DEVS_SPI_ARM_BCM283X. The auxiliary SPI1 and SPI2 devices are not currently supported. By default the MISO, MOSI and SCLK signals are connected to GPIO9, GPIO10 and GPIO11 respectively. The chip select signals are connected to GPIO7 and GPIO8. These pins are managed in GPIO mode, so it is possible to add extra SPI devices by assigning additional GPIO pins to act as chip select lines.

I²C Driver

I2C1 is supported by the CYGPKG_DEVS_I2C_BSC driver. The SDA1 and SCL1 signals are connected to GPIO2 and GPIO3 pins. I2C0 is used by the GPU to operate the ID_SD and ID_SC pins as well as the GPIO extender in the Compute Modules; I2C2 is dedicated to the HDMI interface; so neither of these is available for use.

PWM Driver

PWM is supported by the CYGPKG_DEVS_PWM_BCM driver. The PWM device supports two channels connected to four pins available on the GPIO header. Channel 0 is connected to GPIO12 and GPIO18, pins 12 and 32 on the GPIO header. Channel 1 is connected to GPIO13 and GPIO19, pins 33 and 35 on the GPIO header. Note that some of these may clash with other uses of the same pins, particularly GPIO19 which is also SPI MISO.

USB Support

USB is supported by the CYGPKG_IO_USB package USB protocol stack together with the CYGPKG_DEVS_USB_DWC host controller driver. The stack will recognize and support the USB hub component of the LAN951X/LAN7515 when it is available on the board, together with any hubs that might be plugged in to that. The stack currently only supports CONTROL and BULK transfer types, INTERRUPT and ISOCHRONOUS transfers are not supported. The host controller driver currently supports High, Fast and Low speed devices. USB support is currently oriented towards supporting USB mass storage devices, serial devices including CDC/ACM and FTDI serial adaptors, and the LAN951X/LAN7515 Ethernet component.

Ethernet Driver

Support for the LAN951X/LAN7515 Ethernet component is provided by the CYGPKG_DEVS_ETH_LAN951X driver. This driver is dependent on the USB stack and can only be configured if the USB stack is also present. This driver is also not active until the generic Ethernet support package, CYGPKG_IO_ETH_DRIVERS, is included in the configuration.

The option CYGPKG_DEVS_ETH_LAN951X_SHORT_CIRCUIT controls whether the Ethernet driver uses the Raspberry Pi board type to decide whether the board contains an Ethernet device. If it does not, then initialization of the driver and the entire network stack is prevented, saving startup time. This option can be misled if, for example, a Compute Module is plugged in to a carrier board that has a LAN951X/LAN7515 installed. So by default the option is only enabled for RedBoot builds, and not for eCos builds, where the user is expected to know what they are doing. If the default is not as reqired, it can be changed in the ConfigTool.

WiFi Driver

Support for the wireless network is provided by the CYGPKG_NET_WIFI_BROADCOM_WWD driver. The majority of the wireless configuration is fixed based on the RPi platform configured with no user configuration required. It is enabled by default when the appropriate packages are included in the configuration.

The WiFi chipsets used in the Raspberry Pi platforms require 3rd-party binary firmware images for correct operation. See the WICED specific Chipset Firmware section for details covering the RPi specific images.

The option CYGPKG_HAL_ARM_CORTEXA_PI_WICED_DCT controls whether the WICED Device Configuration Tables (DCT) support is enabled. The enabled functionality can be used by the WICED SDK, and the application world, to hold persistent WiFi configurations.

MMC/SD Driver

Support for the SD/MMC socket is provided by the CYGPKG_DEVS_MMCSD_SDHOST driver. This uses the Broadcom SDHOST controller; the Arasan SDHCI controller is not currently supported, although in future it will be used for the CYW43438 WiFi device on the Pi3 and CM3. On the compute modules, this same driver provides access to the eMMC device.

The MMC/SD bus driver layer (CYGPKG_DEVS_DISK_MMC) is automatically included as part of the hardware-specific configuration for these targets. All that is required to enable MMC/SD support is to include the generic disk I/O infrastructure package (CYGPKG_IO_DISK), along with the intended filesystem, typically, the FAT filesystem (CYGPKG_FS_FAT) and any of its package dependencies (including CYGPKG_LIBC_STRING and CYGPKG_LINUX_COMPAT for FAT).

While earlier variants of the Raspberry Pi had a card detect signal from the SD card socket attached to a GPIO line, this has been dropped in later variants. It also makes no sense for the permanently connected eMMC devices on the compute modules. Therefore, card detection is not currently supported on any RPi boards, so the disk IO layer's removable media support cannot detect card insertion or removal, and the FILEIO layer's automounter cannot currently be used.

GPIO Support

GPIO support is provided by the BCM283X variant HAL , and is documented there. The GPIO API is built around descriptors that encode a GPIO pin number together with its function (IN, OUT or device function) and mode into a single 32 bit value. The mode includes edge and level interrupt recognition and pull up and down settings. The eCosPro subsystem also decoded all GPIO interrupts into separate vectors.

Frequency Control

eCos does not contain any support for dynamic frequency management in the same way that Linux does. The CPUs run at a single frequency throughout. Normally this is the maximum frequency permitted without overclocking. A different frequency may be selected in the configuration, or it may be set at runtime by calling hal_bcm283x_set_freqencies(). See the BCM283X HAL for details.

The option CYGHWR_HAL_ARM_CORTEXA_BCM283X_ARM_FREQ defines the frequency in MHz at which the ARM CPU will run. For RAM startup types, the default value of zero will cause the application to continue using the frequency set up by RedBoot. For other startup types, a value of zero will cause the HAL to select a default frequency based on the board type. A non zero value will force the CPU frequency to the given value.

The option CYGHWR_HAL_ARM_CORTEXA_BCM283X_CORE_FREQ defines the frequency in MHz at which the GPU will run. For RAM startup types, the default value of zero will cause the application to continue using the frequency set up by RedBoot. For other startup types, a value of zero will cause the HAL to select a default frequency based on the board type. A non zero value will force the CPU frequency to the given value.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. The following flags are specific to this port:

`-mcpu=arm1176jzf-s`
: The arm-eabi-gcc compiler supports many variants of the ARM architecture. A `-m` option should be used to select the specific variant in use. For the BCM2835 variants that contain a single ARM11 CPU, (Pi0, Pi1, CM1), this option should be selected.

`-mcpu=cortex-a7`
: For the BCM2836, containing 4 Cortex-A7 CPUs and the BCM2837, containing four Cortex-A53 CPUs, this option should be selected. While the Cortex-A53 is strictly a ARM64 CPU, we can only use it in ARM32 mode, where it supports the same instruction set as the Cortex-A7. So, for simplicity we use the same option for both.

`-mthumb`
: The arm-eabi-gcc compiler will compile C and C++ files into the Thumb2 instruction set when this option is used. The best way to build eCos in Thumb mode is to enable the configuration option `CYGHWR_THUMB`.

Name

SMP Support — Usage

Overview

Support is available for SMP operation of the four CPUs available in the Pi2, Pi3 and CM3 variants. However, debugging support is restricted to using an external SMP-aware JTAG debugger like ARM's DS-5 or a Lauterbach Power Debug probe. RedBoot does not have support for multi-core debugging.

A board intended to be used for SMP development should be initialized in the same way as a single core board by installing the same standard RedBoot SD card image.

SMP support is enabled by setting `CYGPKG_KERNEL_SMP_SUPPORT` to true. SMP applications should only be built using either ROM, JTAG or SMP startup types. ROM applications can be loaded from the SD card in place of RedBoot. The SMP startup is identical to a ROM startup except that the load address is set to allow the application to be loaded into a higher location in RAM from RedBoot. All application types may also be loaded via a JTAG debugger.

Loading an SMP startup application via RedBoot can be done from the RedBoot command line via serial. It may also be loaded via a GDB connection on serial. However, once started running the SMP application will take full control of the system, including redirecting all interrupt sources, exception vectors and virtual vector table entries. This means that RedBoot will no-longer be active. Any breakpoints planted by GDB will result in an exception to the application, Ctrl-C will not work, any Ethernet connections will be lost and serial output will come from the application in plain ASCII. Any GDB connection will be lost and GDB may start reporting packet errors.

It is possible to load an SMP startup program via GDB and have its output displayed on the GDB console. To do this set `CYGSEM_HAL_DIAG_MANGLER` to `"GDB"`, and `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` to `1`. The application will still not be controllable from GDB, but this does simplify the running of test code; avoiding the need to disconnect GDB and connect a terminal emulator to capture or view the output.

SMP development has been tested using the Lauterbach TRACE32 debugger. While DS-5 should also work, given appropriate configuration, this has never been tested. GDB working through a JTAG debugger such as OpenOCD may work, but support for debugging multiple cores is poor.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Raspberry Pi hardware, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the Cortex-A variant HAL and the BCM283X variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

SDRAM

This is located at address 0x00000000 of the physical memory space. The HAL configures the MMU to retain the SDRAM at virtual address 0x00000000 with caching enabled. The same memory is also accessible uncached and unbuffered at virtual location 0x80000000 for use by device drivers. ROM applications are loaded by the GPU starting at 0x000008000. Memory is required for the MMU tables, and must be aligned on a 16Kbyte boundary. These therefore occupy memory from 0x00004000 to 0x00008000, just below the load address. Interrupt and exception vectors are placed at 0x00000000 and the virtual vectors occupy 256 bytes at 0x00000050. For ROM startup, all remaining SDRAM above 0x00008000 is available. JTAG startup applications are loaded from 0x00100000, leaving the bottom 1MiB unused. RAM and SMP startup applications are loaded from location 0x00200000, reserving 2MiB.

Boards with 256MiB or 512MiB of SDRAM will only occupy the least significant portion of this region. Accesses beyond the limit of physical memory will raise an exception. On boards with 1GiB, the peripheral registers overlay the top 16MiB of SDRAM, so not all the SDRAM is available. In all boards, the GPU must reserve a portion of SDRAM. Since eCos does not currently make use of the GPU, the minimum possible 16MiB is reserved. So, the smaller boards have a maximum of 240MiB and 496MiB RAM available, and the 1GiB boards have a maximum of 992MiB available. The GPU reserved region depends on the contents of `config.txt` at boot time, so these figures should not be relied upon. Applications should rely on eCos to manage the quantity of RAM available, or can use the macro `HAL_MEM_REAL_REGION_TOP(0)` to discover the actual size of the SDRAM available.

Peripheral Registers

These occupy a 16MiB physical address space at either 0x20000000 for the BCM2835 based systems or at 0x3F000000 for BCM2836 and BCM2837 based systems. The MMU is used to unify these disparate mappings by relocating both, uncached, to 0x50000000.

Multicore Peripheral Registers

These are only present in the BCM2836 and BCM2837 based systems and contain hardware that is only applicable to these multicore devices. This 1MiB area is identity mapped uncached at 0x40000000.

The virtual address space visible to applications is summarized in the following table. Any address range not mentioned here should not be accessed and will raise an exception if it is.

Base	Size (MiB)	Cache	Description
0x00000000	1008	Enabled	Normal SDRAM access -- to limit of physical RAM, raises an exception beyond that.
0x40000000	1	Disabled	Multicore registers -- multicore systems only, raises an exception in single core systems.
0x50000000	16	Disabled	Peripheral registers.
0x80000000	1008	Disabled	Uncached SDRAM access -- to limit of physical RAM, raises an exception beyond that.

Real-time Characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM32 mode and run in non-SMP mode on a Raspberry Pi3. The BCM283X is a high performance processor, but its general purpose timer is only clocked at 1Mhz. This results in microsecond level resolution which is insufficient precision for the timing of many eCos kernel operations.

Example 281.1. Raspberry Pi3 Real-time characterization

```
             Startup, main thrd : stack used   388 size  1792
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    96 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    3.00 microseconds (3 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  64
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32
   Scheduler operations:    128
   Counters:                 32
   Flags:                    32
   Alarms:                   32
   Stack Size:             1088

EXIT:<done>
```

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The BCM283X processor HAL and the ARM architectural HAL documentation should be consulted for further details.

Name

RedBoot Extensions — Usage

Overview

The Raspberry Pi version of RedBoot provides a number of extensions to the standard RedBoot behaviour. These include the execution of a startup script and some extra commands.

Startup Script

Unlike most RedBoot instances, the Raspberry Pi always has access to a storage device containing a file system. It is also useful for JTAG debugging to be able to have some dynamic hardware initialization. So, on startup RedBoot attempts to mount the boot partition on the SD card and execute the contents of a script file.

The script file is named `redboot.txt` and consists of a sequence of RedBoot commands separated by newlines. Blank lines are ignored. Comments are introduced by the a hash character (#) and extend to the end of the current line.

RedBoot waits 1 second before executing the script, during which time the user may type a Ctrl-C character to abort execution of the script. This time may be changed by rebuilding RedBoot with a different `CYGNUM_REDBOOT_BOOT_SCRIPT_DEFAULT_TIMEOUT` value.

Other ports of RedBoot are typically flash memory resident and use the flash as a persistant store for RedBoot configuration information and files. You will find these areas referred to as the fconfig area and flash image system (FIS) within the RedBoot documentation. As the `redboot.txt` script file can contain any standard RedBoot command, as well as the additional Raspberry Pi commands described below, you can use it to configure any settings that would normally be stored in the fconfig area. For example, you could set a static IP address for the board with the **ip_address** command:

```
ip_address -l 192.168.1.100/24
```

To modify the `redboot.txt` file simply mount the SD card on a PC. You will find `redboot.txt` in the root directory of the boot partition.

INFO Command

The **info** command provides information about the current Raspberry Pi board. RedBoot, and eCos, discover the type of board and its properties at runtime. This command reports what has been found out. As an example, the output for a Pi3 would appear as follows:

```
RedBoot> info
Board Model    = 00000000
Board Revision = 00a02082
                 Model   = B3
                 Version = 1.2
                 CPU     = BCM2837 - Cortex-A53
                 RAM     = 1024MiB
                 Flags   = 07 Ethernet WiFi Bluetooth
Board Serial   = 000000009330d07b
MAC Address    = b8:27:eb:30:d0:7b
SDRAM Size     = 3e600000
DMA Channels   = 0 2 4 5 8 9 10 11 12 13 14
Temperatures:
       Current =  49.388 C
       Maximum =  85.000 C
Clocks:
       ARM     =  1200 MHz (min/orig/max: 600/600/1200 MHz)
       Core    =   400 MHz (min/orig/max: 250/250/400 MHz)
       Timer   =     1 MHz
       UART0   =    48 MHz
       EMMC    =   200 MHz
```

```
RedBoot>
```

And for a Pi0:

```
RedBoot> info
Board Model    = 00000000
Board Revision = 00900092
                 Model   = 0
                 Version = 1.2
                 CPU     = BCM2835 - ARM11
                 RAM     = 512MiB
                 Flags   = 00
Board Serial   = 00000000e868b4c6
MAC Address    = b8:27:eb:68:b4:c6
SDRAM Size     = 1f000000
DMA Channels   = 0 2 4 5 8 9 10 11 12 13 14
Temperatures:
       Current =  29.324 C
       Maximum =  85.000 C
Clocks:
       ARM     =  1000 MHz (min/orig/max: 700/700/1000 MHz)
       Core    =   400 MHz (min/orig/max: 250/250/400 MHz)
       Timer   =     1 MHz
       UART0   =    48 MHz
       EMMC    =   200 MHz
RedBoot>
```

FREQ Command

The **freq** command provides information and control over the ARM CPU frequency and the system CORE frequency. The `-a` option allows the ARM frequency to be changed and the `-c` option allows the system CORE frequency to be changed. In both cases the frequency is expressed in MHz. The command finishes by reporting the clock frequencies in the same format as the **info** command. For example on a Pi3:

```
RedBoot> freq

        Clocks:
       ARM     =  1200 MHz (min/orig/max: 600/600/1200 MHz)
       Core    =   400 MHz (min/orig/max: 250/250/400 MHz)
       Timer   =     1 MHz
       UART0   =    48 MHz
       EMMC    =   200 MHz
RedBoot> freq -a 800
Set ARM frequency to   800 MHz
Clocks:
       ARM     =   800 MHz (min/orig/max: 600/600/1200 MHz)
       Core    =   400 MHz (min/orig/max: 250/250/400 MHz)
       Timer   =     1 MHz
       UART0   =    48 MHz
       EMMC    =   200 MHz
RedBoot> freq -c 300
Set CORE frequency to   300 MHz
Clocks:
       ARM     =   800 MHz (min/orig/max: 600/600/1200 MHz)
       Core    =   300 MHz (min/orig/max: 250/250/400 MHz)
       Timer   =     1 MHz
       UART0   =    48 MHz
       EMMC    =   200 MHz
RedBoot>
```

GPIO Command

The **gpio** command provides information and control of the GPIO pins available in the BCM283X. The command supports a number of sub-commands:

gpio get [pin]

Print the state of a given GPIO pin, or if no pin is given, it prints the state of all pins. The information printed for each pin includes the alternate function value and the name of the function selected, mode setting bits, and the current input level.

gpio in <pin>

Reports the current input level of the pin, 0 or 1.

gpio monitor [-m <msec>] <pin>

Monitor a given pin for changes and print the value every second. The `-m` option allows the monitoring interval to be changed to the given number of milliseconds.

gpio out -0|-1 <pin>

Set the output of the given pin to 0 (`-0`) or 1 (`-1`). The pin may need to be set to output mode with **gpio set** before any effect can be seen.

gpio set [-i|-o|-a <alt>] <pin>

Set the function of a given pin. It can be set to INPUT with the `-i` option, OUTPUT with the `-o` option or to one of six alternate function with the `-a` option.

gpio table

Print a table of all GPIO pins and the names of the alternate functions they can take. The current setting of the pin is indicated by an asterisk against the relevant alternate setting. If no asterisk is present then the pin is in GPIO mode.

gpio toggle [-m <msec>] <pin>

Toggle a pin at a 1 second period with a 50% duty cycle. The `-m` option allows the toggling to occur with the given period in milliseconds. The pin may need to be set to output mode with **gpio set** before any effect can be seen.

JTAG Command

The **jtag** command provides direct support for setting up the JTAG debug pins and querying their state. The arguments to this command are a list of pin numbers. Each of these GPIO pins is put into its JTAG function. Only those pins that can be used for JTAG operation may be entered; at present these are GPIO4 to GPIO6, GPIO12, GPIO13 and GPIO22 to GPIO27. On completion the command lists the pins that are in JTAG mode. If no pins are given, then the current JTAG pin assignments are listed. Pins may be disabled by preceeding them with a hyphen; this puts the pin into GPIO input mode.

The selection of JTAG pins to use may depend on the functionality of any HATs or other hardware attached to the GPIO header. It may be necessary to mix and match pins to get a complete set. In some situations it may not be possible to find a set of pins that will work, in which case you may need to use serial debugging only.

The following table defines the possible GPIO pin alternatives for the JTAG signals, as well as their mapping on to the 40-way expansion bus used on standard RPi boards. Each JTAG signal has two alternative mappings, apart from TRST which can only be set to GPIO pin 22. Note that RTCK is not required or supported by all JTAG debuggers and may not need to be set.

JTAG Signal	Alt 4 GPIO pin	(Alt 4 40-way pin)	Alt 5 GPIO pin	(Alt 5 40-way pin)
TDI	26	37	4	7
TRST	22	15	n/a	n/a
TDO	24	18	5	29
TCK	25	22	13	33
TMS	27	13	12	32
RTCK	23	16	6	31

For example, the **jtag** command used in the default redboot.txt file, sets and reports the BCM pins as follows:

```
RedBoot> jtag 4 22 24 25 27
PIN FUNC
 22 ARM_TRST
 23 ARM_RTCK
 24 ARM_TDO
```

```
25 ARM_TCK
26 ARM_TDI
27 ARM_TMS
```

LED Command

The **led** command controls the behaviour of the board's ACT LED. By default RedBoot blinks the LED at 1 Hz with a 50% duty cycle; this serves as an indicator that RedBoot is up and running when the serial line is not connected. It takes one of three argument values. **`on`** disables blinking and switches the LED on. **`off`** also disables blinking and switches the LED off. **`blink`** re-enables the 1Hz blinking. Note that these setting only apply when RedBoot is running. Once and application has been loaded and is running, control of the LED passes to it.

USB Command

The **usb** command prints out some information from the USB stack. This includes some gathered statistics and information on each of the USB devices currently attached to the USB bus.

Chapter 282. Virtual Machine Support

Name

eCos Support for ARM Virtual Machines — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on ARM Aarch32 Virtual Machines running under a variety of hypervizors. It supports Virtual Machines using a limited number of real device emulations as well as some VirtIO based devices. This package contains things that are common to all VM targets. An additional package is needed to customize support for a specific hypervizor. At present virtual machines running under QEMU and Xvisor are supported by these packages.

eCos applications are typically developed using the host-based gdb debugger, communicating with a "gdb stub" built-in to either RedBoot or the hypervisor. For RedBoot-based development, the VM is set up to boot into RedBoot either from a ROM image or from an image inserted into RAM from the hypervisor. RedBoot incorporates a gdb stub that enables eCos applications to be downloaded and debugged either via a serial line or over Ethernet. When running under QEMU, such applications may also be debugged using QEMU's GDB stub interface.

Support for SMP operation is available, although debugging support is limited. There is no SMP debug support in RedBoot. The emulated virtual GIC supports up to eight CPUs, eCos is therefore limited to a maximum of eight CPUs..

Finished eCos ROM startup applications can be deployed directly by a hypervisor, copying its image into a VM and booting the VM.

This documentation is expected to be read in conjunction with the ARM architecture HAL documentation and the hypervisor specific packages.

Supported Hardware

eCos currently runs in single processor or multi-processor modes on an ARM Aarch32 Virtual Machine. The following devices are currently supported by this and other generic packages.

Generic Interrupt Controller

The ARM GIC is used to handle interrupts. The GIC needs to be memory-mapped. The mapping of interrupt vectors is handled by a hypervisor specific package.

Generic Timer

The ARM architecture Generic Timer is used to supply the system timer. eCos used the virtual counter and timer in order to insulate it from hypervisor scheduling. The timer is accessed through the CP15 register set.

Emulated UART

ARM PL011 UART macrocell. Most ARM hypervisors support an emulation of this device and drivers are available in RedBoot and eCos to support it.

VirtIO Console

Support for the VirtIO console device class is present in both RedBoot and eCos.

VirtIO NET

Ethernet access is via a VirtIO NET device. The hypervisor is then responsible for routing packets to other VMs or an external network connection.

VirtIO RPMSG

Support is present for using a VirtIO RPMSG interface. This supports the RPMSG subsystem library to present a standard RPMSG API to user applications.

In general, devices are initialized only as far as is necessary for eCos to run. Other devices are not touched unless the appropriate driver is loaded. Further devices may be supported by the hypervisor specific HAL package and additional device drivers.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 7.3.0, arm-eabi-gdb version 8.1, and binutils version 2.30.

Name

Configuration — Platform-specific Configuration Options

Overview

The Virtual Machine platform HAL package is loaded automatically when eCos is configured for any virtual target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

SMP Support

SMP support is limited to a maximum of eight CPUs by the design of the ARM GIC. The exact number of CPUs that eCos supports is defined by the `CYGNUM_HAL_ARM_CORTEXA_VIRTUAL_CPU_COUNT` configuration option. The default value for this option is four, but each hypervisor package may set this to a value that corresponds to the number of CPUs configured by the hypervisor. It may also be changed by the user within certain constraints.

eCos does not handle dynamic configuration of CPUs and cannot detect the number of CPUs present at startup. So the value specified for `CYGNUM_HAL_ARM_CORTEXA_VIRTUAL_CPU_COUNT` should never exceed the number of CPUs configured by the hypervisor. It should be possible to run eCos with fewer CPUs than the hypervisor configures, since any extra CPUs will not be started. However, this is hypervisor dependent, see the documentation on each hypervisor for details.

UART Serial Driver

There are two common serial devices supported for the VM. The ARM PL011 macrocell is supported by a serial driver and as a command line input for RedBoot. The VirtIO console driver is similarly supported by a driver and as a RedBoot input; it is dependent on the VIRTIO driver and can only be configured if VIRTIO driver is also present.

Ethernet Driver

Support for the VirtIO NET device is provided by the `CYGPKG_DEVS_ETH_VIRTUAL` driver. This driver is dependent on the VIRTIO driver and can only be configured if the VIRTIO driver is also present. This driver is also not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RPMSG Driver

Support for a VirtIO RPMSG interface is present in package `CYGPKG_DEVS_RPMSG_VIRTUAL`. This driver is dependent on the VIRTIO driver and can only be configured if the VIRTIO driver is also present.

The RPMSG driver is accessed via the RPMSG API library, details of which may be found here.

VirtIO Driver

Support for generic VirtIO devices is provided by the VIRTIO driver (`CYGPKG_DEVS_VIRTIO`). This provides the generic initialization and management of queues common to all VirtIO devices.

The VirtIO driver is not normally accessed directly from applications, but only from client device drivers. For reference, details of the VirtIO driver may be found here.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the ARM Aarch32 Virtual Machine, and should be read in conjunction with that specification. The platform HAL package complements the ARM architectural HAL, the Cortex-A variant HAL and the VIRTUAL variant HAL. It provides functionality which is specific to the target board.

Startup

Following a reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

Chapter 283. QEMU Virtual Machine Support

Name

eCos Support for QEMU Virtual Machines — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on ARM Aarch32 Virtual Machines running under QEMU. While QEMU is capable of emulating a variety of real board and devices, this package specifically supports running eCos using the generic "virt" target. As such it is similar to a VM running under a hypervisor on a real host and is treated as such here. It supports Virtual Machines using a limited number of real device emulations as well as some VirtIO based devices.

eCos applications are typically developed using the host-based gdb debugger, communicating with a "gdb stub" built-in to either RedBoot or QEMU. For RedBoot-based development, the VM is set up to boot into RedBoot either from a ROM image or from an image inserted into RAM when QEMU was started. RedBoot incorporates a gdb stub that enables eCos applications to be downloaded and debugged either via a serial line or over Ethernet. Such applications may also be debugged using QEMU's GDB stub interface.

Support for SMP operation is available, although debugging support is restricted to use of an external debugger connected to QEMU's GDB debug port. There is no SMP debug support in RedBoot. QEMU supports up to eight CPUs in the ARM virtual machine, by default eCos is configured to use four CPUs.

Finished eCos ROM startup applications can be deployed directly by replacing the RedBoot binary with the application binary when QEMU is started.

This documentation is expected to be read in conjunction with the ARM architecture HAL and Virtual Machine Support documentation; further device support and subsystems are described and documented there.

Supported Hardware

eCos currently runs in single processor mode on an ARM Aarch32 Virtual Machine. The following devices are currently supported by this port.

Generic Interrupt Controller
: The ARM GIC is used to handle interrupts. The GIC needs to be memory-mapped. Interrupt vector mapping is defined in this package.

Generic Timer
: The ARM architecture Generic Timer is used to supply the system timer. eCos uses the physical counter and timer. The timer is accessed through the CP15 register set.

Emulated UART
: ARM PL011 UART macrocell. QEMU supports an emulation of this device and drivers are available in RedBoot and eCos to support it.

VirtIO Console
: Support for the VirtIO console device class is present in both RedBoot and eCos.

VirtIO NET
: Ethernet access is via a VirtIO NET device. QEMU is then responsible for routing packets to other VMs or the wider network.

VirtIO RPMSG
: Support is present for using a VirtIO RPMSG interface. This supports the RPMSG subsystem library to present a standard RPMSG API to user applications.

In general, devices are initialized only as far as is necessary for eCos to run. Other devices are not touched unless the appropriate driver is loaded.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 7.3.0, arm-eabi-gdb version 8.1, and binutils version 2.30.

Name

Setup — Preparing for eCos Development

Overview

In a typical development environment, the VM boots into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the VM therefore usually involves arranging for a suitable RedBoot image to be executed on startup.

QEMU Installation

This section describes how to run eCos under QEMU. The reader should be familiar with QEMU, how to install it onto their host and how to invoke it. The examples in this section describe running QEMU under Linux. This has been tested using QEMU version 4.2.0.

eCos applications can be run under QEMU either directly or by first loading RedBoot and then using that to load and execute the application. In both cases it is necessary to configure QEMU to emulate a virtual machine that matches the target for which eCos has been compiled. A typical QEMU invocation is shown below.

```
qemu-system-arm -M virt -m 32 -nographic -s -smp cpus=8 -kernel app \
          -netdev user,id=mynet,net=10.4.0.0/24,hostfwd=tcp::9000-:9000 \
          -device virtio-net-device,netdev=mynet -device virtio-serial-device \
          -chardev socket,id=vio,host=0.0.0.0,port=4322,server,telnet,nowait \
          -device virtserialport,chardev=vio
```

This will run an eCos application in an Aarch32 virtual machine with the main serial port routed to standard IO. Breaking that command line down into its components:

```
-M virt -m 32 -nographic -s -smp cpus=8
```

The `-M` option selects a generic ARMv7 virtual machine emulation. The `-m` option sets the main RAM size to 32MiB. The `-nographic` suppresses use of a graphical interface, confining QEMU to a command line interface. The `-s` option enables the GDB server. The `-smp cpus=8` option instantiates eight CPUs. Initially only CPU0 is running and will run non-SMP builds. If eCos is built to use more CPUs, then it will enable the additional CPUs when the scheduler starts. By default eCos is configured to use four CPUs.

```
-kernel app
```

This specifies the application to load. The application may be either an ELF executable or a binary file. Only applications built using the ROM startup type should be used here. This application executable should be RedBoot if it is intended to run RAM startup application via GDB.

```
-netdev user,id=mynet,net=10.4.0.0/24,hostfwd=tcp::9000-:9000
-device virtio-net-device,netdev=mynet
```

These options set up the networking interface. In this case we are using QEMU's user networking support, which avoids the need to set up additional interfaces on the host and does not need privileged access. This option runs the virtual machine in a private subnet, in this case `10.4.0.0/24`, which should be chosen so as not to clash with the existing network. The `hostfwd` option maps the host's TCP port 9000 to the virtual machine's port 9000; which is RedBoot's telnet/GDB port. Additional port mappings may be added if necessary.

```
-device virtio-serial-device
-chardev socket,id=vio,host=0.0.0.0,port=4322,server,telnet,nowait
-device virtserialport,chardev=vio
```

These options map the virtual machine's second serial port on to a telnet server on local port 4322.

The above command line uses standard IO for the main console. An alternative would be to attach the console to a Telnet socket. The following additional options will do this:

```
-serial tcp:0.0.0.0:4321,server,telnet,nowait
```

Use of `telnet` here provides support for the RedBoot command line interface. However, if the intention is to use GDB to load and run applications via the console, then the `telnet` option should be omitted since the telnet protocol does not interact well with the GDB protocol. The same consideration applies to the arguments for the second serial line given earlier.

For simplicity, a shell script, **ecos_qemu**, is available in the `etc` directory of the RedBoot install directory which runs an eCos application using the options above. It is recommended that this script and the executable to be run are copied out to a working directory. This script may be edited to adjust the arguments if a different configuration is needed. Running RedBoot using the script under Linux, will look something like this:

```
$ ./ecos_qemu redboot.elf
APP       redboot.elf
QEMU-ARGS
QEMU      qemu-system-arm
CMD       -M virt -m 32 -nographic -s -kernel redboot.elf -netdev user,id=mynet,net=10.4.0.0/24,
hostfwd=tcp::9000-:9000 -device virtio-net-device,netdev=mynet -device virtio-serial-device
-chardev socket,id=vio,host=0.0.0.0,port=4322,server,telnet,nowait -device virtserialport,
chardev=vio

Ctrl-A X to exit
Ctrl-A C for qemu monitor

```

Rebuilding RedBoot

Typical users should never need to rebuild RedBoot. If you do intend to modify RedBoot then please note that rebuilding it is currently only supported from the Linux command line.

The steps needed to rebuild the ROM version of RedBoot are:

```
$ mkdir redboot_qemu_rom
$ cd redboot_qemu_rom
$ ecosconfig new virtual_qemu redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/cortexa/virrual/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the files `redboot.elf` and `redboot.bin`. Either of these files can now be used to start RedBoot.

Name

Configuration — Platform-specific Configuration Options

Overview

The QEMU platform HAL package is loaded automatically when eCos is configured for a QEMU target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports three separate startup types:

RAM This startup type is normally used during application development when using the RedBoot ROM monitor. arm-eabi-gdb is used to load the RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

This startup type is also used to for applications that are loaded from the RedBoot command line with the **load** command.

In QEMU VMs RAM applications are loaded at address 0x40500000, leaving the bottom 5MiB free for RedBoot.

ROM This startup type can be used for finished applications which will be booted direct into the VM from the hypervisor. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

In QEMU VMs ROM applications are loaded by QEMU at 0x40010000 in main RAM. The bottom 4MiB are treated as a read-only area. ROM applications will place exception vectors, DATA and BSS starting from 0x40400000.

SMP This startup type can be used for finished applications that can be loaded into RAM via RedBoot or from the QEMU command line. The load address is set to the same as for RAM applications, however, the application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. Once started, this application takes full control of the system and RedBoot will not be called again. This means that debugging via RedBoot will not be possible, only external debugging via QEMU's debug port is supported.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

UART Serial Driver

There are two serial devices supported for the VM. The ARM PL011 macrocell is supported by a serial driver and as a command line input for RedBoot. The VirtIO console driver is similarly supported by a driver and as a RedBoot input; it is dependent on the VIRTIO driver and can only be configured if VIRTIO driver is also present. In QEMU these serial interfaces may be routed to a variety of host devices including stdio, TCP streams or pseudo-terminals.

Ethernet Driver

Support for the VirtIO NET device is provided by the `CYGPKG_DEVS_ETH_VIRTUAL` driver. This driver is dependent on the VIRTIO driver and can only be configured if the VIRTIO driver is also present. This driver is also not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RPMSG Driver

Support for a VirtIO RPMSG interface is present in package `CYGPKG_DEVS_RPMSG_VIRTUAL`. This driver is dependent on the VIRTIO driver and can only be configured if the VIRTIO driver is also present.

The RPMSG driver is accessed via the RPMSG API library, details of which may be found here.

VirtIO Driver

Support for generic VirtIO devices is provided by the VIRTIO driver (`CYGPKG_DEVS_VIRTIO`). This provides the generic initialization and management of queues common to all VirtIO devices.

The VirtIO driver is not normally accessed directly from application, but only from client device drivers. For reference, details of the VirtIO driver may be found here.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. The following flags are specific to this port:

`-mcpu=cortex-a15`	The QEMU `virt` target contains a Cortex-A15 CPU emulation.

Name

SMP Support — Usage

Overview

Support is available for SMP operation. However, debugging support is restricted to using an external SMP-aware debugger connected to QEMU's GDB stub port. RedBoot does not have support for multi-core debugging.

SMP support is enabled by setting `CYGPKG_KERNEL_SMP_SUPPORT` to true. SMP applications should only be built using either ROM or SMP startup types. ROM applications can be loaded from the QEMU command line in place of RedBoot. The SMP startup is identical to a ROM startup except that the load address is set to allow the application to be loaded into a higher location in RAM from RedBoot. SMP startup applications can also be loaded from the command line if the ELF file is used, a binary file will not work.

By default eCos is configured to use four CPUs. However, QEMU can support up to eight CPUs and the `ecos_qemu` script instantiates all eight. CPUs are only enabled when eCos starts, so unused CPUs will not consume host cycles. The number of CPUs may be changed by setting `CYGNUM_HAL_ARM_CORTEXA_VIRTUAL_CPU_COUNT`.

Loading an SMP startup application via RedBoot can be done from the RedBoot command line via serial. It may also be loaded via a GDB connection on serial. However, once started running the SMP application will take full control of the system, including redirecting all interrupt sources, exception vectors and virtual vector table entries. This means that RedBoot will no longer be active. Any breakpoints planted by GDB will result in an exception to the application, Ctrl-C will not work, any Ethernet connections will be lost and serial output will come from the application in plain ASCII. Any GDB connection will be lost and GDB may start reporting packet errors.

It is possible to load an SMP startup program via GDB and have its output displayed on the GDB console. To do this set `CYGSEM_HAL_DIAG_MANGLER` to `"GDB"`, and `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` to `1`. The application will still not be controllable from GDB, but this does simplify the running of test code; avoiding the need to disconnect GDB and connect a terminal emulator to capture or view the output.

SMP applications may be debugged via the QEMU GDB debug port using a standard GDB. In this case the different CPUs are presented to GDB as separate threads. The command **info threads** can be used to list the CPUs and the **thread** command can be used to switch between them. eCos threads are not visible in this mode.

QEMU runs each virtual CPU in a separate thread. These in turn can be scheduled onto separate CPUs of the host system. As a result the virtual machine CPUs are subject to the scheduling decisions of the host. If the host is a typically-idle development workstation then this should not pose a problem. However, if the host is busy, a server or shared system, then the other workloads may affect the relative progress of the various virtual CPUs. If the eCos application makes strict use of synchronization primitives then there should be no problem. However, if it assumes that the CPUs all progress a the same rate, then it may see some issues. These issues can partly be alleviated by running QEMU at a higher priority, or on reserved CPUs.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the ARM Aarch32 Virtual Machine, and should be read in conjunction with that specification. This HAL package complements the ARM architectural HAL, the Cortex-A variant HAL and the Virtual variant HAL. It provides functionality which is specific to the target emulator.

Startup

On emulator startup or reset the HAL will initialize or reinitialize those peripherals that are to be used. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

QEMU VM Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

RAM

This is located at address 0x40000000 of the physical memory space and is 32MiB in size. The HAL configures the MMU to retain the RAM at virtual address 0x40000000 with caching enabled. The same memory is also accessible uncached and unbuffered at virtual address 0x50000000 for use by device drivers. ROM applications can use RAM starting at 0x4040000020. Interrupt and exception vectors are placed at 0x40400000 and the virtual vectors occupy 256 bytes at 0x40400050. For ROM startup, all remaining RAM is available. RAM startup applications are loaded from location 0x40500000, reserving 5MiB.

ROM applications are loaded into the bottom 4MiB of RAM, at 0x40010000, which is treated like a read-only memory for this purpose. This, for example, allows RedBoot to perform a reset by jumping to 0x40010000.

Peripheral Registers

These occupy regions of memory at 0x08000000, 0x09000000 and 0x0a000000 of varying sizes. These include the GIC registers, emulated peripherals such as the PL011 UART or VirtIO devices.

The virtual address space visible to applications is summarized in the following table. Any address range not mentioned here should not be accessed and will raise an exception if it is.

Base	**Size (MiB)**	**Cache**	**Description**
0x08000000	1	Disabled	GIC registers.
0x09000000	16	Disabled	Emulated device registers.
0x0A000000	16	Disabled	VirtIO device registers.
0x40000000	32	Enabled	Normal RAM access.
0x50000000	32	Disabled	Uncached access to RAM.

Real-time Characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM32 mode and run in non-SMP mode under QEMU 4.2.0 running under Linux on a 6 processor Intel i7-8700K CPU running at up to 3.70GHz.

Example 283.1. VM Real-time characterization

```
             Startup, main thrd : stack used   404 size  1792
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    96 size  1280

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The ARM architectural HAL documentation should be consulted for further details.

Chapter 284. Xvisor Virtual Machine Support

Name

eCos Support for Xvisor Virtual Machines — Overview

Description

This document covers the configuration and usage of eCos and RedBoot on ARM Aarch32 Virtual Machines running under the Xvisor hypervisor. Only devices that are emulated by Xvisor, or are accessed through VirtIO interfaces are used, so this should run under Xvisor on any ARM host.

eCos applications are typically developed using the host-based gdb debugger, communicating with a "gdb stub" built-in to RedBoot. The VM is set up to boot into RedBoot from a ROM image. RedBoot incorporates a gdb stub that enables eCos applications to be downloaded and debugged either via a serial line or over Ethernet.

Support for SMP operation is available, although debugging support is restricted to use diagnostic messages. There is no SMP debug support in RedBoot. The emulated virtual GIC supports up to eight CPUs, by default eCos is configured to use four CPUs.

Finished eCos ROM startup applications can be deployed directly by the hypervisor by replacing RedBoot with the application binary.

This documentation is expected to be read in conjunction with the ARM architecture HAL and Virtual Machine Support documentation; further device support and subsystems are described and documented there.

Supported Hardware

eCos currently runs in single processor mode on an ARM Aarch32 Virtual Machine. The following devices are currently supported by this port.

Generic Interrupt Controller
: The ARM GIC is used to handle interrupts. The GIC needs to be memory-mapped. Interrupt vector mapping is defined in this package.

Generic Timer
: The ARM architecture Generic Timer is used to supply the system timer. eCos used the virtual counter and timer in order to insulate it from hypervisor scheduling. The timer is accessed through the CP15 register set.

Emulated UART
: ARM PL011 UART macrocell. Xvisor supports an emulation of this device and drivers are available in RedBoot and eCos to support it.

VirtIO Console
: Support for the VirtIO console device class is present in both RedBoot and eCos.

VirtIO NET
: Ethernet access is via a VirtIO NET device. The hypervisor is then responsible for routing packets to other VMs or an external network connection.

VirtIO RPMSG
: Support is present for using a VirtIO RPMSG interface. This supports the RPMSG subsystem library to present a standard RPMSG API to user applications.

In general, devices are initialized only as far as is necessary for eCos to run. Other devices are not touched unless the appropriate driver is loaded.

Tools

The board support is intended to work with GNU tools configured for an arm-eabi target. The original port was undertaken using arm-eabi-gcc version 7.3.0, arm-eabi-gdb version 8.1, and binutils version 2.30.

Name

Setup — Preparing for eCos Development

Overview

In a typical development environment, the VM boots into the RedBoot ROM monitor. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**. Preparing the VM therefore usually involves arranging for a suitable RedBoot image to be executed on startup.

Xvisor VM Installation

This section describes how to install RedBoot into an Xvisor guest VM and start it running. The reader should be familiar with Xvisor, how to install it onto a target platform and how, in general, a guest VM is created.

To create an eCos VM under Xvisor, it is necessary to instantiate a virtual machine, populate it with the executable of RedBoot, and then set it running. To do this a number of files are copied to the `etc` directory of a RedBoot installation which are used set up a VM to run eCos. These files are as follows:

`evm.dts`
: This is a Linux device tree source file. It needs to be compiled into a device tree binary file using the **dtc** device tree compiler. This file is specific to use on Rockchip-based boards such as the Pine Rockpro64 or M2000.

`boot.xscript`
: This is a sample Xvisor boot script that instantiates a Linux guest together with a eCos VM running RedBoot. It may be used as it is, or used as a template for your own script.

`nor_flash.list`
: A list of addresses and file names used to populate the virtual flash in a VM. This defines the software that will run from reset in the VM. In this case the sole entry installs a binary of RedBoot at the start of flash.

`install`
: A shell script that automates the installation of a RedBoot executable into a Xvisor disk image. It creates the necessary sub-directory in the disk image, compiles and installs the device tree, RedBoot binary and flash list. It does not copy the `boot.xscript` file, which may be copied separately if required. Following this, a **make** should be run in the Xvisor build directory to rebuild the disk image. The image may then be transferred to the target system bootstrap medium.

See the next section, Rebuilding RedBoot, for an example of using the `install` script to install RedBoot into an Xvisor VM.

Once the files are installed, Xvisor may be started and the eCos VM will be executed. Depending on the default setting for the initial serial connection, and whether the `boot.xscript` file has been copied, you may see a startup banner from RedBoot similar to the following:

```
XVisor# vserial bind evm1/uart0
[evm1/uart0] +No network interfaces found

RedBoot(tm) bootstrap and debug environment [ROM]

```

Rebuilding RedBoot

Typical users should never need to rebuild RedBoot. If you do intend to modify RedBoot then please note that rebuilding it is currently only supported from the Linux command line.

The steps needed to rebuild the ROM version of RedBoot are:

```
$ mkdir redboot_virtual_rom
$ cd redboot_virtual_rom
$ ecosconfig new virtual_xvisor redboot
$ ecosconfig import $ECOS_REPOSITORY/hal/arm/cortexa/virtual/VERSION/misc/redboot_ROM.ecm
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This image can now be installed into an Xvisor boot disk image using the install script. Assuming the root directory for Xvisor is in `$XVISOR` the following commands will do this.

```
$ cd install
$ ./etc/install $XVISOR/disk

Install RedBoot in disk image

Done
$
```

If required, `boot.xscript` may also be copied into `$XVISOR/disk`.

For convenience, eCosPro releases include a prebuilt RedBoot image as well as the `install` subdirectory resulting from the creation of RedBoot. These are located within the `loaders` sub-directory of the eCosPro installation, and the install script may be run from within these subdirectories. For example:

```
$ cd ecos-4.4.0/loaders/virtual_xvisor/redboot_ROM.install
$ ./etc/install $XVISOR/disk

Install RedBoot in disk image

Done
$
```

It is now necessary to rebuild the Xvisor RAM disk. Exactly how this is done can depend on the target host, how it boots and how that RAM disk is loaded. Usually this involves using **genext2fs** to make a disk image; usually an Xvisor executable and a device tree are also created. Refer to the directions for installing Xvisor on the host for details.

Name

Configuration — Platform-specific Configuration Options

Overview

The xvisor platform HAL package is loaded automatically when eCos is configured for the xvisor target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The platform HAL package supports two separate startup types:

RAM This startup type is normally used during application development when using the RedBoot ROM monitor. arm-eabi-gdb is used to load the RAM startup application into memory and debug it. It is assumed that the hardware has already been initialized by RedBoot. By default the application will use the eCos virtual vectors mechanism to obtain services from RedBoot, including diagnostic output.

This startup type is also used to for applications that are loaded from the RedBoot command line with the **load** command.

In Xvisor VMs RAM applications are loaded at address 0x40200000, leaving the bottom 2MiB free for RedBoot's use.

ROM This startup type can be used for finished applications which will be booted direct into the VM from the hypervisor. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization.

In Xvisor VMs ROM application are loaded by the hypervisor at address 0x00000000 in the emulated flash memory. RedBoot uses RAM starting from 0x40000020. Interrupt and exception vectors are placed at 0x40000000 with the virtual vectors following.

SMP This startup type can be used for finished applications that can be loaded into RAM via RedBoot. The load address is set to the same as for RAM applications, however, the application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. Once started, this application takes full control of the system and RedBoot will not be called again. This means that debugging via RedBoot will not be possible. The intent of this startup type is to allow SMP test programs to be run from RedBoot.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building RedBoot.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostics.

UART Serial Driver

There are two serial devices supported for the VM. The ARM PL011 macrocell is supported by a serial driver and as a command line input for RedBoot. The VirtIO console driver is similarly supported by a driver and as a RedBoot input; it is dependent on the VIRTIO driver and can only be configured if VIRTIO driver is also present. Both of these will typically be routed by the hypervisor to either a real external device or a serial interface of another VM.

Ethernet Driver

Support for the VirtIO NET device is provided by the `CYGPKG_DEVS_ETH_VIRTUAL` driver. This driver is dependent on the VIRTIO driver and can only be configured if the VIRTIO driver is also present. This driver is also not active until the generic Ethernet support package, `CYGPKG_IO_ETH_DRIVERS`, is included in the configuration.

RPMSG Driver

Support for a VirtIO RPMSG interface is present in package `CYGPKG_DEVS_RPMSG_VIRTUAL`. This driver is dependent on the VIRTIO driver and can only be configured if the VIRTIO driver is also present.

The RPMSG driver is accessed via the RPMSG API library, details of which may be found here.

VirtIO Driver

Support for generic VirtIO devices is provided by the VIRTIO driver (`CYGPKG_DEVS_VIRTIO`). This provides the generic initialization and management of queues common to all VirtIO devices.

The VirtIO driver is not normally accessed directly from application, but only from client device drivers. For reference, details of the VirtIO driver may be found here.

Compiler Flags

The platform HAL defines the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. The following flags are specific to this port:

`-mcpu=cortex-a15`
: The Xvisor virtual machine configures a generic ARMv7a CPU. This option selects a suitable Cortex-A CPU variant that will support the execution of Aarch32 code.

Name

SMP Support — Usage

Overview

Support is available for SMP operation. However, debugging support is restricted to using `diag_printf()` and related functions. RedBoot does not have support for multi-core debugging and Xvisor has no support for connecting a debugger to a virtual machine.

A board intended to be used for SMP development should be initialized in the same way as a single core board. RedBoot only uses a single CPU. The device tree for the VM should be defined with four CPUs. The example device tree files described in the Setup section show how this is done.

SMP support is enabled by setting `CYGPKG_KERNEL_SMP_SUPPORT` to true. SMP applications should only be built using either ROM or SMP startup types. ROM applications can be loaded from Xvisor in place of RedBoot. The SMP startup is identical to a ROM startup except that the load address is set to allow the application to be loaded into a higher location in RAM from RedBoot.

By default eCos is configured to use four CPUs. Xvisor can support up to eight CPUs. The example device tree currently only defines four CPUs. Extra CPUs may be added by editing this file. The number of CPUs supported by eCos may be changed by setting `CYGNUM_HAL_ARM_CORTEXA_VIRTUAL_CPU_COUNT`. The number of CPUs supported by eCos should never exceed the number configured in the device tree.

Loading an SMP startup application via RedBoot can be done from the RedBoot command line via serial. It may also be loaded via a GDB connection on serial. However, once started running the SMP application will take full control of the system, including redirecting all interrupt sources, exception vectors and virtual vector table entries. This means that RedBoot will no longer be active. Any breakpoints planted by GDB will result in an exception to the application, Ctrl-C will not work, any Ethernet connections will be lost and serial output will come from the application in plain ASCII. Any GDB connection will be lost and GDB may start reporting packet errors.

It is possible to load an SMP startup application via GDB and have its output displayed on the GDB console. To do this set `CYGSEM_HAL_DIAG_MANGLER` to `"GDB"`, and `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` to `1`. The application will still not be controllable from GDB, but this does simplify the running of test code; avoiding the need to disconnect GDB and connect a terminal emulator to capture or view the output.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the ARM Aarch32 Virtual Machine, and should be read in conjunction with that specification. This HAL package complements the ARM architectural HAL, the Cortex-A variant HAL and the Virtual variant HAL. It provides functionality which is specific to the target hypervisor and the board on which it is running.

Startup

Following a reset, the HAL will initialize or reinitialize most of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

Xvisor VM Linker Scripts and Memory Maps

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Virtual Flash
: This is located at 0x00000000 and is 32MiB in size. The hypervisor is responsible for loading the initial image, typically RedBoot, in to the start of this region. When the VM is kicked into life execution starts here.

RAM
: This is located at address 0x40000000 of the physical memory space and is 32MiB in size. The HAL configures the MMU to retain the RAM at virtual address 0x40000000 with caching enabled. The same memory is also accessible uncached and unbuffered at virtual address 0x50000000 for use by device drivers. ROM applications can use RAM starting at 0x4000000020. Interrupt and exception vectors are placed at 0x40000000 and the virtual vectors occupy 256 bytes at 0x00000050. For ROM startup, all remaining RAM is available. RAM startup applications are loaded from location 0x40200000, reserving 2MiB.

Shared memory
: A shared memory region is allocated at address 0x38000000. This area can be mapped to memory shared between the eCos VM and any other VM. It may be used to load applications into the VM using the RedBoot **load** command and may also be used to enable communications between applications in the eCos VM and the other VM.

Peripheral Registers
: These occupy regions of memory at 0x08000000, 0x09000000 and 0x0a000000 of varying sizes. These include the GIC registers, emulated peripherals such as the PL011 UART or VirtIO devices.

The virtual address space visible to applications is summarized in the following table. Any address range not mentioned here should not be accessed and will raise an exception if it is.

Base	Size (MiB)	Cache	Description
0x00000000	32	Disabled	Virtual flash.
0x08000000	1	Disabled	GIC registers.
0x09000000	16	Disabled	Emulated device registers.
0x0A000000	16	Disabled	VirtIO device registers.
0x38000000	16	Disabled	Shared memory.
0x40000000	32	Enabled	Normal SDRAM access.
0x50000000	32	Disabled	Uncached access to RAM.

Real-time Characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built in ARM32 mode and run in non-SMP mode on a VCPU bound to host CPU 3 of Xvisor running on a Pine Rockpro64.

Example 284.1. VM Real-time characterization

```
             Startup, main thrd : stack used   404 size  1792
             Startup :  Interrupt stack used  4096 size  4096
             Startup : Idlethread stack used    96 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 1 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    5.35 microseconds (102 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                  64

Other Issues

The platform HAL does not affect the implementation of other parts of the eCos HAL specification. The ARM architectural HAL documentation should be consulted for further details.

Part LXXVIII. Cortex-M Architecture

Table of Contents

Chapter 285. Cortex-M Architectural Support

Name

CYGPKG_HAL_CORTEXM — eCos Support for the Cortex-M Architecture

Description

The Cortex-M implements a new version of the ARM architecture intended for deeply embedded applications. The processor runs the Thumb-2 instruction set and implements an exception and interrupt model quite different from that supported by previous members of the ARM architecture. For this reason the Cortex-M HAL is implemented as an entirely new architecture within eCos.

In addition to the processor, the Cortex-M architecture also provides definitions of a Nested Vectored Interrupt Controller (NVIC) and a system tick timer. Both of these are used by eCos. If available on the target platform, and when suitably configured, the eCos Cortex-M HAL can make use of the Instrumentation Trace Macrocell (ITM) for diagnostics and instrumentation. Other features of the architecture such as the Memory Protection Unit, and the other debug units are not directly used by eCos at present.

Name

Options — Configuring the Cortex-M Architectural HAL Package

Description

The Cortex-M architectural HAL is included in all ecos.db entries for Cortex-M targets, so the package will be loaded automatically when creating a configuration. It should never be necessary to load the package explicitly or to unload it.

The Cortex-M architectural HAL contains a number of configuration points. Few of these should be altered by the user, they are mainly present for the variant and platform HALs to select different architectural features.

CYGINT_HAL_CORTEXM_BIGENDIAN

> This interface controls whether the CPU is run in big endian mode. It should be implemented by either the variant or platform HAL to reflect the setting of the hardware.

CYGHWR_HAL_CORTEXM_BIGENDIAN

> This option is active only if `CYGINT_HAL_CORTEXM_BIGENDIAN` is implemented. It provides the main test point for HAL, eCos and application code to test for a big endian target.

CYGHWR_HAL_CORTEXM

> The Cortex-M architecture has two main variants at present. The M1 is based on the ARMV6 architecture specification and executes an extended variant of the Thumb instruction set and has some differences in the interrupt controller. The M3 and M4 are based on the ARMV7 architecture specification and execute the Thumb2 instruction set. The M4 is an extended M3 family providing hardware FPU and DSP extensions. This option should be set using a `requires` command in the variant HAL to indicate which CPU variant is in use.

CYGINT_HAL_CORTEXM_FPU

> This interface controls whether the CPU is capable of supporting a hardware FPU (Floating Point Unit). It is the “common” FPU marker and is implemented whan either the variant or platform HAL in turn implements a supported FPU type.
>
> For example, a Cortex-M4F target may define `CYGINT_HAL_FPV4_SP_D16` when it provides the ARMv7 VFPv4-D16 architecture floating point unit.

CYGHWR_HAL_CORTEXM_FPU

> On targets which are capable of hardware FPU operation, this option is used to select whether soft or hard floating point operation is desired. It provides the main test point for HAL, eCos and application code to test for a hard-FP target. It is inactive if `CYGINT_HAL_CORTEXM_FPU` is not implemented.
>
> Even though an architecture may provide a hardware FPU, it is not always suitable for all applications. For example, there is the associated scheduler and RAM cost in preserving FPU contect for multi-threaded applications. If `CYGHWR_HAL_ARM_FPU` is enabled then some further configuration options are made available:

CYGNUM_HAL_CORTEXM_PRIORITY_MAX

> Most Cortex-M variants do not implement the full range of priorities defined by the architecture. Instead they only implement a few of the most significant bits of the 8 bit priority range. The option `CYGNUM_HAL_CORTEXM_PRIORITY_LEVEL_BITS` must be defined by the variant HAL to give this number. This option then uses that value to calculate the maximum allowable priority for interrupts.

CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE

> By default the architectural HAL does not implement diagnostic support, with the default `Serial` support being left to the variant or platform HAL.

However, if the variant provides the on-chip ITM then selecting `ITM` for this option will configure the system to use the generic architectural HAL ITM stimulus port diagnostic output. Accessing ITM diagnostic output will require corresponding support from the SWD host tools being used to connect to the hardware.

The `discard` option configures the system so that all diagnostic output is discarded. This can be used when no I/O channel is available for diagnostics.

CYGPKG_HAL_CORTEXM_SYSTEM_DEBUG_ITM

If the variant includes ITM support then this option can be enabled to allow configuration of the stimulus ports to be used for HAL diagnostics or instrumentation as required.

Compiler Flags

It is normally the responsibility of the platform HAL to define the default compiler and linker flags for all packages, although it is possible to override these on a per-package basis. Most of the flags used are the same as for other architectures supported by eCos. For all Cortex-M3 targets the options "-mcpu=cortex-m3" and "-mthumb" must always be defined.

When hardware floating point support is to be used, additional flags are required, as discussed later.

Linker Scripts

The linker script, supplied by either the variant or platform HALs, must define some symbols that the architecture HAL depends on:

hal_vsr_table

This defines the location of the VSR table. The address must obey the rules for locating the CPU vector table defined in the Cortex-M architecture specification. Usually it should be placed at the base of internal SRAM, at 0x20000000. The size of the table depends on the CPU variant in use.

hal_virtual_vector_table

This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This table needs to be word aligned. It is usually placed in internal SRAM just after the VSR table, perhaps aligned to a convenient boundary.

hal_interrupt_stack

This defines the location of the interrupt stack, and is assigned to the CPU's MSP register. The stack grows down so it should be placed at the top of memory. It is usually placed at the top of internal SRAM. For RAM applications, which are loaded after initialization is complete, it can be placed in external RAM.

hal_startup_stack

This defines the location of the startup stack and is assiged to the CPU's PSP register. This value will be installed in slot zero of the initial vector table to be loaded automatically by the CPU on reset. The stack grows down so it should be placed near the top of memory. It is usually placed near top of internal SRAM, just below the interrupt stack. The default is to initially place this stack at the halfway point of the space allocated for the interrupt stack. This avoids allocating a unique space for it, and when the application starts it will usually move the PSP to another location, leaving all of the interrupt stack space available for the interrupts. For RAM applications, which are loaded after initialization is complete, it can be placed near the top of external RAM.

Name

Floating Point — Overview of use of floating point

Overview

The Cortex-M architectural HAL provides support for a hardware Floating Point Unit (FPU) if one is present, to provide accelerated floating point math operations.

Support is currently provided for the FPU designs found on the Cortex-M4 and Cortex-M7 architectural variants. However even with these variants, the FPU is an optional feature and a more specific classification of, for example, Cortex-M4F indicates the presence of the FPU.

Furthermore, even if an FPU is present, as indicated by a platform HAL package, it is not required to be used, and the default is not to use it (therefore defaulting to software FP) so that the developer must take the step of enabling hardware FPU support if it is desired. Equally the developer is still permitted to keep using software floating point, which may simplify and reduce code size and stack use (due to the larger register contexts required for FP) in some cases. This software floating point is provided by the compiler (GCC) runtime, based on the compiler flags in use.

Configuration

As described earlier, in order to enable hardware floating point support in this HAL package you must enable the configuration option `CYGHWR_HAL_CORTEXM_FPU` (Use hardware FPU) which can be found within the `CYGPKG_HAL_CORTEXM_FPU` (Floating Point Support) CDL component.

Configuration of the FPU support is an important step as the use of the FPU not only affects code generation and requires some initialization, but also an understanding of whether multiple kernel threads in the application may be using FP operations, in which case the method of saving/restoring the FPU register bank on context switches must be set appropriately.

Compile and link flags

Both the application and eCos must be built and linked with matching compiler/linker flags appropriate to the configuration selected for FPU support. It is usually easiest to examine the `CYGBLD_GLOBAL_CFLAGS` configuration option, or simply the build output, to see the relevant flags in use. These are the flags to look for, and a brief summary of their purpose:

`-mcpu=cortex-m4`
: No Cortex-M3 core supports FPU operations, so `-mcpu=cortex-m4` is required to allow the correct instructions to be generated. For the moment, use of this option also applies when using the Cortex-M7 although this will likely change in a future compiler update.

`-mfloat-abi=hard`
: This directs the compiler to generate FPU instructions for floating point operations. If this option is absent, the default of `-mfloat-abi=soft`, i.e. software FP is used.

`-mfpu=…`
: This option indicates which hardware FPU is present, covering the number of registers, their sizes, and so on. For the moment, only `-mfpu=fpv4-sp-d16`, as used on the Cortex-M4F and M7F, is supported. This corresponds to the VFPv4 specification with 32 single precision registers, also usable as 16 double precision registers.

Threads and context switching with FP

With the hardware FPU support enabled, it is then possible to configure the `CYGHWR_HAL_CORTEXM_FPU_SWITCH` (FPU context switch) configuration option in order to control how FPU registers are saved/restored in context switches. There are three settings: ALL, LAZY, and NONE.

ALL This mode is the most straightforward, and means that on every context switch, all FPU registers are saved and restored between threads.

This mode makes the most sense if you need determinism and/or most or all of your threads will use FP. However if few threads use FP, it can result in a lot of overhead due to saves and restores of unchanged registers.

Enabling the `ALL` mode also takes advantage of the Cortex-M lazy exception stacking feature in order to reduce interrupt/exception latency. This means that after an exception or interrupt, the core reserves space for the FPU register context on the stack, but does not actually save the FPU register contents onto the stack unless needed.

LAZY In this mode, if a thread has not used the FPU, the FPU context will not be saved or restored for it. The HAL installs exception handlers on the Cortex-M UsageFault and HardFault exceptions in order to detect the first time the FPU is accessed by that thread. Once the FPU is accessed, the fault handler enables the FPU for that thread, and from then on, the FPU context will be saved and restored when switching from or to that thread.

In a system where some or many threads do not use the FPU, this can greatly improve context switch time. However if the system spends most of its time swapping between two or more threads which do both use the FPU, then there may be additional overhead compared to the `ALL` mode (due to the need to check if the FPU was enabled for a particular thread on switch). This means the worst case context switch time is longer than with `ALL` mode. It also reduces determinism as there is an unavoidable latency at the point the thread first accesses the FPU, so that the fault handler can execute to enable the FPU; and determinism is further affected as context switch time depends on whether threads use the FPU.

The `LAZY` mode does not save on stack usage, as the number of registers which might need to be saved remains the same.

Unlike the `ALL` mode, there is not yet support for lazy exception stacking for those threads which have the FPU enabled, which means if the FPU is enabled at the time of interrupt or exception, much of the FPU register context (the FPSCR, and half the data registers) will be saved. Please contact eCosCentric if it would be of interest to enhance eCos by adding adding lazy exception stacking to the `LAZY` context switching mode.

NONE In this mode, the FPU is enabled, but no floating point context is stored at any point, which naturally means there is no overhead on context switch. However this means that only one thread or context may use the FPU at a time.

If using this mode, either all FP operations must be constrained to a single thread. Or there must be locking to ensure that multiple threads do not access the FPU registers simultaneously. But if you rely on locking, great care must be taken as the compiler has the potential to reorder floating point accesses outside of the critical region if it is still in the same function. The use of the `HAL_REORDER_BARRIER()` call from the `<cyg/hal/hal_arch.h>` HAL header can be useful to prevent reordering across a particular point in the code.

Floating point specific tests

The kernel package has a number of tests to exercise floating point operations, especially when switching threads. Some of these tests take particular account of the Cortex-M features in determining what to test. The relevant test names in the kernel package all have the prefix "fp".

FP in exception contexts

Floating point must not be used in an ISR or from kernel exception handlers. If used, FPU registers will not be restored correctly on the return from the ISR/exception.

However if the `ALL` context switch mode is in use, it is permitted to use floating point in DSR routines, including kernel alarm functions. They may also be used in `NONE` mode, but as expected, this could only be if no threads are using floating point; this can be ensured in threads by using the kernel scheduler lock to prevent DSRs from running temporarily, although clearly that has an impact on real-time behaviour. As mentioned earlier, it would also be advised to combine the lock with use of `HAL_REORDER_BARRIER()`.

Do not use floating point operations in DSRs when LAZY context switch mode is used. There is no guarantee of which thread context will be current when the DSR is run, meaning that if the interrupt occured while a thread that does not use FP was running, the DSR would cause the FPU to enabled for that thread from then on.

Name

HAL Port — Implementation Details

Description

This documentation explains how the eCos HAL specification has been mapped onto the Cortex-M hardware and should be read in conjunction with the Architecture Reference Manual and the Technical Reference Manual. It should be noted that the architectural HAL is usually complemented by a variant HAL and a platform HAL, and those may affect or redefine some parts of the implementation.

Exports

The architectural HAL provides header files `cyg/hal/hal_arch.h`, `cyg/hal/hal_intr.h` and `cyg/hal/hal_io.h`. These header files export the functionality provided by all the Cortex-M HALs for a given target, automatically including headers from the lower-level HALs as appropriate. For example the platform HAL may provide a header `cyg/hal/plf_io.h` containing additional I/O functionality, but that header will be automatically included by `cyg/hal/hal_io.h` so there is no need to include it directly.

Additionally, the architecture HAL provides the `cyg/hal/basetype.h` header, which defines the basic properties of the architecture, including endianness, data type sizes and alignment constraints.

Startup

The conventional bootstrap mechanism involves a table of exception vectors at the base of memory. The first two words of this table give the initial program counter and stack pointer. For ROM startup only these two words are defined at the beginning of the ROM image. The rest of the vector table is constructed at runtime in on-chip SRAM.

The architectural HAL provides a default implementation of the low-level startup code which will be appropriate in nearly all scenarios. For a ROM startup this includes copying initialized data from flash to RAM. For all startup types it will involve zeroing bss regions and setting up the general C environment. It will also set up the initial exception priorities, switches the CPU into the correct execution mode, enables the debug monitor and enables error exception handling.

In addition to the setup it does itself, the initialization code calls out to the variant and platform HALs to perform their own initialization. The first such function is `hal_system_init` which is called at the very start of initialization. This function is supplied by the platform HAL and should do minimal initialization to allow the rest of the initialization code to run. Typically it will set up GPIO lines, enable clocks and access to external RAM. This function runs before the data and bss sections have been initialized, so it cannot rely on global or static data. Full initialization is handled by `hal_variant_init` and `hal_platform_init`. The former should complete clock and GPIO initialization and switch from the startup clocking speed to the default rate, which may involve enabling PLLs etc. The platform initialization routine will complete any initialization needed for devices external to the microprocessor.

The architectural HAL also initializes the VSR and virtual vector tables, sets up HAL diagnostics, and invokes C++ static constructors, prior to calling the first application entry point `cyg_start`. This code resides in `src/hal_misc.c`.

The current code assumes that there is no memory management or MPU and hence will not perform any MPU initialization. Other functional units may be initialized by the variant or platform HALs.

Interrupts and Exceptions

The eCos interrupt and exception architecture is built around a table of pointers to Vector Service Routines that translate hardware exceptions and interrupts into the function calls expected by eCos. The Cortex-M vector table provides exactly this functionality, so it is used directly as the eCos VSR table. The `HAL_VSR_GET` and `HAL_VSR_SET` macros therefore manipulate the vector table directly. The `hal_intr.h` header provides definitions for all the standard Cortex-M exception vectors.

The vector table is constructed at runtime at the base of internal SRAM, which is always located at address 0x20000000, and the Vector Table Offset Register set to use it. For ROM and JTAG startup all entries are initialized. For RAM startup only the interrupt vectors are (re-)initialized to point to the VSR in the loaded code, the exception vectors are left pointing to the VSRs of the loading software, usually RedBoot or GDB stubs.

When an exception occurs it is delivered to a shared VSR, `hal_default_exception_vsr` in `vectors.S` This saves the CPU state and calls `hal_deliver_exception` in `hal_misc.c`, which passes the exception on to either the kernel or the GDB stub handler. If it returns then the CPU state is restored and the code continued.

Interrupts are numbered from zero starting at VSR table entry 15, which is the SysTick timer interrupt. The remaining interrupt numbers are defined by the variant HAL, and possibly the platform HAL. These definitions are used to declare interrupt handling tables in the architecture HAL.

When an interrupt occurs it is delivered to a shared VSR, `hal_default_interrupt_vsr`, which saves some state and calls `hal_deliver_interrupt`. This function is passed the interrupt number to be delivered, generated by subtracting 15 from the value of the IPSR register. It looks up the ISR in the interrupt tables and calls it. If the return value of the ISR has the `CYG_ISR_CALL_DSR` bit set then it calls `cyg_interrupt_post_dsr` to mark the DSR for execution and also sets the PENDSVSET bit in the NVIC ICSR register to set the PendSVC exception pending.

Interrupts are delivered onto the main or interrupt stack, which differs from the process stack that threads execute on. The interrupt priority mechanism allows interrupts to nest on the interrupt stack (irrespective of the CDL option `CYGSEM_HAL_COMMON_INTERRUPTS_ALLOW_NESTING`) and only when the last interrupt has been executed will the PendSVC exception be called. The PendSVC handler arranges for `interrupt_end` to be called by pushing a new exception frame on the process stack, preserving its own exception frame, and returning. This causes `interrupt_end` to be called in thread mode on the process stack, which will cause any pending DSRs to be called, and a context switch to a new thread if necessary. When execution resumes on this thread it returns to `hal_interrupt_end_done`, which uses a SWI to pop its own exception frame and use the preserved PendSVC frame to resume the interrupted thread where it left off.

The architectural HAL provides default implementations of `HAL_DISABLE_INTERRUPTS`, `HAL_RESTORE_INTERRUPTS`, `HAL_ENABLE_INTERRUPTS` and `HAL_QUERY_INTERRUPTS`. These involve manipulation of the CPU BASEPRI register. Similarly there are default implementations of the interrupt controller macros `HAL_INTERRUPT_MASK`, and `HAL_INTERRUPT_UNMASK` macros. These manipulate the NVIC interrupt mask registers, and the TICKINT bit of the SYSTICK CSR register. `HAL_INTERRUPT_ACKNOWLEDGE` and `HAL_INTERRUPT_CONFIGURE` are no-ops at the architectural level.

`HAL_INTERRUPT_SET_LEVEL` manipulates the NVIC interrupt priority registers. The valid range of interrupts supported depends on the number of interrupt priority bits supported by the CPU variant. Priority level 0 is reserved for exceptions and the debug monitor. Interrupts are only allowed to start at the first implemented priority below this: 0x10 if the CPU implements 4 priority bits, 0x20 if it implements 3, and 0x01 if it implements all 8. This macro shifts the priority level supplied to start at the implemented maximum and clamps the higher end to 0xFF. So on a CPU that implements 4 priority bits, level 0 will be mapped to 0x10, levels above 0xf0 will all be mapped to 0xFF.

For all of these macros, a variant specific version may also be defined: `HAL_VAR_INTERRUPT_MASK`, `HAL_VAR_INTERRUPT_UNMASK`, `HAL_VAR_INTERRUPT_ACKNOWLEDGE`, `HAL_VAR_INTERRUPT_SET_LEVEL` and `HAL_VAR_INTERRUPT_CONFIGURE`. These are each called by the architecture macros after any architecture defined operations are completed. These macros allow the variant HAL to modify the architecture HAL support, or implement further interrupts that are not directly supported by the NVIC. In support of this, the variant HAL must define `CYGNUM_HAL_INTERRUPT_NVIC_MAX` which separates interrupts handled by the NVIC from any extended vectors defined by the variant HAL.

Stacks and Stack Sizes

`cyg/hal/hal_arch.h` defines values for minimal and recommended thread stack sizes, `CYGNUM_HAL_STACK_SIZE_MINIMUM` and `CYGNUM_HAL_STACK_SIZE_TYPICAL`. These values depend on a number of configuration options.

The Cortex-M architecture HAL always uses a separate stack for startup and interrupt handling. This is usually allocated to uninitialized memory at the top of the available internal or external RAM, depending on the startup type. Thus the configuration option `CYGIMP_HAL_COMMON_INTERRUPTS_USE_INTERRUPT_STACK` has no effect.

Thread Contexts and setjmp/longjmp

`cyg/hal/hal_arch.h` defines a thread context data structure, the context-related macros, and the `setjmp`/`longjmp` support. The implementations can be found in `src/context.S`. The context structure is defined as a discriminated union with different layouts for thread, exception and interrupt saved states. This approach allows the most efficient code and layout to be used in each context. The only expense is that debug code must be slightly more careful in accessing a saved state.

Bit Indexing

The architectural HAL provides inline assembler implementations of `HAL_LSBIT_INDEX` and `HAL_MSBIT_INDEX` which use the CPU count-leading-zero instruction.

Idle Thread Processing

The architecture HAL provides a default `HAL_IDLE_THREAD_ACTION` implementation that executes a `WFI`, wait for interrupt, instruction. This puts the CPU into a low power mode ready to respond quickly to the next interrupt.

A potential problem can occur with this however, as this instruction is known to cause difficulties when debugging via a JTAG hardware debugger. A frequent symptom is a report from the debugger that it was unable to stop the target. Therefore if using a JTAG debugger, it is strongly recommended to disable the use of `WFI` by enabling the configuration option titled "Disable HAL-specific idle action" (`CYGIMP_KERNEL_THREADS_IDLE_NO_HAL_ACTION`) which can be found in the eCos kernel package, in the "Thread-related options" component. This automatically happens when additional eCos debugging support is enabled using `CYGPKG_INFRA_DEBUG`, or if the HAL startup type (`CYG_HAL_STARTUP`) is set to "JTAG". But it needs to be set manually for other startup types, notably when debugging an application installed into Flash, which would have "ROM" startup type.

When using Single Wire Debug (SWD) hardware debuggers this is not an issue. Since the `CYG_HAL_STARTUP` setting "JTAG" is used irrespective of the hardware debugger type this would normally disable the use of `WFI` within the idle thread. However, when ITM is configured as available, the `CYGHWR_HAL_CORTEXM_SYSTEM_DEBUG_ALLOW_IDLE` option can be enabled to override the disabling, allowing the normal `WFI` idle behaviour.

Clock Support

The architectural HAL provides a default implementation of the various system clock macros such as `HAL_CLOCK_INITIALIZE`. These macros use the architecture defined SysTick timer to implement the eCos system clock. The architecture HAL expects the variant HAL to define and initialize a variable named `hal_cortexm_systick_clock`, which should contain the frequency in Hz of the clock supplied to the SysTick timer input. To allow for varying CPU clock rates, the SysTick timer is always programmed to take a 1MHz input clock, and `CYGNUM_HAL_RTC_PERIOD` is then expressed in terms of this.

HAL I/O

The Cortex-M architecture does not have a separate I/O bus. Instead all hardware is assumed to be memory-mapped. Further it is assumed that all peripherals on the memory bus will switch endianness with the processor and that there is no need for any byte swapping. Hence the various HAL macros for performing I/O simply involve pointers to volatile memory.

The variant and platform files included by the `cyg/hal/hal_io.h` header will typically also provide details of some or all of the peripherals, for example register offsets and the meaning of various bits in those registers.

Cache Handling

The current Cortex-M implementations do not support caches, so no cache handling is currently included in the architecture port. Instead it is the responsibility of the variant HAL to supply the `cyg/hal/hal_cache.h` header.

Linker Scripts

The architectural HAL will generate the linker script for eCos applications. This involves the architectural file src/cortexm.ld and a .ldi memory layout file, typically provided by the platform HAL. It is the .ldi file which places code and data in the appropriate places for the startup type, but most of the hard work is done via macros in the cortexm.ld file.

Diagnostic Support

The architectural HAL implements diagnostic support for ITM stimulus port if available, or for discarding all output. However, by default, the diagnostics output is left to the variant or platform HAL, depending on whether suitable peripherals are available on-chip or off-chip. The CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE can be configured to direct the diagnostic output support used.

See Cortex-M Hardware Debug for more detail regarding using the ITM stimulus port.

SMP Support

The Cortex-M architectural HAL does not provide any SMP support.

Debug Support

The architectural HAL provides basic support for gdb stubs using the debug monitor exceptions. Breakpoints are implemented using a fixed-size list of breakpoints, as per the configuration option CYGNUM_HAL_BREAKPOINT_LIST_SIZE. When a JTAG device is connected to a Cortex-M device, it will steal breakpoints and other exceptions from the running code. Therefore debugging from RedBoot or the GDB stubs can only be done after detaching any JTAG debugger and power-cycling the board.

HAL_DELAY_US() Macro

cyg/hal/hal_intr.h provides a simple implementation of the HAL_DELAY_US macro based around reading the SysTick timer. The timer must therefore be initialized before this macro is used, and HAL_CLOCK_INITIALIZE() is called during initialization after the variant and platform initialization functions are called, but before constructors are invoked.

Profiling Support

The Cortex-M variant may support the Data Watchpoint and Trace (DWT) feature, and if available then it is possible to use the DWT to provide non-intrusive PC sampling without any eCos run-time configuration or support being needed. The SWD hardware debugger being used controls the enabling and processing of PC sample data for subsequent use by profiling tools.

When using local memory based profiling the Cortex-M architectural HAL implements the mcount function, allowing profiling tools like gprof to determine the application's call graph. It does not implement the profiling timer. Instead that functionality needs to be provided by the variant or platform HAL.

Name

Cortex-M Hardware Debug — Overview of hardware debug features

Introduction

Some Cortex-M designs may include the Instrumentation Trace Macrocell (ITM) and Data Watchpoint and Trace (DWT) features. The ITM allows for software generated “instrumentation” to be output via the Single Wire Debug (SWD) hardware interface in a relatively non-intrusive fashion. The SWD ITM support provides for much higher data rates than can normally be achieved via a UART, so they can provide for software controlled debug I/O support with a significantly reduced system overhead, which may be important for some eCos applications.

There is no explicit eCos support for making use of the DWT features, since the hardware debug tools being used can control the feature use independently of the eCos application. The specific hardware debug tools being used may provide support as required. For example the Ronetix PEEDI has built-in support for tracking DWT PC sample events for profiling.

Instrumentation Trace Macrocell (ITM)

If the Cortex-M ITM support is enabled in the CDL configuration then HAL diagnostics can be directed to a ITM stimulus port, and if instrumentation is enabled then event records directed to a different stimulus port. How the output data is processed or captured is dependent on the hardware tool being used to drive the SWD interface.

The following sections give a brief overview of using the Ronetix PEEDI hardware debugger, and the OpenOCD tool in conjunction with the STMicroelectronics ST-LINKv2 adapter. This is by no means an exhaustive list since many 3rd-party hardware tools exist, and any tool capable of handling ITM stimulus port output can normally be configured to accept console (HAL diagnostic) input or record captured data (instrumentation). More detail of specific variant or target SWD/JTAG setup and ITM stimulus port support may be found in the relevant eCos platform specific documentation.

Ronetix PEEDI

The documentation supplied with the Ronetix PEEDI provides an overview of using the Cortex-M ITM features. However, the example PEEDI configuration file *BASE_DIR*`/packages/hal/cortexm/arch/current/misc/peedi.cortexm3.swd.cfg` provided with eCos has comments on how the PEEDI can be configured to provide access to the data written to ITM stimulus ports on specific TCP network ports. It also provides an example of using the DWT PC sampling feature to gather non-intrusive application execution profiling.

The simplest use would be to use the telnet command to connect to the stimulus port connection being used for HAL diagnostics. When an application configured for ITM diagnostics is executed then the output will appear on the configured network port:

```
$ telnet peedi-0 2001
Trying 127.0.0.1...
Connected to localhost.
Escape character is '^]'.
INFO:<code from 0x20000290 -> 0x2000e254, CRC 2a20>
…
```

Similarly the Linux nc command could be used to save data from an instrumentation port to a file for post-processing. For example, if the eCos application is built with Kernel instrumentation enabled and configured for ITM output, then the stimulus port output can be captured and processed using the example instdump tool provided in the Kernel package.

```
$ nc peedi-0 2003 > inst.bin
^C
$ instdump -r inst.bin elfapp
Threads:
 threadid 1 threadobj 200045D0 "idle_thread"

     0:[THREAD:CREATE][THREAD 4095][TSHAL 4][TSTICK 0][ARG1:200045D0] { ts 4 microseconds }
```

```
    1:[SCHED:LOCK][THREAD 4095][TSHAL 45][TSTICK 0][ARG1:00000002] { ts 45 microseconds }
    …
```

OpenOCD

The OpenOCD ITM support is limited to using the ST-LINKv2 hardware interface to the target board. For example, as built-in to the STM32F4DISCOVERY and STM32x0G-EVAL platforms. The ST-LINKv2 firmware on the boards should be at least `JTAG v17`, so older boards may need to have their ST-LINK firmware updated via the relevant STMicroelectronics tool prior to being used for ITM stimulus port support.

The *`BASE_DIR`*`/packages/hal/cortexm/stm32/stm32f4dis/current/misc/openocd.stm32f4dis.cfg` file provides an example OpenOCD configuration file that captures ITM stimulus port data and directs it to a file named `tpiu.out` in the current directory at the time **openocd** was invoked. This file can then be interpreted by a program **parseitm** which can be found in this package in the directory `packages/hal/cortexm/arch/`*`VERSION`*`/host` relative to the root of your eCos installation. It can be compiled simply with:

```
$ gcc -o parseitm parseitm.c
```

You simply run it with the desired ITM stimulus port and name of the file containing the ITM output, and it will echo all ITM stimulus for that port, continuing to read from the file until interrupted with Ctrl-C for example:

```
$ parseitm -p 31 -f tpiu.out
```

Note

Note that limited buffer space in debug hardware such as the ST-LINK can result in some ITM data becoming lost due to buffer overruns. eCosPro provides a workaround of throttling data within the `CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE` CDL configuration component of this package in order to reduce or avoid lost ITM data.

Two approaches are available: "Chunk" or "Per-Character" throttling. In the case of Chunk throttling, a configurable number of characters are output before a delay is applied to allow the buffer to be emptied. However this can result in a longer delay while waiting for the buffer to empty. Alternatively, Per-Character throttling imposes a small delay after every character, whether it is needed or not.

More detail on the behaviour of these configuration options can be found in the description of the "ITM Throttling" component (`CYGHWR_HAL_CORTEXM_ITM_DIAGNOSTICS_THROTTLE`) and its sub-options within the eCos Configuration Tool.

These are just default examples; it is also possible to configure the eCos kernel to send its instrumentation output via ITM, and applications may make use of other stimulus ports for application-specific functionality.

Chapter 286. Kinetis Variant HAL

Name

`CYGPKG_HAL_CORTEXM_KINETIS` — eCos Support for the Kinetis Microprocessor Family

Description

The Freescale Kinetis K series of Cortex-M microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for the on-chip flash, serial, I²C, SPI, Ethernet, RTC/wallclock and watchdog devices. In addition it provides common functionality and definitions that Kinetis based platform ports may require, as well as definitions useful to application developers.

This documentation covers the Kinetis functionality provided, but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the Kinetis variant HAL provides. The areas that are specific to platfom HALs and not the Kinetis variant HAL include:

- memory map and related configuration and setup
- Clock parameters
- GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED/LCD control

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

On-chip memory

The Freescale Kinetis parts include on-chip SRAM, and on-chip FLASH. The SRAM and FLASH can vary in size depending on the model. There is also support in some models for external memory, which eCos may use where available.

Typically, an eCos platform HAL port will expect a GDB stub ROM monitor or RedBoot image to be programmed into the Kinetis on-chip FLASH memory for development, and the board would boot this image from reset. The stub ROM/RedBoot provides GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels. The JTAG interface may also be used for development if a suitable JTAG device is available. If RedBoot is present it may also be used to manage the on-chip and external flash memory. For production purposes, applications are programmed into external or on-chip FLASH and will be self-booting.

On-chip FLASH

The package `CYGPKG_DEVS_FLASH_KINETIS` ("Kinetis FLASH memory support") provides a driver for the on-chip flash. This driver conforms to the Version 2 flash driver API, and is automatically enabled if the generic "Flash device drivers" (`CYGPKG_IO_FLASH`) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific Kinetis variant which has been selected in the eCos configuration.

Cache Handling

The variant HAL supplies the `cyg/hal/hal_cache.h` header file to describe cache support to the generic eCos code. Some Kinetis K series parts have access to a Cortex-M4 core cache (the `CYGINT_HAL_CACHE` will be defined by the platform if appropriate). If the configured part does not provide a cache then the header will supply null macros for the required functions.

When a cache is available the HAL currently supports a 16KiB cache, split into a 8KiB data cache and a 8KiB instruction cache.

The architecture HAL also defines a macro `HAL_MEMORY_BARRIER()` which acts to synchronize the pipeline, delaying execution until all previous operations, including all pending writes, are complete. This will usually be necessary when interacting with devices that access memory directly.

Note

The use of the default Cortex-M architecture `HAL_MEMORY_BARRIER` macro requires that the CPU core supports the barrier instructions (`ID_ISAR4[19..16]` is not `0`). This is the case for the Freescale Kinetis family.

Serial I/O

The Kinetis variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_FREESCALE_UART` which provides all support for the Kinetis on-chip serial devices. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor or RedBoot for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

The HAL defines CDL interfaces, `CYGINT_HAL_FREESCALE_UART0` to `CYGINT_HAL_FREESCALE_UART5` for each of the available UARTs. The platform HAL CDL should contain an **implements** directive for each such UART that is available for use on the board. This will enable use of the UART for diagnostic use.

The Kinetis UARTs provide `TX` and `RX` data lines plus hardware flow control using `RTS`/`CTS` for those UARTs that have the signals available on the platform hardware.

Note

The `UART0` and `UART1` devices are clocked from the main core clock, with the remaining UARTs clocked from the bus clock. This can affect baud rate accuracy at higher configured speeds depending on the main CPU clock configuration, and the physical UART being used.

Interrupts

The Kinetis HAL relies on the architectural HAL to provide support for the interrupts directly routed to the NVIC. The `cyg/hal/var_intr.h` header defines the vector mapping for these.

GPIO

The variant HAL provides support for packaging the configuration of a GPIO line into a single 32-bit descriptor that can then be used with macros to configure the pin and set and read its value. This is useful to drivers and other packages that need to configure and use different I/O lines for different devices.

A descriptor is created with the `CYGHWR_HAL_KINETIS_PIN(port,bit,mux,cnf)` macro, where the parameters required are:

`port`
: This identifies the GPIO port to which the pin is attached. Ports are identified by the letters from `A` to `F`.

`bit`
: This gives the bit or pin number within the port. These are numbered from `0` to `31`.

`mux`
: This paramater specifies how the pin should be used, and should be in the range `0` to `7`. The value `0` corresponds to the pin being disabled (Analog), with `1` used to specify GPIO control. The other values `2` to `7` are used to indicate alternative function mappings as defined by the CPU variant.

`cnf`
: This option allows explicit Port Control register configuration settings to be specified. The bits as held in the *`cnf`* value are defined as per the relevant Kinetis Reference Manual.

The macro `CYGHWR_HAL_KINETIS_PIN_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used. This can be useful when defining pin configurations for a series of instances of a peripheral (e.g. UART ports), but where not all instances support all the same pins (e.g. hardware flow control lines).

The function `hal_set_pin_function(pin)` configures the pin according to the descriptor and must be called before other GPIO operations are performed on the pin.

The macros to manipulate GPIO state all take a suitably constructed GPIO pin descriptor as an argument. It is recommended to consult the header file `<cyg/hal/var_io_gpio.h>` (also present in the `include` subdirectory of the Kinetis variant HAL package within the eCos source repository), for the complete list if needed.

RTC/Wallclock

eCos includes a RTC (known in eCos as a wallclock) device driver for the on-chip RTC in the Kinetis family. This is located in the package `CYGPKG_DEVICES_WALLCLOCK_KINETIS_RTC` (“Real-time clock”).

Profiling Support

The Kinetis HAL contains support for **gprof**-based profiling using a sampling timer. The default timer used is `PIT0`, which is one of the basic periodic interrupt timers, leaving the more complex timers for application code. The timer used is selected by the CYGHWR_HAL_CORTEXM_KINETIS_PROFILE_PIT_CHANNEL configuration option. This timer is only enabled when the gprof profiling package (CYGPKG_PROFILE_GPROF) is included and enabled in the eCos configuration, otherwise it remains available for application use.

Clock Control

The CDL section CYGHWR_HAL_CORTEXM_KINETIS_CLOCKING contains many options to configure the various Kinetis on-chip clocks, based on platform supplied default values. The CDL will calculate the main CYGNUM_HAL_CORTEXM_KINETIS_MCGOUT_FREQ frequency value, which in turn is used in conjunction with the configured clock divider values to set the frequencies of the relevant subsystems.

The actual calculated values of the main clocks, in Hz, are stored in the global variables hal_kinetis_sysclk and hal_kinetis_busclk. The clock supplied to the Cortex-M SysTick timer, HCLK/8, is also assigned to the global variable hal_cortexm_systick_clock. These variables are used, rather than configuration options, in anticipation of future support for power management by varying the system clock rate.

Note that when changing or configuring any of these clock settings, you should consult the relevant processor datasheet as there may be both upper and lower constraints on the frequencies of some clock signals, including intermediate clocks. There are also some clocks where, while there is no strict constraint, clock stability is improved if values are chosen wisely. Finally, be aware that increasing clock speeds using this package may have an effect on platform specific properties, such as memory timings which may have to be adjusted accordingly.

Chapter 287. Freescale TWR-K60N512 and TWR-K60D100M Platform HAL

Name

CYGPKG_HAL_CORTEXM_KINETIS_TWR_K60N512 — eCos Support for the Freescale TWR-K60N512 and TWR-K60D100M boards

Description

The Freescale TWR-K60N512 and TWR-K60D100M boards are almost identical, so the CYGPKG_HAL_CORTEXM_KINETIS_TWR_K60N512 package provides support for both variants. The only functional differences are whether a revision 1 or revision 2 Kinetis K60 sub-family CPU is used, and a different on-board 3-axis accelerometer.

The TWR-K60N512 board has a MK60N512VMD100 revision 1 microcontroller and the TWR-K60D100M board has a MK60DN512VMD10 revision 2 microcontroller. Both microcontrollers incorporate 512KB of internal flash ROM and 128KB of internal SRAM.

In either case the stand-alone board may be targetted, but for access to some peripherals it is assumed that a TWR-ELEV setup, with a TWR-SER daughterboard is being used. For example, with a TWR-SER board present it provides a connector for Ethernet. The motherboards have limited I/O interfaces, with most of the I/O signals being propogated via multi-pin connectors.

The motherboards also provide an on-board JTAG debug circuit (OSJTAG) with virtual serial port, a 3-axis accelerometer, a potentiometer, a MicroSD card slot, and some LEDs and buttons.

The TWR-SER daughterboard also provides in addition to the Ethernet connector access to a RS232/484 DB9 connection, a USB Mini-AB connector and a 3-pin CAN connector.

For these boards, the expected eCos development model is that programs may be downloaded and debugged via the on-board OSJTAG USB interface, or via a hardware debugger (JTAG/SWD) attached to the JTAG socket. However, if required, it is possible to build and install RedBoot or a GDB stub image into the internal FLASH so that the CPU boots directly into that monitor, and that the GDB debugger accesses the monitor via serial or Ethernet.

This documentation describes platform-specific elements of the TWR-K60N512 and TWR-K60D100M board support within eCos. The Kinetis variant HAL documentation covers various topics including HAL support common to Kinetis variants, and on-chip device support. This document complements the Kinetis documentation.

Supported Hardware

The K60 parts used have two on-chip memory regions. There is a SRAM region of 128KiB present at 0x1FFF0000 and a 512KiB FLASH region present at 0x00000000.

The Kinetis variant HAL includes support for the six on-chip serial devices which are documented in the variant HAL. For these boards UART3 is connected to the J8 DB9 connector, with hardware flow control (RTS/CTS) lines available. Additionally UART5 is connected as a virtual serial through the on-board OSJTAG J13 USB connection, without support for hardware flow control lines.

Device drivers are provided for the Kinetis on-chip Ethernet MAC, I²C interface and SPI interface. Additionally support is provided for the on-chip watchdog, RTC (wallclock) and a flash driver exists to permit management of the Kinetis's on-chip flash.

The Kinetis K60 processor, and the TWR-K60N512/TWR-K60D100M platforms, provide a wide variety of peripherals, but unless support is specifically indicated it should be assumed that support is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3a, **arm-eabi-gdb** version 7.6, and **binutils** version 2.23.2.

Name

Setup — Preparing the TWR-K60N512/TWR-K60D100M Board for eCos Development

Overview

Since the target motherboard provides a built-in hardware debug solution, it is expected that the most common development method when targeting the CPU is to use this hardware debug interface (instead of GDB stubs or RedBoot) for development. This will either be by loading smaller applications into on-chip SRAM, or by programming larger applications directly into on-chip flash. In the first case, eCos applications should be configured for the variant JTAG startup type, and in the second case for the variant ROM startup type.

Nevertheless, it is still possible to program RedBoot or a GDB stub ROM image into on-chip flash and download and debug via a serial UART, if pins for the UART are available. In that case, eCos applications are configured for a variant RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. For serial communications, all versions run with 8 bits, no parity, and 1 stop bit at 38400 baud. This rate can be changed in the eCos configuration used for building the RedBoot or GDB stub ROM image.

HAL Startup Types

For the `twr_k60n512` and `twr_k60d100m` platforms the Kinetis variant HAL support provides some common startup types. The following variant HAL provided startup types may be selected for applications:

Configuration	Description
ROM	Stand-alone programs running from internal FLASH
SRAM	Programs loading via hardware debugger into on-chip SRAM, but expecting RedBoot or GDB stub ROM
RAM	Programs loading via RedBoot or GDB stub ROM into on-chip SRAM
JTAG	Stand-alone programs running from on-chip SRAM, loaded via hardware debugger

Further details are available later in this manual.

Preparing OSJTAG interface

The support for using the on-chip OSJTAG interface for hardware debugging and diagnostic output requires that the OSJTAG firmware is at least version `v30.21`. The firmware for the OSJTAG interface can be checked, and updated if needed, using the relevant firmware updater tool available for download via the Freescale website. Unfortunately the official firmware updater is only available for the Windows platform at the moment.

Programming ROM images

To program ROM startup applications into flash, including the GDB stub ROM or RedBoot, a hardware debugger that understands the Kinetis flash may be used. For example, the Ronetix PEEDI provides suitable support.

Warning

Due to a security feature of the Kinetis CPUs care should be taken to avoid completely erasing the flash to ensure the required `FSEC` value in the flash configuration field is not lost. For example when using the PEEDI the user should NOT use the “erase” suffix to the **flash program** command. The Kinetis aware **flash erase chip** should be executed to erase the flash prior to using the **flash program** command.

Programming ROM images with a Ronetix PEEDI

This section describes how to program ROM images using a Ronetix PEEDI debugger.

The PEEDI must be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. It must then be used to download and program the ROM image into the internal flash. The following steps give a typical outline for doing this. Consult the PEEDI documentation for alternative approaches, such as using FTP or HTTP instead of TFTP.

Preparing the Ronetix PEEDI JTAG debugger

1. Prepare a PC to act as a host and start a TFTP server on it.

2. Connect the PEEDI JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the PEEDI (straight through, not null modem).

3. Verify the PEEDI is using up-to-date firmware, of version 12.3.0 or later. Older PEEDI firmware does not support the Kinetis family correctly, particularly if wishing to use the PEEDI's own '**flash**' commands to modify the on-chip flash. If the firmware is not recent enough, follow the PEEDI User Manual's instructions which describe how to update the PEEDI firmware.

4. Locate the PEEDI configuration file `peedi_twr_k60n512.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/kinetis/twr_k60n512/`*`VERSION`*`/misc` relative to the root of your eCos installation.

5. Place the PEEDI configuration file in a location on the PC accessible to the TFTP server. Later you will configure the PEEDI to load this file via TFTP as its configuration file.

6. Open `peedi_twr_k60n512.cfg` in an editor such as emacs or notepad and insert your own license information in the `[LICENSE]` section.

7. Install and configure the PEEDI in line with the PEEDI Quick Start Guide or User's Manual, especially configuring PEEDI's RedBoot with the network information. Configure it to use the `peedi_twr_k60n512.cfg` target configuration file on the TFTP server at the appropriate point of the **config** process, for example with a path such as: `tftp://192.168.7.9/peedi_twr_k60n512.cfg`

8. Reset the PEEDI.

9. Connect to the PEEDI's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see output similar to the following:

```
$ telnet 192.168.7.225
Trying 192.168.7.225...
Connected to 192.168.7.225.
Escape character is '^]'.

```

Preparing the TWR-K60N512/TWR-K60D100M board for programming with PEEDI

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the PEEDI device.

If programming a RedBoot, GDB stub ROM, or an application, which uses serial output, you should first:

1. If OSJTAG firmware 30.21 or later is installed then the motherboard J13 USB provides a standard CDC-ACM virtual serial connection to the host computer. The alternative is to connect a null modem cable between the DB9 RS232 connector on the TWR-SER daughterboard and the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** on Linux or PuTTY on Windows. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

For all applications, you must:

1. Connect the board to the PEEDI using an appropriate 20-pin cable from the JTAG interface connector to the Target port on the PEEDI. This will normally be a PEEDI-CORTEX20 adapter.

2. Power up the `TWR-K60N512`/`TWR-K60D100M` board.

3. Connect to the PEEDI's telnet CLI on port 23 as before.

4. Confirm correct connection with the PEEDI with the **reset reset** command as follows:

   ```
   twr_k60n512> reset reset
   ++ info: user reset
   twr_k60n512>
   ++ info: RESET and TRST asserted
   ++ info: TRST released
   ++ info: TAP : IDCODE = 0x2BA01477, Cortex M3 SWD
   ++ info: RESET released
   ++ info: core connected

   CORE0 -> CortexM4 - stopped by breakpoint
            PC=0x1FFF0006, xPSR=0x01000000

   core #0 stopped
   ++ info: core 0: initialized

   twr_k60n512>
   ```

Installation into flash

The following describes the procedure for installing a ROM application into on-chip flash, using the GDB stub ROM image as an example of such an application.

1. Use **arm-eabi-objcopy** to convert the linked application, in ELF format, into binary format. For example:

   ```
   $ arm-eabi-objcopy -O binary programname programname.bin
   ```

2. Copy the binary file (.bin file) into a location on the host computer accessible to its TFTP server.

3. Connect to the PEEDI's telnet interface, and program the image into flash with the following commands, replacing *`TFTP_SERVER`* with the address of the TFTP server and *`/BINPATH`* with the location of the .bin file relative to the TFTP server root directory. For example for a RedBoot ROM image:

   ```
   twr_k60n512> flash erase chip

   erasing chip at 0x00000000
   done.

   ++ info: successfully erased 1 byte in 0.33 sec

   twr_k60n512> flash program tftp://TFTP_SERVER/BINPATH/redboot.bin bin 0x00000000
   ++ info: Programming image file: tftp://TFTP_SERVER/redboot.bin
   ++ info: Programming directly
   ++ info: At absolute address:    0x00000000
   programming at 0x00000000
   programming at 0x00001000
   programming at 0x00002000
   programming at 0x00003000
   programming at 0x00004000
   programming at 0x00005000
   ```

```
programming at 0x00006000
programming at 0x00007000
programming at 0x00008000
programming at 0x00009000
programming at 0x0000A000
programming at 0x0000B000
programming at 0x0000C000
programming at 0x0000D000
programming at 0x0000E000
programming at 0x0000F000
programming at 0x00010000
programming at 0x00011000
programming at 0x00012000
programming at 0x00013000
programming at 0x00014000
programming at 0x00015000

++ info: successfully programmed 88.00 KB in 0.74 sec

twr_k60n512>
```

The installation into flash is now complete. For applications which print output on startup to the USART3 RS232 serial port, such as the GDB stub ROM application, this can easily by tested by powering off the board, disconnecting the JTAG, and then powering on the board again. In the case of the GDB stub ROM image, output similar to the following should be visible (although specific numbers may differ):

```
$T050f:72250008;0d:f0ff0120;#8a
```

RedBoot Installation

Only the `ROM_VAR` RedBoot configuration is supported. This is for RedBoot running from internal FLASH, using on-chip SRAM. For serial communications this uses 8 bits, no parity, and 1 stop bit at 38400 baud. This rate can be changed using the RedBoot **baud** command, or in the eCos configuration used for building RedBoot.

Rebuilding RedBoot

Should it prove necessary to rebuild a RedBoot binary, this is done most conveniently at the command line. The steps needed to rebuild the ROM version of RedBoot for the `TWR-K60N512` are:

```
$ mkdir redboot_twr_k60n512_rom
$ cd redboot_twr_k60n512_rom
$ ecosconfig new twr_k60n512 redboot
[ … ecosconfig output elided … ]
$ ecosconfig import $ECOS_REPOSITORY/hal/cortexm/kinetis/twr_k60n512/VERSION/misc/redboot_ROM_VAR.ecm
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `redboot.bin`. This may be programmed to the board using the above procedure, or by using RedBoot's own flash update mechanisms.

The other versions of RedBoot - RAM, ROM_FPU, ROM_VAR - may be similarly built by choosing the appropriate alternative .ecm file.

Initializing RedBoot flash Configuration

RedBoot manages the internal flash for the storage of application programs and configuration data. The flash needs to be initialized with the following commands:

```
RedBoot> fis init
About to initialize [format] FLASH image system - continue (y/n)? y
*** Initialize FLASH Image System
```

```
... Erase from 0x0007f800-0x0007ffff: .
... Program from 0x2000e800-0x2000f000 to 0x0007f800: .
RedBoot> fconfig -i
Initialize non-volatile configuration - continue (y/n)? y
Run script at boot: false
Console baud rate: 115200
Update RedBoot non-volatile configuration - continue (y/n)? y
... Erase from 0x0007f800-0x0007ffff: .
... Program from 0x2000e800-0x2000f000 to 0x0007f800: .
RedBoot>
```

Issue the **reset** command to RedBoot, and verify the the target board comes up as expected with the correct settings.

You may also need to run the **fconfig -i** command if you have updated your RedBoot from a previous version with a different configuration which might not have any new config fields used by the newly programmed RedBoot.

Name

Configuration — Platform-specific Configuration Options

Overview

The CYGPKG_HAL_CORTEXM_KINETIS_TWR_K60N512 platform HAL package is loaded automatically when eCos is configured for either the twr_k60n512 or twr_k60d100m targets. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The target board platform HAL package supports the standard variant HAL startup types:

ROM
: This startup type can be used for finished applications which will be programmed into internal flash ROM at location 0x00000000. Data and BSS will be put into on-chip SRAM starting from 0x1FFF0000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. eCos startup code will perform all necessary hardware initialization.

RAM
: This is the startup type which is used if relying on either a RedBoot or a GDB stub ROM image programmed into internal flash to download and run applications into on-chip SRAM via arm-eabi-gdb. It is assumed that the hardware has already been initialized by the ROM monitor. By default the application will use the eCos virtual vectors mechanism to obtain services from the ROM monitor, including diagnostic output.

JTAG
: This is the startup type used to build applications that are loaded via a hardware debug interface into on-chip SRAM. The application will be self-contained with no dependencies on services provided by other software. For the variant JTAG startup type the eCos run-time will perform all necessary hardware initialization.

Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option CYGSEM_HAL_ROM_MONITOR should be set. Typically this option is set only when building the GDB stub ROM (or RedBoot).

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option CYGSEM_HAL_USE_ROM_MONITOR should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The platform HAL uses the Kinetis's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, can be directed to either UART3 (default) or UART5 as required.

As well as the polled HAL diagnostic interface, there is also a CYGPKG_IO_SERIAL_FREESCALE_UART package which contains all the code necessary to support interrupt-driven operation with greater functionality. All six UARTs can be supported by this driver. Note that it is not recommended to use this driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option (within the generic serial driver support package CYGPKG_IO_SERIAL) is enabled in the configuration. By default this will only enable support in the driver for the UART2 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports.

Ethernet Driver

The TWR-SER daughterboard is fitted with an Ethernet port connected via a KSZ8041NL PHY to the K60 on-chip Ethernet MAC. This is supported in eCosPro with a driver contained in the package CYGPKG_DEVS_ETH_FREESCALE_ENET.

The driver will be inactive (not built and greyed out in the eCos Configuration Tool) unless the “Common Ethernet support” (CYGPKG_IO_ETH_DRIVERS) package is included in your configuration. As the Kinetis ethernet driver is likely to be used in deeply embedded, low footprint, applications it is most appropriate to choose the lwip_eth template as a starting point when choosing an eCos configuration, which will cause the necessary packages to be automatically included.

SPI Driver

A Kinetis SPI bus driver is available in the package “Freescale DSPI driver” (CYGPKG_DEVS_SPI_FREESCALE_DSPI).

No SPI devices are instantiated by default. Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the Freescale DSPI device driver.

I²C Driver

A Kinetis I²C hardware driver is available in the package “Freescale I2C driver” (CYGPKG_DEVS_I2C_FREESCALE_I2C).

Flash Driver

The Kinetis's on-chip flash may be programmed and managed using the flash driver located in the “Kinetis FLASH memory support” (CYGPKG_DEVS_FLASH_KINETIS) package. This driver is enabled automatically if the generic “Flash device drivers” (CYGPKG_IO_FLASH) package is included in the eCos configuration.

The driver will configure itself automatically for the size and parameters of the specific Kinetis variant present on the TWR-K60N512/TWR-K60D100M board.

Name

JTAG/SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM, including the GDB stub ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M4 core of the K60-series only supports six such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should *not* be necessary when using a SWD-based hardware debugger.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. If ITM output is required the architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use. The host hardware debugger configuration may also need to be updated to provide the necessary ITM enable and capture support.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

Normally a notable disadvantage with JTAG/SWD debugging is that it does not allow thread-aware debugging, such as the ability to inspect different eCos threads or their stack backtraces, set thread-specific breakpoints, and so on. Fortunately the Ronetix PEEDI JTAG unit does support thread-aware debugging of eCos applications, however extra configuration steps are required. Similarly OpenOCD has support for interpreting eCos thread information. Consult the PEEDI or OpenOCD documentation for more details as usage is beyond the scope of this document.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board OSJTAG interface available via the USB J13 connection.

An example OpenOCD configuration file `openocd_twr_k60n512.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/kinetis/twr_k60n512/`*`VERSION`*`/misc` relative to the root of your eCos installation.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd_twr_k60n512.cfg
Open On-Chip Debugger 0.8.0-dev-hg8c51ca8dbc00-dirty (2013-09-09-17:18)
Licensed under GNU GPL v2

```

By default **openocd** provides a telnet console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

To debug the target from the command line, **arm-eabi-gdb** should be connected to OpenOCD using it's default GDB server port of `3333`. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333

(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then you may need to define a “preload” gdb macro to emit any necessary commands to OpenOCD prior to loading or executing. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

If you need to build your own copy of OpenOCD then when configuring the **openocd** tool build, the **configure** script can be given the option `--enable-osbdm` to provide for OSJTAG support.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi_twr_k60n512.cfg` file supplied in the platform HAL package should be used to setup and configure the hardware to an appropriate state to load programs.

The `peedi_twr_k60n512.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to hardware breakpoints. If the breakpoint type is changed remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

The PEEDI provides a telnet console on the standard telnet port (`23`) for configuration and control, and gdb remote debugging access via port `9000`. For example, to use the command line **arm-eabi-gdb** to connect to the target via the PEEDI, you would issue the following gdb command:

```
(gdb) target remote 111.222.333.444:9000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi_twr_k60n512.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, and then the '**go**' command is given, the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after reset. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi_twr_k60n512.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset and run the resident flash program without being required to always type '**go**' every time. Finally, it is also possible to set a temporary default (unless the PEEDI is reset) by giving an argument to the **reset** command, for example **reset run**. Use the command **help reset** at the PEEDI command prompt for more options.

Suitably configured applications can be loaded either via GDB, or directly via the telnet CLI into RAM for execution. For example:

```
twr_k60n512> memory load tftp://192.168.7.9/test.bin bin 0x20000000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x20000000
loading at 0x20000000
loading at 0x20004000

Successfully loaded 28KB (29064 bytes) in 0.1s
twr_k60n512> go 0x20000000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

For Eclipse users wishing to debug ROM startup programs resident in flash, it is worth highlighting that it is possible to use the eCosCentric Eclipse plugin to automatically reprogram flash as the load sequence. To do so, you will need to install and use a TFTP server so that your application can be accessed from the PEEDI from there. You may then use a GDB command file, as described in more detail in the “Eclipse/CDT for eCos application development” manual. This file can then contain contents similar to the following example:

```
define doload
  shell arm-eabi-objcopy -O binary /path/to/eclipse/workspace/projectname/Debug/myapp /path/to/tftp/server/area/myapp.bin
  monitor flash program tftp://10.1.1.1/myapp.bin bin 0x08000000 erase
  set $pc=0x08000000
end
```

Obviously you will need to adjust the paths and names for your system and TFTP server requirements.

Configuration of JTAG/SWD applications

In order to configure the application to be downloaded and debugged via a hardware debugger, it is recommended to use one of the JTAG startup types (JTAG or ROM), which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` will be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option will be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could also be made by hand, but use of one of the JTAG startup types will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. By default the K60's JTAG startup types output diagnostics via the USB CDC/ACM serial port on the J13 USB connector. Alternatively diagnostic output can be configured to appear in GDB instead. For this to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. Then, after you load your application but before running it, you must give GDB the command:

```
(gdb) set hwdebug on
```

Eclipse users can do this by creating a GDB command file with the contents:

```
define postload
  set hwdebug on
end
```

This will be referenced from their Eclipse debug launch configuration. Using GDB command files is described in more detail in the "Eclipse/CDT for eCos application development" manual.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Freescale TWR-K60N512 and TWR-K60D100M hardware, and should be read in conjunction with that specification. The `CYGPKG_HAL_CORTEXM_KINETIS_TWR_K60N512` platform HAL package complements the Cortex-M architectural HAL and the Kinetis variant HAL. It provides functionality which is specific to the target boards.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services, and for the platform JTAG startup where the host debugger configuration is responsible for initialising the DDRMC world for the external SDRAM used to hold the application being loaded.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/twr_k60n512_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM
: This is located at address 0x1FFF0000 of the memory space, and is 128KiB in size. The eCos VSR table occupies the bottom 512-bytes. The virtual vector table starts at 0x1FFF0200 and extends to 0x20000300. For ROM, and JTAG startups, the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH
: This is located at address 0x00000000 of the memory space. This region is 1MiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals
: These are accessible from locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the Kinetis User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to 0x1FFF0000 for all startup types, and space for 128 entries allocated, though the K60 sub-family in use may use less entries.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20000200.

hal_interrupt_stack
: This defines the location of the interrupt stack. For all startup types this is allocated to the top of internal SRAM, 0x20010000.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Diagnostic LEDs

Four LEDs are fitted on the board for diagnostic purposes:

Platform HAL manifest	Colour	Board Label
`CYGHWR_IO_KINETIS_PIN_LED1`	Orange	`E1`
`CYGHWR_IO_KINETIS_PIN_LED2`	Yellow	`E2`
`CYGHWR_IO_KINETIS_PIN_LED3`	Green	`E3`
`CYGHWR_IO_KINETIS_PIN_LED4`	Blue	`E4`

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow the LEDs to be set:

```
extern void hal_twr_k60n512_led(char c);
```

The lowest 4-bits of the argument `c` correspond to each of the 4 LEDs (with LED1 as the least significant bit).

The platform HAL will automatically light all of the LEDs when the platform initialisation is complete, however the LEDs are free for application use.

Real-time Characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for the variant ROM startup with optimization flag -O3.

Example 287.1. twr_k60n512 Real-time characterization

```
INFO:<code from 0x00000410 -> 0x000181dc, CRC 0356>
             Startup, main thrd : stack used   112 size  1536
             Startup : Idlethread stack used    84 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    8.00 microseconds (8 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   6
   Thread switches:         128
   Mutexes:                  32
   Mailboxes:                32
   Semaphores:               32

Chapter 288. Freescale TWR-K70F120M Platform HAL

Name

CYGPKG_HAL_CORTEXM_KINETIS_TWR_K70F120M — eCos Support for the Freescale TWR-K70F120M board

Description

The Freescale TWR-K70F120M board has a MK70FN1M0VMJ12 microcontroller which incorporates 1MB of internal flash ROM and 128KB of internal SRAM. The stand-alone board may be targetted, but for access to some peripherals it is assumed that a TWR-ELEV setup, with a TWR-SER daughterboard is being used. For example, with a TWR-SER board present it provides a connector for Ethernet. The TWR-K70F120M motherboard has limited I/O interfaces, with most of the I/O signals being propogated via multi-pin connectors.

The TWR-K70F120M motherboard also provides an on-board JTAG debug circuit (OSJTAG) with virtual serial port, 128MB of DDR2 SDRAM, 256MB of SLC NAND, a MMA8451Q 3-axis accelerometer, a potentiometer, a MicroSD card slot, and some LEDs and buttons.

The TWR-SER daughterboard also provides in addition to the Ethernet connector access to a RS232/484 DB9 connection, a USB Mini-AB connector and a 3-pin CAN connector.

On this board, the expected eCos development model is that programs may be downloaded and debugged via the on-board OSJTAG USB interface, or via a hardware debugger (JTAG/SWD) attached to the JTAG socket. While it is possible to build and install RedBoot or a GDB stub image into the internal FLASH, this is not currently supported.

This documentation describes platform-specific elements of the TWR-K70F120M board support within eCos. The Kinetis variant HAL documentation covers various topics including HAL support common to Kinetis variants, and on-chip device support. This document complements the Kinetis documentation.

Supported Hardware

The MK70FN1M0VMJ12 has two on-chip memory regions. There is a SRAM region of 128KiB present at 0x1FFF0000 and a 1MiB FLASH region present at 0x00000000. The TWR-K70F120M motherboard has 128MiB of SDRAM mapped to 0x08000000.

The Kinetis variant HAL includes support for the six on-chip serial devices which are documented in the variant HAL. For the TWR-K70F120M UART2 is connected to the J8 DB9 connector and also as a virtual serial through the on-board OSJTAG J13 USB connection. There is no connection for hardware flow control (RTS/CTS) lines on this UART3 connection.

Device drivers are provided for the Kinetis on-chip Ethernet MAC, I²C interface and SPI interface. Additionally support is provided for the on-chip watchdog, RTC (wallclock) and a flash driver exists to permit management of the Kinetis's on-chip flash.

Also, whilst the board is fitted with a SLC NAND flash, this is not presently supported by the HAL port. The Kinetis MK70FN1M0VMJ12 processor, and the TWR-K70F120M platform, provide a wide variety of peripherals, but unless support is specifically indicated it should be assumed that support is not included.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3a, **arm-eabi-gdb** version 7.6, and **binutils** version 2.23.2.

Name

Setup — Preparing the TWR-K70F120M Board for eCos Development

Overview

Since the target motherboard provides a built-in hardware debug solution, it is expected that the most common development method when targeting the CPU is to use this hardware debug interface for development. This will either be by loading smaller applications into on-chip SRAM, or by programming larger applications directly into on-chip flash. In the first case, eCos applications should be configured for the variant JTAG startup type, and in the second case for the variant ROM startup type. Since the `TWR-K70F120M` motherboard provides 128MB of external SDRAM it is also possible to configure larger applications for hardware debug using that external memory using the platform JTAG startup type.

Note

When using the platform JTAG startup type to load application programs into the external SDRAM the host hardware debugger configuration is responsible for initialising the necessary CPU I/O to allow GDB to load the application into SDRAM.

HAL Startup Types

For the `twr_k70f120m` platform the Kinetis variant HAL support provides some common startup types, which are extended by the platform HAL. The following variant HAL provided startup types may be selected for applications:

Configuration	Description
ROM	Stand-alone programs running from internal FLASH
SRAM	Programs loading via hardware debugger into **on-chip SRAM**, but expecting RedBoot or GDB stub ROM
RAM	Currently not supported: Programs loading via RedBoot or GDB stub ROM into **on-chip SRAM**
JTAG	Stand-alone programs running from **on-chip SRAM**, loaded via hardware debugger

The following `TWR-K70F120M` platform specific startup types may also be selected for applications:

Configuration	Description
ByVariant	The variant defines the startup configuration
ROM	Stand-alone programs running from internal FLASH
RAM	Currently not supported: Programs loading via RedBoot or GDB stub ROM into **off-chip SDRAM**
JTAG	Stand-alone programs running from **off-chip SDRAM**, loaded via hardware debugger

Further details are available later in this manual.

Preparing OSJTAG interface

The support for using the on-chip OSJTAG interface for hardware debugging and diagnostic output requires that the OSJTAG firmware is at least version `v30.21`. The firmware for the OSJTAG interface can be checked, and updated if needed, using the relevant firmware updater tool available for download via the Freescale website. Unfortunately the official firmware updater is only available for the Windows platform at the moment.

Programming ROM images

To program ROM startup applications into flash a hardware debugger that understands the Kinetis flash may be used. For example, the Ronetix PEEDI provides suitable support.

Warning

Due to a security feature of the Kinetis CPUs care should be taken to avoid completely erasing the flash to ensure the required `FSEC` value in the flash configuration field is not lost. For example when using the PEEDI the user should NOT use the “erase” suffix to the **flash program** command. The Kinetis aware **flash erase chip** should be executed to erase the flash prior to using the **flash program** command.

Programming ROM images with a Ronetix PEEDI

This section describes how to program ROM images using a Ronetix PEEDI debugger.

The PEEDI must be configured to allow communication with your local network, and configured with the parameters for interfacing with the target board. It must then be used to download and program the ROM image into the internal flash. The following steps give a typical outline for doing this. Consult the PEEDI documentation for alternative approaches, such as using FTP or HTTP instead of TFTP.

Preparing the Ronetix PEEDI JTAG debugger

1. Prepare a PC to act as a host and start a TFTP server on it.
2. Connect the PEEDI JTAG debugger via both serial and ethernet to the host PC and power it on. Use the serial cable supplied with the PEEDI (straight through, not null modem).
3. Verify the PEEDI is using up-to-date firmware, of version 12.3.0 or later. Older PEEDI firmware does not support the Kinetis family correctly, particularly if wishing to use the PEEDI's own '**flash**' commands to modify the on-chip flash. If the firmware is not recent enough, follow the PEEDI User Manual's instructions which describe how to update the PEEDI firmware.
4. Locate the PEEDI configuration file `peedi_twr_k70f120m.cfg` within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/kinetis/twr_k70f120m/`*`VERSION`*`/misc` relative to the root of your eCos installation.
5. Place the PEEDI configuration file in a location on the PC accessible to the TFTP server. Later you will configure the PEEDI to load this file via TFTP as its configuration file.
6. Open `peedi_twr_k70f120m.cfg` in an editor such as emacs or notepad and insert your own license information in the `[LICENSE]` section.
7. Install and configure the PEEDI in line with the PEEDI Quick Start Guide or User's Manual, especially configuring PEEDI's RedBoot with the network information. Configure it to use the `peedi_twr_k70f120m.cfg` target configuration file on the TFTP server at the appropriate point of the **config** process, for example with a path such as: `tftp://192.168.7.9/peedi_twr_k70f120m.cfg`
8. Reset the PEEDI.
9. Connect to the PEEDI's CLI interface via TCP/IP on the standard telnet port 23. The **telnet** application is suitable for this. You should see output similar to the following:

```
$ telnet 192.168.7.225
Trying 192.168.7.225...
Connected to 192.168.7.225.
Escape character is '^]'.

Preparing the TWR-K70F120M board for programming with PEEDI

Follow the steps in this section in order to allow communication between the board and the host PC, and between the board and the PEEDI device.

If programming an application which uses serial output, you should first:

1. If OSJTAG firmware 30.21 or later is installed then the motherboard J13 USB provides a standard CDC-ACM virtual serial connection to the host computer. The alternative is to connect a null modem cable between the DB9 RS232 connector on the TWR-SER daughterboard and the host computer.

2. Start a suitable terminal emulator on the host computer such as **minicom** on Linux or PuTTY on Windows. Set the communication parameters to 38400 baud, 8 data bits, no parity bit and 1 stop bit with no flow control.

For all applications, you must:

1. Connect the board to the PEEDI using an appropriate 20-pin cable from the JTAG interface connector to the Target port on the PEEDI. This will normally be a PEEDI-CORTEX20 adapter.

2. Power up the `TWR-K70F120M` board.

3. Connect to the PEEDI's telnet CLI on port 23 as before.

4. Confirm correct connection with the PEEDI with the **reset reset** command as follows:

```
twr_k70f120m> reset reset
++ info: user reset
twr_k70f120m>
++ info: RESET and TRST asserted
++ info: TRST released
++ info: TAP : IDCODE = 0x2BA01477, Cortex M3 SWD
++ info: RESET released
++ info: core connected

CORE0 -> CortexM4 - stopped by breakpoint
         PC=0x1FFF0006, xPSR=0x01000000

core #0 stopped
++ info: core 0: initialized

twr_k70f120m>
```

Installation into flash

The following describes the procedure for installing a ROM application into on-chip flash, using the GDB stub ROM image as an example of such an application.

1. Use **arm-eabi-objcopy** to convert the linked application, in ELF format, into binary format. For example:

```
$ arm-eabi-objcopy -O binary programname programname.bin
```

2. Copy the binary file (.bin file) into a location on the host computer accessible to its TFTP server.

3. Connect to the PEEDI's telnet interface, and program the image into flash with the following commands, replacing *`TFTP_SERVER`* with the address of the TFTP server and *`/BINPATH`* with the location of the .bin file relative to the TFTP server root directory. For example for a RedBoot ROM image:

```
twr_k70f120m> flash erase chip

erasing chip at 0x00000000
done.
```

```
++ info: successfully erased 1 byte in 0.33 sec

twr_k70f120m> flash program tftp://TFTP_SERVER/BINPATH/redboot.bin bin 0x00000000
++ info: Programming image file: tftp://TFTP_SERVER/redboot.bin
++ info: Programming directly
++ info: At absolute address:    0x00000000
programming at 0x00000000
programming at 0x00001000
programming at 0x00002000

programming at 0x00015000

++ info: successfully programmed 88.00 KB in 0.74 sec

twr_k70f120m>
```

The installation into flash is now complete. For applications which print output on startup to the USART3 RS232 serial port, such as the GDB stub ROM application, this can easily by tested by powering off the board, disconnecting the JTAG, and then powering on the board again. In the case of the GDB stub ROM image, output similar to the following should be visible (although specific numbers may differ):

```
$T050f:72250008;0d:f0ff0120;#8a
```

RedBoot

RedBoot is currently unsupported.

Name

Configuration — Platform-specific Configuration Options

Overview

The Freescale TWR-K70F120M platform HAL package is loaded automatically when eCos is configured for the `twr_k70f120m` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The TWR-K70F120M board platform HAL package supports separate variant and platform startup types:

ROM

> This startup type can be used for finished applications which will be programmed into internal flash ROM at location 0x00000000. Data and BSS will be put into internal SRAM starting from 0x1FFF0000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with ROM mapped at location zero. eCos startup code will perform all necessary hardware initialization.

RAM

> Currently unsupported, this is the startup type which is used if relying on either a RedBoot or a GDB stub ROM image programmed into internal flash to download and run applications into RAM via arm-eabi-gdb. It is assumed that the hardware has already been initialized by the ROM monitor. By default the application will use the eCos virtual vectors mechanism to obtain services from the ROM monitor, including diagnostic output.

JTAG

> This is the startup type used to build applications that are loaded via a hardware debug interface. The application will be self-contained with no dependencies on services provided by other software. For the variant JTAG startup type the eCos run-time will perform all necessary hardware initialization. When using the platform JTAG startup type the hardware debugger configuration is responsible for initialising the clocks and DDRMC necessary to allow access to the off-chip SDRAM where applications will be loaded.

Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the GDB stub ROM (or RedBoot).

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The TWR-K70F120M board uses the Kinetis's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, is only expected to be available to be used on the UART2 port.

As well as the polled HAL diagnostic interface, there is also a CYGPKG_IO_SERIAL_FREESCALE_UART package which contains all the code necessary to support interrupt-driven operation with greater functionality. All six UARTs can be supported by this driver. Note that it is not recommended to use this driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option (within the generic serial driver support package CYGPKG_IO_SERIAL) is enabled in the configuration. By default this will only enable support in the driver for the UART2 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports.

Ethernet Driver

The TWR-SER daughterboard is fitted with an Ethernet port connected via a KSZ8041NL PHY to the TWR-K70F120M on-chip Ethernet MAC. This is supported in eCosPro with a driver contained in the package CYGPKG_DEVS_ETH_FREESCALE_ENET.

The driver will be inactive (not built and greyed out in the eCos Configuration Tool) unless the “Common Ethernet support” (CYGPKG_IO_ETH_DRIVERS) package is included in your configuration. As the Kinetis ethernet driver is likely to be used in deeply embedded, low footprint, applications it is most appropriate to choose the lwip_eth template as a starting point when choosing an eCos configuration, which will cause the necessary packages to be automatically included.

SPI Driver

A Kinetis SPI bus driver is available in the package “Freescale DSPI driver” (CYGPKG_DEVS_SPI_FREESCALE_DSPI).

No SPI devices are instantiated by default. Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the Freescale DSPI device driver.

I²C Driver

A Kinetis I²C hardware driver is available in the package “Freescale I2C driver” (CYGPKG_DEVS_I2C_FREESCALE_I2C).

Flash Driver

The Kinetis's on-chip flash may be programmed and managed using the flash driver located in the “Kinetis FLASH memory support” (CYGPKG_DEVS_FLASH_KINETIS) package. This driver is enabled automatically if the generic “Flash device drivers” (CYGPKG_IO_FLASH) package is included in the eCos configuration.

The driver will configure itself automatically for the size and parameters of the specific Kinetis variant present on the TWR-K70F120M board.

Name

JTAG/SWD support — Usage

Use of JTAG/SWD for debugging

JTAG/SWD can be used to single-step and debug loaded applications, or even applications resident in ROM, including the GDB stub ROM.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M4 core of the K70-series only supports six such hardware breakpoints, so they may need to be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints such as at `main()`. Some JTAG/SWD devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. This should **not** be necessary when using a SWD-based hardware debugger.

The default eCos configuration does not enable the use of ITM stimulus ports for the output of HAL diagnostics or Kernel instrumentation. If ITM output is required the architecture HAL package `CYGPKG_HAL_CORTEXM` provides options to enable such use. The host hardware debugger configuration may also need to be updated to provide the necessary ITM enable and capture support.

For HAL diagnostic (e.g. `diag_printf()`) output the architecture CDL option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_INTERFACE` should be updated to select `ITM` as the output destination. Once the `ITM` option has been configured the option `CYGHWR_HAL_CORTEXM_DIAGNOSTICS_ITM_PORT` allows the actual stimulus port used for the diagnostics to be selected.

When the Kernel instrumentation option `CYGPKG_KERNEL_INSTRUMENT` is enabled then the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION` option can be enabled to direct instrumentation record output via an ITM stimulus port, rather than into a local memory buffer. The stimulus port used can be configured via the `CYGHWR_HAL_CORTEXM_ITM_INSTRUMENTATION_PORT_BASE` option.

Normally a notable disadvantage with JTAG/SWD debugging is that it does not allow thread-aware debugging, such as the ability to inspect different eCos threads or their stack backtraces, set thread-specific breakpoints, and so on. Fortunately the Ronetix PEEDI JTAG unit does support thread-aware debugging of eCos applications, however extra configuration steps are required. Similarly OpenOCD has support for interpreting eCos thread information. Consult the PEEDI or OpenOCD documentation for more details as usage is beyond the scope of this document.

OpenOCD notes

The OpenOCD debugger can be configured to support the on-board OSJTAG interface available via the USB J13 connection.

An example OpenOCD configuration file `openocd_twr_k70f120m.cfg` is provided within the eCos platform HAL package in the source repository. This will be in the directory `packages/hal/cortexm/kinetis/twr_k70f120m/`*`VERSION`*`/misc` relative to the root of your eCos installation.

This configuration file can be used with OpenOCD on the host as follows:

```
$ openocd -f openocd_twr_k70f120m.cfg
Open On-Chip Debugger 0.8.0-dev-hg8c51ca8dbc00-dirty (2013-09-09-17:18)
Licensed under GNU GPL v2
For bug reports, read
    http://openocd.sourceforge.net/doc/doxygen/bugs.html
Info : only one transport option; autoselect 'jtag'
srst_only separate srst_gates_jtag srst_open_drain connect_deassert_srst
cortex_m3 reset_config sysresetreq
Info : add flash_bank kinetis k70.pflash
Info : OSBDM has opened
Info : This adapter doesn't support configurable speed
Info : JTAG tap: k70.cpu tap/device found: 0x4ba00477 (mfg: 0x23b, part: 0xba00, ver: 0x4)
START...
Info : k70.cpu: hardware has 6 breakpoints, 4 watchpoints
END...
Info : accepting 'gdb' connection from 3333
Halting CPU...
Info : JTAG tap: k70.cpu tap/device found: 0x4ba00477 (mfg: 0x23b, part: 0xba00, ver: 0x4)
START...
END...
```

By default **openocd** provides a telnet console on port `4444`, and this can be used to interact with the target system. This console interface can be used to perform debugging, program the flash, etc.

To debug the target from the command line, **arm-eabi-gdb** should be connected to OpenOCD using it's default GDB server port of `3333`. For example:

```
(gdb) target remote localhost:3333
Remote debugging using localhost:3333
0x1fff0006 in ?? ()
(gdb) monitor reset halt
JTAG tap: k70.cpu tap/device found: 0x4ba00477 (mfg: 0x23b, part: 0xba00, ver: 0x4)
target state: halted
target halted due to debug-request, current mode: Thread
xPSR: 0x01000000 pc: 0x00004e9c msp: 0x2000f800
(gdb)
```

The application can then be loaded and executed under GDB as normal. If you are using Eclipse then you may need to define a “preload” gdb macro to emit any necessary commands to OpenOCD prior to loading or executing. See the “Hardware Assisted Debugging” section of the “Eclipse/CDT for eCos application development” document's “Debugging eCos applications” chapter.

If you need to build your own copy of OpenOCD then when configuring the **openocd** tool build, the **configure** script can be given the option `--enable-osbdm` to provide for OSJTAG support.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi_twr_k70f120m.cfg` file supplied in the platform HAL package should be used to setup and configure the hardware to an appropriate state to load programs.

The `peedi_twr_k70f120m.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to hardware breakpoints. If the breakpoint type is changed remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

The PEEDI provides a telnet console on the standard telnet port (`23`) for configuration and control, and gdb remote debugging access via port `9000`. For example, to use the command line **arm-eabi-gdb** to connect to the target via the PEEDI, you would issue the following gdb command:

```
(gdb) target remote 111.222.333.444:9000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi_twr_k70f120m.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, and then the '**go**' command is given, the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after reset. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi_twr_k70f120m.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset and run the resident flash program without being required to always type '**go**' every time. Finally, it is also possible to set a temporary default (unless the PEEDI is reset) by giving an argument to the **reset** command, for example **reset run**. Use the command **help reset** at the PEEDI command prompt for more options.

Suitably configured applications can be loaded either via GDB, or directly via the telnet CLI into RAM for execution. For example:

```
twr_k70f120m> memory load tftp://192.168.7.9/test.bin bin 0x20000000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x20000000
loading at 0x20000000
loading at 0x20004000

Successfully loaded 28KB (29064 bytes) in 0.1s
twr_k70f120m> go 0x20000000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

For Eclipse users wishing to debug ROM startup programs resident in flash, it is worth highlighting that it is possible to use the eCosCentric Eclipse plugin to automatically reprogram flash as the load sequence. To do so, you will need to install and use a TFTP server so that your application can be accessed from the PEEDI from there. You may then use a GDB command file, as described in more detail in the “Eclipse/CDT for eCos application development” manual. This file can then contain contents similar to the following example:

```
define doload
  shell arm-eabi-objcopy -O binary /path/to/eclipse/workspace/projectname/Debug/myapp /path/to/tftp/server/area/myapp.bin
  monitor flash program tftp://10.1.1.1/myapp.bin bin 0x08000000 erase
  set $pc=0x08000000
end
```

Obviously you will need to adjust the paths and names for your system and TFTP server requirements.

Configuration of JTAG/SWD applications

In order to configure the application to be downloaded and debugged via a hardware debugger, it is recommended to use one of the JTAG startup types (JTAG or ROM), which will implicitly cause two important settings to change. Firstly, `CYGSEM_HAL_USE_ROM_MONITOR` will be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option will be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. These configuration changes could also be made by hand, but use of one of the JTAG startup types will just work.

With these changes, any diagnostic output will appear out of the configured diagnostic channel. By default the K60's JTAG startup types output diagnostics via the USB CDC/ACM serial port on the J13 USB connector. Alternatively diagnostic output can be configured to appear in GDB instead. For this to work, you must enable the configuration option `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` in the common HAL package. Then, after you load your application but before running it, you must give GDB the command:

```
(gdb) set hwdebug on
```

Eclipse users can do this by creating a GDB command file with the contents:

```
define postload
  set hwdebug on
end
```

This will be referenced from their Eclipse debug launch configuration. Using GDB command files is described in more detail in the "Eclipse/CDT for eCos application development" manual.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the Freescale TWR-K70F120M hardware, and should be read in conjunction with that specification. The Freescale TWR-K70F120M platform HAL package complements the Cortex-M architectural HAL and the Kinetis variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services, and for the platform JTAG startup where the host debugger configuration is responsible for initialising the DDRMC world for the external SDRAM used to hold the application being loaded.

For ROM startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/twr_k70f120m_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM
: This is located at address 0x1FFF0000 of the memory space, and is 128KiB in size. The eCos VSR table occupies the bottom 512-bytes. The virtual vector table starts at 0x1FFF0200 and extends to 0x20000300. For ROM, and JTAG startups, the top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH
: This is located at address 0x00000000 of the memory space. This region is 1MiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals
: These are accessible from locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the Kinetis User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to 0x1FFF0000 for all startup types, and space for 128 entries allocated, though the K70 sub-family only use 121 entries.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20000200.

hal_interrupt_stack
: This defines the location of the interrupt stack. For all startup types this is allocated to the top of internal SRAM, 0x20010000.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Diagnostic LEDs

Four LEDs are fitted on the board for diagnostic purposes:

Platform HAL manifest	Colour	Board Label
CYGHWR_IO_TWRK70F120M_PIN_LED1	Orange	E1
CYGHWR_IO_TWRK70F120M_PIN_LED2	Yellow	E2
CYGHWR_IO_TWRK70F120M_PIN_LED3	Green	E3
CYGHWR_IO_TWRK70F120M_PIN_LED4	Blue	E4

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow the LEDs to be set:

```
extern void hal_twr_k70f120m_led(char c);
```

The lowest 4-bits of the argument `c` correspond to each of the 4 LEDs (with LED1 as the least significant bit).

The platform HAL will automatically light all of the LEDs when the platform initialisation is complete, however the LEDs are free for application use.

Real-time Characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for the variant ROM startup with optimization flag -O2.

Example 288.1. twr_k70f120m Real-time characterization

```
INFO:<code from 0x00000410 -> 0x00009d6c, CRC 3328>
             Startup, main thrd : stack used   240 size  2336
             Startup : Idlethread stack used   216 size  1440

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    4.00 microseconds (4 raw clock ticks)

Testing parameters:
   Clock samples:            32
   Threads:                   3
   Thread switches:         128

Chapter 289. LM3S Variant HAL

Name

CYGPKG_HAL_CORTEXM_LM3S — eCos Support for the LM3S Microprocessor Family

Description

The Luminary LM3Sxxxx series of Cortex-M microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for the on-chip flash, serial and watchdog devices. In addition it provides common functionality and definitions that LM3S based platform ports may require, as well as definitions useful to application developers.

This documentation covers the LM3S functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the LM3S variant HAL provides. The areas that are specific to platform HALs and not the LM3S variant HAL include:

- memory map and related configuration and setup
- Clock parameters
- GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED/LCD control

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

On-chip memory

The ST LM3S parts include on-chip SRAM, and on-chip FLASH. The RAM consists of up to 64KiB and the FLASH can be up to 512KiB in size depending on model.

Typically, an eCos platform HAL port will expect a GDB stub ROM monitor to be programmed into the LM3S on-chip ROM memory for development, and the board would boot this image from reset. The stub ROM provides GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels. The JTAG interface may also be used for development if a suitable JTAG device is available. For production purposes, applications are programmed into external or on-chip FLASH and will be self-booting.

On-Chip FLASH

The package `CYGPKG_DEVS_FLASH_LM3S` provides a driver for the on-chip flash. This driver conforms to the Version 2 flash driver API. It queries the microcontroller's device capabilities registers to determine the size and layout of the flash at runtime.

Cache Handling

The LM3S does not contain any caches, however, the variant HAL supplies the `cyg/hal/hal_cache.h` header to satisfy generic code. This header describes zero sized caches and provides null macros for the required functions.

Serial I/O

The LM3S variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_CORTEXM_LM3S` which provides configuration for the generic `CYGPKG_IO_SERIAL_ARM_PL011` driver package. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

The HAL defines CDL interfaces, `CYGINT_HAL_LM3S_UART0` to `CYGINT_HAL_LM3S_UART4` for each of the possible UARTs. At present no LM3S device has more that 3 UARTs, so these interfaces contain support for future expansion. The platform HAL CDL should contain an **implements** directive for each such UART that is available for use on the board. This will enable use of the UART for diagnostic use.

The LM3S UARTs provide only TX and RX data lines, although the PL011 macrocell is theoretically capable of RTS/CTS flow control.

Interrupts

The LM3S HAL relies on the architectural HAL to provide support for the interrupts directly routed to the NVIC. The `cyg/hal/var_intr.h` header defines the vector mapping for these.

GPIO

The variant HAL provides support for packaging the configuration of a GPIO line into a single 32-bit descriptor that can then be used with macros to configure the pin and set and read its value.

Clock Distribution

The variant HAL provides support for packaging the clock control parameters of a device into a single 32-bit descriptor that can then be used with macros to enable and disable the device's clock.

I2C Support

The variant HAL provides a driver for the I²C bus device. There is a configuration option, `CYGNUM_HAL_LM3S_I2C_BUS0_CLOCK`, that defines the clock speed at which the bus operates. The platform HAL must define the set of devices attached to the bus.

SPI Support

The SSI device is based on the ARM PL022 SSP primecell and SPI support is provided via the separate `CYGPKG_DEVS_SPI_ARM_PL022` driver. The platform HAL must define the bus instances and devices attached to them.

Profiling Support

The LM3S HAL contains support for **gprof**-base profiling using a sampling timer. The default timer used is Timer 0. The timer used is selected by a set of `#define`s in `src/lm3s_misc.c` which can be changed to refer to a different timer if required. This timer is only enabled when `CYGPKG_PROFILE_GPROF` is enabled, otherwise it remains available for application use.

Clock Control

The platform HAL must provide the input clock frequency (`CYGARC_HAL_CORTEXM_LM3S_INPUT_CLOCK`) in its CDL file. This is then combined with the following options defined in this package to define the default system clocks:

CYGHWR_HAL_CORTEXM_LM3S_CLOCK_SOURCE

> This defines the source of the main system clock. It can take one of six values: `INT` selects the internal ocillator, `INTby4` selects the internal ocillator divided by 4, `MAIN` selects the main ocillator, `PLL` selects the PLL, `30K` selects the 30KHz internal clock, `32K` selects the 32KHz internal clock. It defaults to `PLL`.

CYGHWR_HAL_CORTEXM_LM3S_CLOCK_SYSCLK_DIV

> This defines the divider applied to the 400MHz PLL output to generate the system clock. This can take values between 1 and 16. The default value is 4, giving a 50MHz system clock.

CYGHWR_HAL_CORTEXM_LM3S_CLOCK_PWM_DIV

> This defines the prescaler divider for the Pulse Width Modulator. It may take any power of 2 value between 1 and 64. The default is 1.

The actual values of the system clock, in Hz, is stored in the global variable `hal_lm3s_sysclk`. The clock supplied to the SysTick timer, SYSCLK/4, is also assigned to `hal_cortexm_systick_clock`. These variables are used, rather than configuration options, in anticipation of future support for power management by varying the system clock rate.

Name

GPIO Support — Details

Synopsis

#include <cyg/hal/hal_io.h>

pin = **CYGHWR_HAL_LM3S_GPIO**(*port*, *bit*, *drive*, *mode*);

CYGHWR_HAL_LM3S_GPIO_SET (*pin*);

CYGHWR_HAL_LM3S_GPIO_OUT (*pin*, *val*);

CYGHWR_HAL_LM3S_GPIO_IN (*pin*, **val*);

Description

The LM3S HAL provides a number of macros to support the encoding of GPIO pin identity and configuration into a single 32 bit descriptor. This is useful to drivers and other packages that need to configure and use different lines for different devices.

A descriptor is created with `CYGHWR_HAL_LM3S_GPIO(port, bit, mode)` which takes the following arguments:

port
: This identifies the GPIO port to which the pin is attached. Ports are identified by letters from A to F.

bit
: This gives the bit or pin number within the port. These are numbered from 0 to 8.

drive
: This defines the drive level for the external pad. It may be set to `2mA`, `4mA` or `8mA`. It may also be set to `8mAS` to add slew rate control.

mode
: This defines the mode in which the pin is to be used. The following values are currently defined: `IN_PULLUP` defines the pin as a GPIO input with a pull up resistor, `IN_PULLDOWN` defines the pin as a GPIO input with a pull down resistor, `OUT_OPENDRAIN` defines the pin as a GPIO output with an open drain, `ALT_DIGITAL` defines the pin as a digital line under the control of a peripheral. `ALT_OD` defines the pin as a digital open drain line under the control of a peripheral. `ALT_ODPU` defines the pin as a digital open drain line with pull up under the control of a peripheral. `ALT_ODPD` defines the pin as a digital open drain line with pull down under the control of a peripheral. `ALT_PP` defines the pin as a digital push-pull line under the control of a peripheral. `ALT_PPPU` defines the pin as a digital pushpull line with pull up under the control of a peripheral. `ALT_PPPD` defines the pin as a digital pushpull line with pull down under the control of a peripheral. This set may be extended as further requirements emerge, so check the sources for new definitions.

The following examples show how this macro may be used:

```
// Define port A pin 0 as a digital device pin with 2mA drive level
#define CYGHWR_HAL_LM3S_UART0_RX                CYGHWR_HAL_LM3S_GPIO( A,  0, 2mA, ALT_DIGITAL )
```

Additionally, the macro `CYGHWR_HAL_LM3S_GPIO_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used.

The remaining macros all take a GPIO pin descriptor as an argument. `CYGHWR_HAL_LM3S_GPIO_SET` configures the pin according to the descriptor and must be called before any other macros. `CYGHWR_HAL_LM3S_GPIO_OUT` sets the output to the value of the least significant bit of the *val* argument. The *val* argument of `CYGHWR_HAL_LM3S_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

Chapter 290. LM3S8962-EVAL Platform HAL

Name

CYGPKG_HAL_CORTEXM_LM3S_LM3S8962_EVAL — eCos Support for the LM3S8962-EVAL Board

Description

The LM3S8962-EVAL board contains a LM3S8962 microcontroller. It has connectors for one UART, MicroSD, USB, CAN, JTAG and various other devices.

For typical eCos development, a GDB stub image is programmed into internal FLASH and the CPU boots directly into that. It is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART0. Alternatively test programs may be downloaded and debugged via a JTAG debugger attached to the JTAG socket. Avaliable RAM is limited to 64KB, so development for larger applications may also consist of programming them to flash and using JTAG to debug them from there.

This documentation describes platform-specific elements of the LM3S8962-EVAL board support within eCos. The LM3S variant HAL documentation covers various topics including HAL support common to LM3S variants, and on-chip device support. This document complements the LM3S documentation.

Supported Hardware

The LM3S has two on-chip memory regions. A RAM region of 64KiB is present at 0x20000000. A FLASH region is present at 0x00000000.

The LM3S variant HAL includes support for the on-chip serial devices which are documented in the variant HAL. UART0 is connected to a USB adaptor, which also serves to provide the board with power.

The platform HAL contains configuration and definitions that allow the ARM PL022 primecell device to be used for SPI devices.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.3.2, **arm-eabi-gdb** version 6.8, and **binutils** version 2.18.

Name

Setup — Preparing the LM3S8962-EVAL Board for eCos Development

Overview

In a typical development environment, the LM3S8962-EVAL board boots from internal flash into the GDB Stubrom. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**.

Stubrom Installation

For serial communications, the Stubrom runs with 8 bits, no parity, and 1 stop bit at 38400 baud. This rate can be changed in the platform HAL configuration. Under normal circumstances, the Stubrom runs in-place from the internal Flash.

Programming The Stubrom

To program the Stubrom into the internal flash either a JTAG debugger that understands the LM3S flash may be used, such as a Ronetix PEEDI or an Abatron BDI3000, or the TI **LM Flash Programmer** may be used. Configuration files for the PEEDI and BDI3000 are supplied in the LM3S8962-EVAL HAL package, and brief instructions for downloading the Stubrom are given in there. If no JTAG debugger is available, then the Stubrom must be downloading using the **LM Flash Programmer**. The following are brief instructions for doing this. The reader is referred to the documentation that comes with the loader for full details.

1. Download the **LM Flash Programmer** and Stellaris FTDI Windows driver either from TI or Luminary Micro websites, or from the CD supplied with the board and install it on a PC running Windows that has an available USB port.

2. Copy the file `stubrom.bin` to a suitable location on the Windows PC.

3. Connect the USB cable supplied with the board between the board and the PC. Follow any instructions to install the driver.

4. Start the **LM Flash Programmer** and in the Configuration tab select the LM3S8962 Ethernet an CAN evaluation board.

5. In the Program tab either type in or browse to the `stubrom.bin` file. Select *"Erase Entire Flash"* and *"Verify After Program"*. Ensure that the *"Program Address Offset"* is zero.

6. Press *"Program"* button and the loader should download and verify the binary file. The programming is now complete and the **LM Flash Programmer** can now be exited.

Whatever mechanism is used to program the Stubrom, something similar to the following output should be seen on the Windows USB virtual COM port when the reset button is pressed:

```
+$T050f:1a220000;0d:f0ff0020;#a7
```

Rebuilding The Stubrom

Should it prove necessary to rebuild the Stubrom binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of the Stubrom are:

```
$ mkdir stubs_lm3s8962_rom
$ cd stubs_lm3s8962_rom
$ ecosconfig new lm3s8962 stubs
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `stubrom.bin`.

Name

Configuration — Platform-specific Configuration Options

Overview

The LM3S8962-EVAL board platform HAL package is loaded automatically when eCos is configured for an `lm3s8962_eval` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The LM3S8962-EVAL board platform HAL package supports three separate startup types:

RAM This is the startup type which is normally used during application development. The board has GDB stubs programmed into internal Flash at location 0x00000000 and uses internal RAM at location 0x20000000. arm-eabi-gdb is then used to load a RAM startup application into memory from 0x20001000 and debug it. It is assumed that the hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain services from the stubs, including diagnostic output.

ROM This startup type can be used for finished applications which will be programmed into internal ROM at location 0x00000000. Data and BSS will be put into internal RAM starting from 0x20000400. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset into ROM at location zero. eCos startup code will perform all necessary hardware initialization.

JTAG This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000400 and entered at that address. eCos startup code will perform all necessary hardware initialization.

Monitors and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the Stubrom.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port 0 will be claimed for HAL diagnostics.

UART Serial Driver

The LM3S8962-EVAL board uses the LM3S's internal UART serial support. As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_CORTEXM_LM3S` package which configures the `CYGPKG_IO_SERIAL_ARM_PL011` for use in the LM3S series. Both UARTs can be supported by this driver, although only UART0 is actually routed to an external connector. Note that it is not recommended to enable this driver on the port used for HAL diagnostic I/O. This driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including the Stubrom.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M3 core of the LM3S only supports two such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.lm3s8962.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs.

The `peedi.lm3s8962.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.lm3s8962.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi.lm3s8962.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
lm3s> memory load tftp://192.168.7.9/test.bin bin 0x20000000
++ info: Loading image file:  tftp://192.168.7.9/test.bin
++ info: At absolute address: 0x00000000
loading at 0x20000000
loading at 0x20004000

Successfully loaded 28KB (29064 bytes) in 0.1s
lm3s> go 0x20000000
```

Consult the PEEDI documentation for information on other formats and loading mechanisms.

Abatron BDI3000 notes

On the Abatron BDI3000, the `bdi3000.lm3s8962.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs.

The `bdi3000.lm3s8962.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **boot** command on the BDI3000 command line interface.

On the BDI3000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI3000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI3000 is powered up, the target will always run the initialization section of the `bdi3000.lm3s8962.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
LM3S> load 0x20000000 test.bin bin
Loading /test.bin , please wait ....
Loading program file passed
LM3S> go 0x20000000
```

Consult the BDI3000 documentation for information on other formats and loading mechanisms.

Configuration of JTAG applications

JTAG applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Both of these settings are made automatically if the JTAG startup type is selected.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the LM3S8962-EVAL board hardware, and should be read in conjunction with that specification. The LM3S8962-EVAL platform HAL package complements the ARM architectural HAL and the LM3S variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM and JTAG startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/lm3s8962_eval_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM
: This is located at address 0x20000000 of the memory space, and is 64KiB in size. The eCos VSR table occupies the bottom 512 bytes. The virtual vector table starts at 0x00000200 and extends to 0x00000300. The top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH
: This is located at address 0x00000000 of the memory space. This region is 256KiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals
: These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the LM3S User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to 0x20000000 for all startup types, and space for 128 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20000200. To permit expansion and possible addition of other tables, the linker scripts then allocate further sections from 0x20000400.

hal_interrupt_stack
: This defines the location of the interrupt stack. For all startups, this is allocated to the top of internal SRAM, 0x20010000.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Chapter 291. LPC1XXX Variant HAL

Name

`CYGPKG_HAL_CORTEXM_LPC1XXX` — eCos Support for the LPC1XXX Microprocessor Family

Description

The NXP LPC1XXX series of Cortex-M microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for the on-chip flash, serial, SPI and I²C devices. In addition it provides common functionality and definitions that LPC1XXX based platform ports may require, as well as definitions useful to application developers.

This documentation covers the LPC1XXX functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the LPC1XXX variant HAL provides. The areas that are specific to platform HALs and not the LPC1XXX variant HAL include:

- memory map and related configuration and setup
- Clock parameters
- GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED/LCD control

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

On-chip memory

The LPC1XXX parts include on-chip SRAM, and on-chip FLASH. The RAM consists of up to 64KiB in one or two disjoint blocks, and the FLASH can be up to 512KiB in size depending on model.

Typically, an eCos platform HAL port will expect a GDB stub ROM monitor to be programmed into the LPC1XXX on-chip ROM memory for development, and the board would boot this image from reset. The stub ROM provides GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels. The JTAG interface may also be used for development if a suitable JTAG device is available. For production purposes, applications are programmed into on-chip FLASH and will be self-booting.

On-Chip FLASH

The package `CYGPKG_DEVS_FLASH_LPC2XXX` provides a driver for the on-chip flash. This driver conforms to the Version 2 flash driver API. It queries the microcontroller's device capabilities registers to determine the size and layout of the flash at runtime. This driver is shared with the LPC2xxx microcontroller family, and its name reflects that.

Cache Handling

The LPC1XXX does not contain any caches, however, the variant HAL supplies the `cyg/hal/hal_cache.h` header to satisfy generic code. This header describes zero sized caches and provides null macros for the required functions.

Serial I/O

The LPC1XXX variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: `CYGPKG_IO_SERIAL_CORTEXM_LPC1XXX` which provides configuration for the generic `CYGPKG_IO_SERIAL_GENERIC_16X5X` driver package. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

The HAL defines CDL interfaces, `CYGINT_HAL_LPC1XXX_UART0` to `CYGINT_HAL_LPC1XXX_UART3` for each of the possible UARTs. The platform HAL CDL should contain an **implements** directive for each such UART that is available for use on the board. This will enable use of the UART for diagnostic use.

UARTs 0, 2 and 3 only support TX and RX lines, however UART1 supports the full set of modem control lines.

Interrupts

The LPC1XXX HAL relies on the architectural HAL to provide support for the interrupts directly routed to the NVIC. The `cyg/hal/var_intr.h` header defines the vector mapping for these.

GPIO

The variant HAL provides support for packaging the configuration of a GPIO line into a single 32-bit descriptor that can then be used with macros to configure the pin and set and read its value.

Clock Distribution

The variant HAL provides support for packaging the clock control parameters of a device into a single 32-bit descriptor that can then be used with macros to enable and disable the device's clock.

I2C Support

A separate driver, `CYGPKG_DEVS_I2C_NXPI2C` provides support for I²C devices. The platform HAL must define the set of devices attached to each bus and must also configure the pins used for each I²C bus.

SPI Support

The SSP device is based on the ARM PL022 SSP primecell and SPI support is provided via the separate `CYGPKG_DEVS_SPI_ARM_PL022` driver. The platform HAL must define the bus instances and devices attached to them.

Profiling Support

The LPC1XXX HAL contains support for **gprof**-base profiling using a sampling timer. The default timer used is Timer 0. The timer used is selected by a set of `#define`s in `src/lpc1xxx_misc.c` which can be changed to refer to a different timer if required. This timer is only enabled when `CYGPKG_PROFILE_GPROF` is enabled, otherwise it remains available for application use.

Clock Control

The platform HAL must provide the input clock frequency (`CYGHWR_HAL_LPC1XXX_INPUT_CLOCK`) in its CDL file. This is then combined with the following options defined in this package to define the default system clocks:

CYGHWR_HAL_CORTEXM_LPC1XXX_CLOCK_SOURCE

> This defines the source of the main system clock. It can take one of three values: `IRC` selects the internal ocillator, `OSC` selects the main ocillator, `RTC` selects the 32KHz internal clock. It defaults to `OSC`.

CYGHWR_HAL_CORTEXM_LPC1XXX_CLOCK_SYSCLK_DIV

> This defines the divider applied to the 400MHz PLL output to generate the system clock. This can take values between 1 and 16. The default value is 4, giving a 50MHz system clock.

CYGHWR_HAL_CORTEXM_LPC1XXX_PLL0_MUL

> This defines the multiplier applied by PLL0 to the selected clock input. It can vary between 6 and 512. The default is 6.

CYGHWR_HAL_CORTEXM_LPC1XXX_PLL0_PREDIV

> This defines the pre-divider for PLL0. It may take any value betwen 1 and 32. The default is 1.

CYGHWR_HAL_CORTEXM_LPC1XXX_CCLK_SOURCE

> This defines the source of the main CPU clock, CCLK. The options are `PLL` to select PLL0 and `SYSCLK` to bypass the PLL and use the system clock directly. The default is `PLL`.

CYGHWR_HAL_CORTEXM_LPC1XXX_CCLK_DIV

> This defines the divider applied to the selected CCLK. It may range between 3 and 256. The default is 3.

The actual frequency of the system clock, in Hz, is stored in the global variable `hal_lpc1xxx_sysclk`. Similarly the frequency of the PLL output clock is stored in `hal_lpc1xxx_pllclk` and of CCLK in `hal_lpc1xxx_cclk`. The clock supplied to the

SysTick timer, CCLK, is also assigned to `hal_cortexm_systick_clock`. These variables are used, rather than configuration options, in anticipation of future support for power management by varying the system clock rate.

Name

GPIO Support — Details

Synopsis

#include <cyg/hal/hal_io.h>

`pin = ` **`CYGHWR_HAL_LPC1XXX_GPIO`**`(`*`port`*`, `*`bit`*`, `*`mode`*`);`

`CYGHWR_HAL_LPC1XXX_GPIO_SET`` (`*`pin`*`);`

`CYGHWR_HAL_LPC1XXX_GPIO_OUT`` (`*`pin`*`, `*`val`*`);`

`CYGHWR_HAL_LPC1XXX_GPIO_IN`` (`*`pin`*`, `*`*val`*`);`

Description

The LPC1XXX HAL provides a number of macros to support the encoding of GPIO pin identity and configuration into a single 32 bit descriptor. This is useful to drivers and other packages that need to configure and use different lines for different devices.

A descriptor is created with `CYGHWR_HAL_LPC1XXX_GPIO(port, bit, mode)` which takes the following arguments:

`port`
: This identifies the GPIO port to which the pin is attached. Ports are identified numerically between 0 and 4.

`bit`
: This gives the bit or pin number within the port. These are numbered from 0 to 31.

`mode`
: This defines the mode in which the pin is to be used. The following values are currently defined: `IN_PULLUP` defines the pin as a GPIO input with a pull up resistor, `IN_PULLDOWN` defines the pin as a GPIO input with a pull down resistor, `OUT_OPENDRAIN` defines the pin as a GPIO output with an open drain, `OUT_PULLUP` defines the pin as a GPIO out with a pull up resistor, `OUT_PULLDOWN` defines the pin as a GPIO output with a pull down resistor, `ALT1`, `ALT2`, `ALT3` define the pin as a line under the control of a peripheral. This set may be extended as further requirements emerge, so check the sources for new definitions.

The following examples show how this macro may be used:

```
// Define port 0 pin 2 as a peripheral pin for alternate peripheral 1
#define CYGHWR_HAL_LPC1XXX_UART0_TX             CYGHWR_HAL_LPC1XXX_GPIO( 0,  2, ALT1 )

// Define port 0 pin 16 as a GPIO output pin with a pull up resistor
#define CYGHWR_HAL_LPC1XXX_SPI_CS0              CYGHWR_HAL_LPC1XXX_GPIO(0, 16, OUT_PULLUP)
```

Additionally, the macro `CYGHWR_HAL_LPC1XXX_GPIO_NONE` may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used.

The remaining macros all take a GPIO pin descriptor as an argument. `CYGHWR_HAL_LPC1XXX_GPIO_SET` configures the pin according to the descriptor and must be called before any other macros. `CYGHWR_HAL_LPC1XXX_GPIO_OUT` sets the output to the value of the least significant bit of the *`val`* argument. The *`val`* argument of `CYGHWR_HAL_LPC1XXX_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

Name

Peripheral Clock and Power Control — Description

Synopsis

#include <cyg/hal/hal_io.h>

pin = **CYGHWR_HAL_LPC1XXX_CLOCK**(*device*, *divider*);

CYGHWR_HAL_LPC1XXX_CLOCK_ENABLE (*desc*);

CYGHWR_HAL_LPC1XXX_CLOCK_DISABLE (*desc*);

Description

The LPC1XXX HAL provides a number of macros to support the management of peripheral power supply and clock frequencies. The macro `CYGHWR_HAL_LPC1XXX_CLOCK( device, divider )` encodes a control descriptor into a 32 bit value. The first argument is the name of the device to be described. The second argument gives the divider to be applied to CCLK for the peripheral clock; it can take the values 1, 2, 4 or 8 for most peripherals and 6 (instead of 8) for the CAN device.

The remaining functions all take a peripheral clock/power descriptor as an argument. `CYGHWR_HAL_LPC1XXX_CLOCK_ENABLE( desc )` turns on the power to the peripheral and sets the clock to the rate given in the descriptor. Likewise `CYGHWR_HAL_LPC1XXX_CLOCK_DISABLE( desc )` disables the power to the device.

Chapter 292. MCB1700 Platform HAL

Name

`CYGPKG_HAL_CORTEXM_LPC1XXX_MCB1700` — eCos Support for the MCB1700 Board

Description

The MCB1700 board contains a LPC1768 microcontroller. It has connectors for two UARTs, MicroSD, USB, CAN, a PHY connected to the on-chip MAC, JTAG and various other devices.

For typical eCos development, a GDB stub image is programmed into internal FLASH and the CPU boots directly into that. It is then possible to download and debug stand-alone and eCos applications via the gdb debugger using UART1. Alternatively test programs may be downloaded and debugged via a JTAG debugger attached to the JTAG socket. Avaliable RAM is limited to 64KiB, split into two disjoint 32KiB regions, so development for larger applications may also consist of programming them to flash and using JTAG to debug them from there.

This documentation describes platform-specific elements of the MCB1700 board support within eCos. The LPC1XXX variant HAL documentation covers various topics including HAL support common to LPC1XXX variants, and on-chip device support. This document complements the LPC1XXX documentation.

Supported Hardware

The LPC1768 has three on-chip memory regions. A RAM region of 32KiB is present at 0x0x10000000 and another is at 0x2007C000. A FLASH region is present at 0x00000000.

The LPC1XXX variant HAL includes support for the on-chip serial devices which are documented in the variant HAL. UART0 has reset and ISP control lines connected to the DTR and RTS lines. eCos uses UART1 for console and debug traffic, leaving UART0 free for ISP use.

The platform HAL contains configuration and definitions that allow the SPI and I²C device drivers to be used. This includes access to microSD cards via the on-board slot.

The on-chip Ethernet MAC and the DP83848 PHY are supported.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.3.2, **arm-eabi-gdb** version 6.8, and **binutils** version 2.18.

Name

Setup — Preparing the MCB1700 Board for eCos Development

Overview

Applications can be developed on the MCB1700 board either by using a hardware JTAG-debugger based approach, or via a serial connection between the host and a GDB Stubrom installed on the board. In this latter case the board boots from internal flash into the Stubrom. eCos applications are configured for RAM startup and then downloaded and run on the board via the debugger **arm-eabi-gdb**.

Stubrom Installation

For serial communications, the Stubrom runs with 8 bits, no parity, and 1 stop bit at 38400 baud. This rate can be changed in the platform HAL configuration. Under normal circumstances, the Stubrom runs in-place from the internal Flash.

Programming The Stubrom

This process assumes that a Microsoft Windows host machine with the Embedded Systems Academy Free Flash Magic utility is available. You can install Flash Magic from http://www.flashmagictool.com. This machine also needs an RS232 serial port, either native or through a USB adaptor. In addition to bidirectional data transfer, control is also needed over the DTR and RTS lines. If necessary copy the `stubrom.hex` file to an easily accessible location. The stubrom file is located within your eCosPro installation in the `\eCosPro\ecos-<ver>loaders\mcb1700\gdbstub\ROM\` directory.

Supply the board with power via the USB DEVICE socket and connect a serial cable between the MCB1700 board COM0 port and the host.

Start Flash Magic and set the Communications section to select the host COM port connected to the board, 38400 baud, device LPC1768, Interface “None (ISP)” and 12MHz Oscillator Frequency. Test communication with the board by using the “ISP->Read Device Signature” menu entry. If communication is not successful, check that the serial cable is connected, and the correct COM port is being used.

Check “Erase blocks used by Hex File” under “Erase”. In the “Hex File” section, select the `stubrom.hex` file. Under “Options”, all boxes should be clear except “Verify after programming”. Now press the “Start” button. The utility should show the progress of the upload.

When the process completes, the utility should be closed. Verify the programming has been successful by connecting to the second (COM1) serial port on the board, start a terminal emulation application such as HyperTerminal or minicom on the host PC and set the serial communication parameters to 38400 baud, 8 data bits, no parity, 1 stop bit (8N1) and no flow control (handshaking). Reset the board and the Stubrom should start. The output should be similar to the following:

```
$T050f:6e220000;0d:f07f0010;#80
```

Rebuilding The Stubrom

Should it prove necessary to rebuild the Stubrom binary, this is done most conveniently at the command line. The steps needed to rebuild the the ROM version of the Stubrom are:

```
$ mkdir stubs_mcb1700_rom
$ cd stubs_mcb1700_rom
$ ecosconfig new mcb1700 stubs
$ ecosconfig resolve
$ ecosconfig tree
$ make
```

At the end of the build the `install/bin` subdirectory should contain the file `stubrom.hex`.

Name

Configuration — Platform-specific Configuration Options

Overview

The MCB1700 board platform HAL package is loaded automatically when eCos is configured for an `mcb1700` target. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The MCB1700 board platform HAL package supports three separate startup types:

RAM
: This is the startup type for application development using a GDB stubs based development approach. The Stubsrom is programmed into internal Flash at location 0x00000000 and uses internal RAM at location 0x10000000. arm-eabi-gdb is then used to load a RAM startup application into memory and debug it. The application code is loaded from 0x10001000 and its data and heap go into SRAM at 0x2007C000. It is assumed that the hardware has already been initialized by the stubs. By default the application will use the eCos virtual vectors mechanism to obtain services from the stubs, including diagnostic output.

ROM
: This startup type can be used for finished applications which will be programmed into internal ROM at location 0x00000000. Data and BSS will be put into internal RAM starting from 0x10000400. The remainder of SRAM at 0x10000000 and all of the SRAM at 0x2007C000 will be used for heap. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset into ROM at location zero. eCos startup code will perform all necessary hardware initialization. This startup type can also be used with JTAG debuggers, writing the application image into the flash and then using JTAG to debug the application. This approach makes the best use of the board's frugal memory resources, but does require the additional step of flashing the image onto the board each time.

JTAG
: This is the startup type used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program code expects to be loaded from 0x20000400 and entered at that address and its data and heap go into SRAM at 0x2007C000. eCos startup code will perform all necessary hardware initialization.

Monitors and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building the Stubrom.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then serial port 1 will be claimed for HAL diagnostics.

UART Serial Driver

The MCB1700 board uses the LPC1XXX's internal UART serial support. As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_CORTEXM_LPC1XXX` package which configures the `CYGPKG_IO_SERIAL_GENERIC_16X5X` driver for use in the LPC1XXX series. Both UARTs can be supported by this driver. Note that it is not recommended to enable this driver on the port used for HAL diagnostic I/O. This driver is not active until the `CYGPKG_IO_SERIAL_DEVICES` configuration option within the generic serial driver support package `CYGPKG_IO_SERIAL` is enabled in the configuration.

Name

JTAG support — Usage

Use of JTAG for debugging

JTAG can be used to single-step and debug loaded applications, or even applications resident in ROM, including the Stubrom.

Debugging of ROM applications is only possible if using hardware breakpoints. The Cortex-M3 core of the LPC1XXX only supports two such hardware breakpoints, so they should be used sparingly. If using a GDB front-end such as Eclipse, check it has not set unnecessary extra breakpoints. Some JTAG devices give the option of whether to set hardware or software breakpoints by default. Be sure to configure your device appropriately.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL.

Ronetix PEEDI notes

On the Ronetix PEEDI, the `peedi.mcb1700.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs.

The `peedi.mcb1700.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **reboot** command on the PEEDI command line interface, or press the reset button to make the changes take effect.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.mcb1700.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the `CORE0_STARTUP_MODE` directive in the `[TARGET]` section of the `peedi.mcb1700.cfg` file. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time.

Abatron BDI3000 notes

On the Abatron BDI3000, the `bdi3000.mcb1700.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs.

The `bdi3000.mcb1700.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `BREAKMODE` directive in the `[TARGET]` section. The supplied version of the file defaults to software breakpoints. With this default, hardware breakpoints can still be set from GDB using the **hbreak** command. The default can be changed to hardware breakpoints, and remember to use the **boot** command on the BDI3000 command line interface.

On the BDI3000, debugging can be performed either via the telnet interface or using **arm-eabi-gdb**. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2001 on the BDI3000's IP address. For example:

```
(gdb) target remote 111.222.333.444:2001
```

By default when the BDI3000 is powered up, the target will always run the initialization section of the `bdi3000.mcb1700.cfg` file, and halts the target. This behaviour is repeated with the **reset** command.

If the board is reset with the '**reset**' command, or by pressing the reset button and the '**go**' command is then given, then the board will boot from ROM as normal. A similar effect can be achieved in GDB by connecting with **target remote** and immediately typing **continue** or **c**.

It is also possible for the target to always run, without initialization, after the reset button has been pressed. This mode is selected with the **reset run** command. This conveniently allows the target to be connected to the JTAG debugger, and be able to reset it with the reset button, without being required to always type '**go**' every time. Thereafter, invoking the **reset** command will repeat the previous reset style. Also in this mode, exceptions will be handled by board software, rather than causing the JTAG debugger to halt the CPU.

Suitably configured RAM applications can be loaded either via GDB, or directly via the telnet CLI. For example:

```
MCB1700> load test.srec srec
Loading test.srec , please wait ....
Loading program file passed
MCB1700> go 0x10000420
```

Consult the BDI3000 documentation for information on other formats and loading mechanisms.

Configuration of JTAG applications

JTAG applications can be loaded directly into RAM without requiring a ROM monitor. This loading can be done directly through the JTAG device, or where supported by the JTAG device, through GDB.

In order to configure the application to support this mode, some configuration settings are required. Firstly `CYGSEM_HAL_USE_ROM_MONITOR` must be disabled. Secondly the `CYGDBG_HAL_DIAG_TO_DEBUG_CHAN` option should be enabled in order to prevent HAL diagnostic output being encoded into GDB ($O) packets. Both of these settings are made automatically if the JTAG startup type is selected.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the MCB1700 board hardware, and should be read in conjunction with that specification. The MCB1700 platform HAL package complements the ARM architectural HAL and the LPC1XXX variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM and JTAG startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and GPIO pins. The details of the early hardware startup may be found in the `src/mcb1700_misc.c` in both `hal_system_init` and `hal_platform_init`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory locations are as follows:

Internal RAM

This is located at addresses 0x10000000 and 0x2007C000 of the memory space, and is 64KiB in size, divided into two 32KiB blocks. The eCos VSR table occupies 512 bytes at 0x10000000. The virtual vector table starts at 0x10000200 and extends to 0x10000300. The top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes down from 0x10008000 are reserved for the interrupt stack.

The second 32KiB block is divided into two 16KiB parts, reflecting its organization in the hardware. The lower 16KiB, at 0x2007C000, are available for application use. The upper 16KiB, at 0x20080000, are used by the ethernet driver for packet buffers. If the ethernet device is not used, this memory may be used by applications.

Internal FLASH

This is located at address 0x00000000 of the memory space. This region is 512KiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals

These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the LPC1XXX User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table

This defines the location of the VSR table. This is set to 0x10000000 for all startup types, and space for 128 entries is reserved.

hal_virtual_vector_table

This defines the location of the virtual vector table used to communicate between an ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x10000200. To permit expansion and possible addition of other tables, the linker scripts then allocate further sections from 0x10000400.

hal_interrupt_stack

This defines the location of the interrupt stack. For all startups, this is allocated to the top of internal SRAM, 0x10008000.

hal_startup_stack

This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Chapter 293. SAM3/4/x70 Variant HAL

Name

`CYGPKG_HAL_CORTEXM_SAM` — eCos Support for the SAM3/4 Microprocessor Family

Description

The Atmel SAM3, SAM4 and SAMX70 series of Cortex-M microcontrollers is supported by eCos with an eCos processor variant HAL and a number of device drivers supporting some of the on-chip peripherals. These include device drivers for the on-chip flash, serial, I²C, SPI, CAN, Ethernet, RTC/wallclock and watchdog devices. In addition it provides common functionality and definitions that SAM based platform ports may require, as well as definitions useful to application developers. Throughout this document this processor family will just be referred to as *SAM*, without any numerical designations.

This documentation covers the SAM functionality provided but should be read in conjunction with the specific HAL documentation for the platform port. That documentation will cover issues that are platform-specific and are not covered here, and may also describe differences that override or supersede what the SAM variant HAL provides. The areas that are specific to platform HALs and not the SAM variant HAL include:

- memory map and related configuration and setup
- Clock parameters
- Pin multiplexing and GPIO setup
- Any special handling for external interrupts, or additional interrupts
- Diagnostic I/O baud rates
- Additional diagnostic I/O devices, if any
- LED/LCD control

Name

On-chip Subsystems and Peripherals — Hardware Support

Hardware support

The SAM family contains many on-chip peripherals, many of which are compatible with devices on Atmel SAM3, SAM4, SAMX70, SAM7, SAM9 and SAMA5 parts. Where possible, the drivers are shared, and in places, package names and terminology show this.

On-chip memory

The Atmel SAM parts include on-chip SRAM, and on-chip FLASH. The RAM can vary in size from as little as 4KiB to 384KiB. The FLASH can be up to 2048KiB in size depending on model. There is also support in some models for external SRAM and Flash, which eCos may use where available.

Typically, an eCos platform HAL port will expect a GDB stub ROM monitor or RedBoot image to be programmed into the SAM on-chip ROM memory for development, and the board would boot this image from reset. The stub ROM/RedBoot provides GDB stub functionality so it is then possible to download and debug stand-alone and eCos applications via the gdb debugger using serial interfaces or other debug channels. The JTAG interface may also be used for development if a suitable JTAG adaptor is available. If RedBoot is present it may also be used to manage the on-chip and external flash memory. For production purposes, applications are programmed into external or on-chip FLASH and will be self-booting.

On-Chip FLASH

The package CYGPKG_DEVS_FLASH_AT91IAP ("FLASH memory support for Atmel AT91 IAP") provides a driver for the on-chip flash. This driver conforms to the Version 2 flash driver API, and is automatically enabled if the generic "Flash device drivers" (CYGPKG_IO_FLASH) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific SAM variant by querying the ChipID register.

Cache Handling

The SAM4 contains a small unified cache controller, the variant HAL supplies the cyg/hal/hal_cache.h header to implement cache control. This header describes the cache size and provides macros for enabling and disabling the cache as well as syncing and invalidating cache lines. The cache controller has limited functionality, so not all cache operations are supported.

The SAMX70 variants contain an instruction and data cache controller defined as part of the Cortex-M architectural specification. Support for this controller is supplied by the architecture HAL.

Serial I/O

The SAM variant HAL supports basic polled HAL diagnostic I/O over any of the on-chip serial devices. There is also a fully interrupt-driven serial device driver suitable for eCos applications for all on-chip serial devices. The serial driver consists of an eCos package: CYGPKG_IO_SERIAL_ARM_AT91 which provides support for the SAM on-chip serial devices. Using the HAL diagnostic I/O support, any of these devices can be used by the ROM monitor or RedBoot for communication with GDB. If a device is needed by the application, either directly or via the serial driver, then it cannot also be used for GDB communication using the HAL I/O support. An alternative serial port should be used instead.

The HAL defines CDL interfaces, CYGINT_HAL_CORTEXM_SAM_UART0, CYGINT_HAL_CORTEXM_SAM_UART1 and CYGINT_HAL_CORTEXM_SAM_USART0 to CYGINT_HAL_CORTEXM_SAM_USART3 for each of the available UARTs and USARTs. The platform HAL CDL should contain an **implements** directive for each such UART that is available for use on the board. This will enable use of the UART for diagnostic use.

Caution

For historical compatibility with the shared device drivers, hardware UART0 is mapped to the driver DEBUG UART, hardware USARTs 0 to 3 are mapped to driver UARTs 0 to 3 and hardware UART1 is mapped to driver UART5.

The SAM UARTs provide only TX and RX data lines while the USARTs also implement hardware flow control using RTS/CTS for those USARTs that have them connected.

Interrupts

The SAM HAL relies on the architectural HAL to provide support for the interrupts directly routed to the NVIC. The `cyg/hal/var_intr.h` header defines the vector mapping for these.

GPIO interrupts are currently not fully decoded, so all interrupts originating from a particular GPIO controller are routed to the single interrupt vector for that controller.

Pin Multiplexing and GPIO

The variant HAL provides support for packaging the configuration of a GPIO line into a single 32-bit descriptor that can then be used with macros to configure the pin and set and read its value. Details are supplied later.

RTC/Wallclock

eCos includes RTC (known in eCos as a wallclock) device drivers for the on-chip RTC in the SAM family. This is located in the package `CYGPKG_DEVICES_WALLCLOCK_ARM_AT91` ("AT91 wallclock driver").

Profiling Support

The SAM HAL contains support for **gprof**-base profiling using a sampling timer. The default timer used is Timer Counter 0. The timer used is selected by a set of `#define`s in `src/sam_misc.c` which can be changed to refer to a different timer if required. This timer is only enabled when the gprof profiling package (`CYGPKG_PROFILE_GPROF`) is included and enabled in the eCos configuration, otherwise it remains available for application use.

Clock Control

The platform HAL must provide the input oscillator frequency (`CYGHWR_HAL_CORTEXM_SAM_OSC_MAIN`) in its CDL file. This is then combined with the following options defined in this package to define the default system clocks:

CYGHWR_HAL_CORTEXM_SAM_CLOCK_PLL_DIVA

PLL input clock divider.

CYGHWR_HAL_CORTEXM_SAM_CLOCK_PLL_MULA

PLL input clock multiplier. The resulting PLL output clock will be the main oscillator frequency multiplied by this value and divided by `CYGHWR_HAL_CORTEXM_SAM_CLOCK_PLL_DIVA`.

CYGHWR_HAL_CORTEXM_SAM_CLOCK_PLLADIV2

This is an additional divide-by-two divider applied to the output from the PLL.

CYGHWR_HAL_CORTEXM_SAM_CLOCK_PRES

Processor clock prescaler. The PLL output clock is divided by this value to give the frequency of the master clock that is then distributed to the CPU and peripherals.

CYGHWR_HAL_CORTEXM_SAM_CLOCK_MDIV

> Master clock prescaler. In the SAMX70 variants, the processor clock is further divided by this prescaler to provide the master clock sent to the peripherals.

CYGHWR_HAL_CORTEXM_SAM_FLASH_WAIT

> This option defines the number of wait states applied to flash memory accesses. This will vary with the main clock frequency. The default is to set this to the maximum value.

The actual values of these clocks, in Hz, is stored in global variables `hal_sam_mainck`, `hal_sam_pllack`, `hal_sam_mclk` and `hal_sam_upllck`. The clock supplied to the SysTick timer, MCLK/8, is also assigned to `hal_cortexm_systick_clock`. These variables are set by examining the actual hardware register settings, rather than from the CDL, so they reflect settings made by any bootloader or JTAG adaptor.

Note that when changing or configuring any of these clock settings, you should consult the relevant processor datasheet as there may be both upper and lower constraints on the frequencies of some clock signals, including intermediate clocks. There are also some clocks where, while there is no strict constraint, clock stability is improved if values are chosen wisely. Finally, be aware that increasing clock speeds using this package may have an effect on platform specific properties, such as memory timings which may have to be adjusted accordingly.

Name

GPIO Support on SAM Processors — Details

Synopsis

#include <cyg/hal/hal_io.h>

cyg_uint32 pin = **CYGHWR_HAL_SAM_PIN**(*port*, *bit*, *mode*, *md*, *pupd*, *if*, *int*, *conf*);

cyg_uint32 pin = **CYGHWR_HAL_SAM_PIN_OUT**(*port*, *bit*, *md*, *pupd*);

cyg_uint32 pin = **CYGHWR_HAL_SAM_PIN_IN**(*port*, *bit*, *md*, *pupd*, *if*, *int*);

CYGHWR_HAL_SAM_PIN_SET (*pin*);

CYGHWR_HAL_SAM_GPIO_OUT (*pin*, *val*);

CYGHWR_HAL_SAM_GPIO_IN (*pin*, *val*);

Description

The SAM HAL provides a number of macros to support the encoding of the GPIO pin identity and I/O configuration into a single 32-bit descriptor. This is useful to drivers and other packages that need to configure and use different lines for different devices.

A descriptor is created with one of the 3 variants depending on how the pin is to be used. The support is implemented by the CYGHWR_HAL_SAM_PIN macro, with CYGHWR_HAL_SAM_PIN_IN and CYGHWR_HAL_SAM_PIN_OUT being shorthand helpers when direct GPIO control of a pin is required: CYGHWR_HAL_SAM_PIN_IN defines the pin as an input whose value can be accessed by the user using the macro CYGHWR_HAL_SAM_GPIO_IN (see later), CYGHWR_HAL_SAM_PIN_OUT defines the pin as an output where the user can set the pin output value with the macro CYGHWR_HAL_SAM_GPIO_OUT (see later).

The CYGHWR_HAL_SAM_PIN macro can be used when defining a pin that will be controlled by an on-chip peripheral.

Note

The HAL supplied header file var_io.h provides existing configuration definitions for the majority of the on-chip peripherals supported by eCos, thus obviating the need for the developer to provide their own pin definitions.

The macro variants take a subset of arguments from the following list:

port
This identifies the PIO controller to which the pin is attached. Ports are identified by letters from A to E.

bit
This gives the bit, or pin number, within the controller port. These are numbered from 0 to 31.

mode
This parameter indicates whether the pin is controlled by an on-chip peripheral, or is to be used as a GPIO pin under application control.

Table 293.1. Pin Mode

mode	Details
GPIOIN	The pin is to be configured as an INPUT, and after configuration the CYGHWR_HAL_SAM_GPIO_IN macro can be used to ascertain the pin state.

mode	Details
GPIOOUT	The pin is to be configured as an OUTPUT, and after configuration the CYGHWR_HAL_SAM_GPIO_OUT macro can be used to drive the pin level.
PER_A, PER_B, PER_C, PER_D	The required peripheral mapping when the pin is to be assigned to an on-chip peripheral. The multiplexing of peripheral signals is defined by the CPU variant being targeted, and is beyond the scope of this documentation. When creating pin configurations for on-chip peripherals the relevant Atmel datasheet or technical reference manual should be consulted.

md

This setting indicates whether the pin should be driven in open-drain mode (OPENDRAIN). If the pin is not to be configured as OPENDRAIN this value is unused, but for clarity can be given the setting NA.

pupd

If this is an input pin, or an output pin configured in open-drain mode (whether controlled by GPIO or a peripheral), this setting can be used to indicate whether a weak pull-up resistor (PU) is used, or a weak pull-down resistor (PD) is used. If neither are to be used, then a value of NONE can be given.

if

For input pins (GPIO or peripheral) a glitch (GLITCH) or debouncing (DEBOUNCE) filter can be configured for the pin. When no input filtering is required, or when the field is not relevant due to the other pin configuration fields, the value NONE can be specified.

int

This parameter indicates whether the pin should have an interrupt configuration defined.

Table 293.2. Interrupt Type

int	Details
EDGE_ANY	When an interrupt event should be raised on a pin edge event (rising or falling).
EDGE_RISE	An interrupt should only be raised on rising (LOW->HIGH) edge transitions.
EDGE_FALL	An interrupt should only be raised on falling (HIGH->LOW) edge transitions.
LEVEL_HIGH	Interrupts should be asserted when the pin is at a HIGH level.
LEVEL_LOW	Interrupts should be asserted when the pin is at a LOW level.
NA	This value can be used when an interrupt configuration is not required, or not applicable due to the other pin configuration parameters.

conf

This parameter provides a simple “extension” mechanism; and is treated as a 32-bit binary value that is OR-ed into the pin descriptor. Care must be taken to ensure that existing bitfields within the binary descriptor are not corrupted.

The following examples show how these macros may be used:

```
// Define port B pin 28 as being controlled by peripheral multiplex A,
// which for this pin on SAM devices is UART0 RX, without any
// pull-ups/pull-downs:
#define CYGHWR_HAL_SAM_USART1_RXD CYGHWR_HAL_SAM_PIN(A, 9,PER_A,OPENDRAIN,NONE,NONE,NA,(0))

// Define port D pin 20 as a GPIO output with a pull-down, for an
// active-low LED:
#define CYGHWR_HAL_SAM_LED_AMBER CYGHWR_HAL_SAM_PIN_OUT(D,20,NA,PD)
```

Additionally, the manifest CYGHWR_HAL_SAM_PIN_NONE may be used in place of a pin descriptor and has a value that no valid descriptor can take. It may therefore be used as a placeholder where no GPIO pin is present or to be used. This can be useful when defining pin configurations for a series of instances of a peripheral (e.g. USART ports), but where not all instances support all the same pins (e.g. hardware flow control lines).

The remaining macros all take a suitably constructed GPIO pin descriptor as an argument. The `CYGHWR_HAL_SAM_PIN_SET` macro configures the pin according to the descriptor and must be called before any other macros. `CYGHWR_HAL_SAM_GPIO_OUT` sets the output to the value of the least significant bit of the *`val`* argument. The *`val`* argument of `CYGHWR_HAL_SAM_GPIO_IN` should be a pointer to an int, which will be set to 0 if the pin input is zero, and 1 otherwise.

Further helper macros are available, and it is recommended to consult the header file `<cyg/hal/var_io.h>` (also present in the `include` subdirectory of the SAM variant HAL package within the eCos source repository), for the complete list if needed.

Name

Peripheral clock control — Details

Synopsis

#include <cyg/hal/hal_io.h>

```
cyg_uint32 CYGHWR_HAL_ATMEL_CLOCK_ENABLE(pid);
```

```
CYGHWR_HAL_ATMEL_CLOCK_DISABLE (pid);
```

Description

The HAL provides macros which may be used to enable or disable peripheral clocks. Effectively this indicates whether the peripheral is powered on (enabled) or powered down (disabled), and so may be used to ensure unused peripherals are turned off to save power. The `CYGHWR_HAL_ATMEL_CLOCK_ENABLE` macro will enforce the maximum frequency limitations for particular peripheral blocks, and will return the frequency of the clock used for the enabled peripheral. Such frequency information may be useful to device drivers if clock divider configuration is required.

It is important to remember that before a peripheral can be used, it must be enabled. It is safe to re-enable a peripheral that is already enabled, although usually a device driver will only do so once in its initialisation. eCos will automatically initialise some peripheral blocks where it needs to use the associated peripherals (such as memory controllers and some (but usually not all) PIO banks), and in eCos-supplied device drivers which are included in the eCos configuration. However this should not be relied on - it is always safest to enable the peripheral clocks anyway just in case. Finally, remember that each PIO bank must be enabled separately.

Each peripheral has a unique ID defined by the HAL, and these values are used as the *`pid`* parameter to the enable and disable macros.

Chapter 294. Atmel SAM4E-EK Platform HAL

Name

`CYGPKG_HAL_CORTEXM_SAM4E_EK` — eCos Support for the SAM4E-EK Board

Description

This document covers the configuration and usage of eCos on the Atmel SAM4E-EK evaluation kits. This board is fitted with a SAM4E16 variant of the SAM4 family of microcontrollers.

For typical eCos development it is expected that programs will be downloaded and debugged via a hardware debugger (JTAG/SWD) attached to the standard ARM 20-pin JTAG (J8) connector. Use of a hardware debugging interface avoids the requirement for a debug monitor application to be present on the platform.

Supported Hardware

The SAM variant HAL includes support for the six on-chip serial devices which are documented in the variant HAL. UART0 is connected to the external connector on the board marked DBGU/J7. There is no support for hardware flow control (RTS/CTS) lines on UART0. USART1 is connected to J5 but is configured to support RS485 rather than RS232; it needs a GPIO line to be pulled low and JP11 set to a non-default setting before RS232 is enabled. USART1 supports RTS/CTS flow control.

The SAM instantiates the SPI bus, and an AT25DF321A serial NOR flash is attached to chip select 3. The platform HAL instantiates this flash driver at the virtual address of 0x70000000.

Device drivers provide support for the two I²C (TWI) interfaces, which are instantiated by the platform HAL. These have been tested using external I²C devices, the only on-board I²C device, the QTouch controller, is not supported.

A driver is available for the CAN devices present on the chip, which are connected to external RJ12 sockets.

The board provides the 10/100 Ethernet (MII/RMII) Micrel KSZ8051MNL PHY providing support via the J20 (labelled “ETHERNET”) connector.

A driver for the AFE (Analog Front-End) Controller is available. A test program that uses the V1 potentiometer is present in the platform HAL.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3e, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.23.2.

Name

Setup — Preparing the SAM4E-EK Board for eCos Development

Overview

In a typical development environment the SAM4E-EK board is programmed via a JTAG/SWD interface. This will either be by loading applications into the on-chip SRAM, or into on-chip flash memory. The following sections deal with JTAG/SWD hardware based debugging approaches.

When debugging via JTAG, you are likely to need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. If you are debugging via SWD this should not be necessary.

For debugging applications are loaded and then executed on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. The following describes setting up to use a Ronetix PEEDI debugger for use with GDB.

PEEDI

For the Ronetix PEEDI, the `peedi.sam4e_ek.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. This includes setting up the PLLs and SDRAM controller.

The `peedi.sam4e_ek.cfg` file also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_CortexM3]` section (NOTE: The PEEDI firmware identifies not just M3 CPUs with the `CortexM3` tag). Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect. However, hardware breakpoints only work below address 0x20000000, so should only be used for applications stored in flash.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the `peedi.sam4e_ek.cfg` file, and halts the target. This behaviour is repeated with the PEEDI **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal and run from the contents of the flash.

Both JTAG and ROM startup types default to output of all diagnostics information via UART0 (DBGU). The default communications parameters are 115200 baud, no parity, 1 stop bit.

It is possible to arrange for diagnostics to be output via the JTAG connection and appear on the gdb console. This requires the configuration option `CYGFUN_HAL_GDB_FILEIO` in the common HAL package to be enabled. This has two sub-options, `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` and `CYGSEM_HAL_DIAG_VIA_GDB_FILEIO_IMMEDIATE`, that are enabled by default when `CYGFUN_HAL_GDB_FILEIO` is enabled and both should remain enabled. In this case, when **arm-eabi-gdb** is attached to the PEEDI, the following gdb command must be issued:

```
(gdb) set hwdebug on
```

Eclipse users can do this by creating a GDB command file with the contents:

```
define preload
  set hwdebug on
end
```

This will be referenced from their Eclipse debug launch configuration. Using GDB command files is described in more detail in the "Eclipse/CDT for eCos application development" manual.

Consult the PEEDI documentation for information on other features.

Name

Configuration — Platform-specific Configuration Options

Overview

The SAM4E-EK motherboard platform HAL package is loaded automatically when eCos is configured for a suitable target, e.g. `sam4e_ek`. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The SAM4E_EK board platform HAL package supports three separate startup types:

JTAG

> This is the default startup type. It is used to build applications that are loaded via a JTAG interface. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20000000 and entered at 0x20000408. eCos startup code will perform all necessary hardware initialization.

ROM

> This startup type can be used for finished applications which will be programmed into internal flash at location 0x00400000. Data and BSS will be put into SRAM starting from 0x20000000. The application will be self-contained with no dependencies on services provided by other software. The program expects to boot from reset with flash mapped at location zero. It will then transfer control to the 0x00400000 region. eCos startup code will perform all necessary hardware initialization.

RAM

> This startup type can be used when a board has a GDB stub ROM resident in internal flash. It enables eCos application development without the necessity for a JTAG debugger, providing arm-eabi-gdb connectivity via UART0 (DBGU). The stub is programmed into the on-chip flash memory at 0x00400000 and uses SRAM at location 0x20000000. arm-eabi-gdb is then used to load RAM startup applications into memory from 0x20001000 and debug them. It is assumed that the hardware has already been initialized by the stub ROM. By default the application will use the eCos virtual vectors mechanism to obtain services from the ROM, including diagnostic output.

RedBoot and Virtual Vectors

If the application is intended to act as a ROM monitor, providing services for other applications, then the configuration option `CYGSEM_HAL_ROM_MONITOR` should be set. Typically this option is set only when building GDB Stubs.

If the application is supposed to make use of services provided by a ROM monitor, via the eCos virtual vector mechanism, then the configuration option `CYGSEM_HAL_USE_ROM_MONITOR` should be set. By default this option is enabled when building for a RAM startup, disabled otherwise. It can be manually disabled for a RAM startup, making the application self-contained, as a testing step before switching to ROM startup.

If the application does not rely on a ROM monitor for diagnostic services then the serial port will be claimed for HAL diagnostic output.

UART Serial Driver

The SAM4E_EK board uses the SAM's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, is only expected to be available to be used on the UART0 (DBGU) port. This is because only UART0 is actually routed to an external RS232 connector.

As well as the polled HAL diagnostic interface, there is also a CYGPKG_IO_SERIAL_ARM_AT91 package which contains all the code necessary to support interrupt-driven operation with greater functionality.

It is not recommended to use the interrupt-driven serial driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option within the generic serial driver support package CYGPKG_IO_SERIAL is enabled in the configuration. By default this will only enable support in the driver for the UART0 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports.

USART1 is disabled by default since it requires pins and clocks to be configured and PA23 to be pulled low and a jumper to be changed to support RS232. The option CYGHWR_HAL_CORTEXM_SAM4E_EK_USART1 enables the hardware to be configured; the user must change JP11 to the 2-3 position in order to enable access to USART1 via J5.

SPI Driver

An SPI bus driver is available for the SAM in the package "Atmel AT91 SPI device driver" (CYGPKG_DEVS_SPI_ARM_AT91).

The only SPI device instantiated by default is for an external AT25DF321A NOR flash.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the AT91 SPI device driver.

I²C Driver

Support for SAM I²C (TWI) busses is provided by the "Atmel TWI (I2C) device driver" package (CYGPKG_DEVS_I2C_ATMEL_TWI). The SAM variant HAL causes the two buses to be instantiated. These have been tested using external I²C devices. The only on-board I²C device, the QTouch controller, is not supported.

Ethernet Driver

The AT91SAM4E-EK board uses the AT91SAM4E's internal EMAC ethernet device attached to an external Micrel KSZ8051MNL PHY. The CYGPKG_DEVS_ETH_ARM_AT91 package contains all the code necessary to support this device and the platform HAL package contains definitions that customize the driver to the board. This driver is not active until the generic Ethernet support package, CYGPKG_IO_ETH_DRIVERS, is included in the configuration.

Both the standard and direct (lwIP only) device drivers are supported. The standard driver is enabled by default; the direct driver can be enabled by setting CYGOPT_IO_ETH_DRIVERS_LWIP_DRIVER_DIRECT option.

CAN Driver

The SAM4E has dual CAN devices for CAN support. Device support is via the Atmel SAM CAN Driver (CYGPKG_DEVS_CAN_SAM) package.

The board has two external CAN sockets, J13 and J14, which are RJ12 female sockets.

Consult the generic Chapter 90, *CAN Support* documentation for further details on use of the CAN API, CAN configuration and device drivers.

Flash Driver

The SAM4E's on-chip Flash may be programmed and managed using the Flash driver located in the "FLASH memory support for Atmel AT91 IAP" (CYGPKG_DEVS_FLASH_AT91IAP) package. This driver is enabled automatically if the generic "Flash device drivers" (CYGPKG_IO_FLASH) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific SAM variant present on the SAM4E-EK board.

A number of aspects of Flash driver behaviour can be configured within that driver, such as program/erase parallelism and program burst size. Consult the driver and Part XVIII, “NOR Flash Support” documentation for more details.

ADC Driver

ADC support is provided by the Atmel AFEC ADC Driver (CYGPKG_DEVS_ADC_ATMEL_AFEC) package. By default AFEC0 AD4 is connected to BNC C2 (jumper JP40 pins 1-2 connected). The jumper JP40 can be changed to select AFEC1 AD0 as the ADC input channel (NOTE: For JP40 2-3 the link J37-6 *MUST* be open). The CYGPKG_HAL_CORTEXM_SAM4E_EK_AFE_CN2_JP40 must be set to reflect the state of the jumper.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the SAM4E-EK board hardware, and should be read in conjunction with that specification. The SAM4E-EK platform HAL package complements the Cortex-M architectural HAL and the SAM variant HAL. It provides functionality which is specific to the target board.

Startup

Following a hard or soft reset the HAL will initialize or reinitialize many of the on-chip peripherals. There is an exception for RAM startup applications which depend on a ROM monitor for certain services.

For ROM and JTAG startup, the HAL will perform additional initialization, programming the various internal registers including the PLL, peripheral clocks and pin multiplexing. The details of the early hardware startup may be found in the `src/sam4e_ek_misc.c` in both `hal_system_init()` and `hal_platform_init()`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory areas are as follows:

Internal SRAM

> This is located at address 0x20000000 of the memory space, and is 128KiB in size. The eCos VSR table occupies the bottom 256 bytes, with the virtual vector table starting at 0x20000100 and extending to 0x20000200. The top `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH

> This is located at address 0x004000000 of the memory space and will be mapped to 0x00000000 at reset. This region is 1024KiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals

> These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the SAM4E User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table
: This defines the location of the VSR table. This is set to 0x20000000 for all startup types, and space for 64 entries is reserved.

hal_virtual_vector_table
: This defines the location of the virtual vector table used to communicate between a ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20000100.

hal_interrupt_stack
: This defines the location of the interrupt stack. For all startup types this is allocated to the top of internal SRAM, 0x20020000.

hal_startup_stack
: This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Diagnostic LEDs

Three LEDs are fitted on the board for diagnostic purposes: D2 (blue), D3 (amber) and D4 (green).

The platform HAL header file at `<cyg/hal/plf_io.h>` defines the following convenience function to allow the LEDs to be set:

```
       extern void hal_sam_led(int val);
```

The lowest 3 bits of the argument `val` correspond to each of the 3 LEDs (with D2 as the least significant bit).

The variant HAL signals progress through clock initialization on the LEDs, leaving them all illuminated if initialization is successful. Following this, the LEDs are available for application use.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for JTAG startup.

Example 294.1. sam4e_ek Real-time characterization

```
             Startup, main thrd : stack used   352 size  1536
             Startup : Idlethread stack used    84 size  1280

eCos Kernel Timings
Notes: all times are in microseconds (.000001) unless otherwise stated

Reading the hardware clock takes 0 'ticks' overhead
... this value will be factored out of all other measurements
Clock interrupt took    9.00 microseconds (9 raw clock ticks)

Testing parameters:

Chapter 295. Atmel SAMX70-EK Platform HAL

Name

`CYGPKG_HAL_CORTEXM_SAMX70_EK` — eCos Support for the SAMX70-EK Board

Description

This document covers the configuration and usage of eCos on the Atmel SAMX70 evaluation kits. This includes the SAME70 Xplained and the SAMV71 Xplained Ultra on which this support has been tested. Boards containing other devices in the SAM E70, S70 and V70 family should be supportable with minimal effort.

For typical eCos development it is expected that programs will be downloaded and debugged via a hardware debugger (JTAG/SWD) attached to either the standard ARM 20-pin JTAG connector or via the on-board EDBG USB socket. Use of a hardware debugging interface avoids the requirement for a debug monitor application to be present on the platform.

Supported Hardware

The SAM variant HAL includes support for the on-chip serial devices which are documented in the variant HAL. USART0 is connected to the EXT1 external connector. USART1 is connected to the EXT2 external connector and the EDBG USB socket where it is available as a CDC/ACM interface. There is no support for hardware flow control in either of these devices. USART1 is configured as the default diagnostics console.

Device drivers provide support for the two I²C (TWI) interfaces, which are instantiated by the platform HAL. These have been tested using external I²C devices.

A driver is available for the CAN devices present on the chip, which are available on pins on the various boards.

A driver for the AFE (Analog Front-End) Controller is available. A test program that uses an external potentiometer is present in the platform HAL.

Tools

The board port is intended to work with GNU tools configured for an **arm-eabi** target. The original port was done using **arm-eabi-gcc** version 4.7.3e, **arm-eabi-gdb** version 7.6.1, and **binutils** version 2.23.2.

Name

Setup — Preparing the SAMX70-EK Board for eCos Development

Overview

In a typical development environment the SAMX70-EK board is programmed via a JTAG/SWD interface. This will either be by loading applications into the on-chip SRAM, or into on-chip flash memory. The following sections deal with JTAG/SWD hardware based debugging approaches.

When debugging via JTAG, you may need to disable the default HAL idle thread action, otherwise there may be issues where the target fails to halt and the debugging session is unreliable. More details can be found in the Cortex-M architectural HAL. If you are debugging via SWD this should not be necessary.

For debugging applications are loaded and then executed on the board via the debugger **arm-eabi-gdb**, or via the Eclipse IDE. The following describes setting up to use a Ronetix PEEDI debugger for use with GDB.

PEEDI

For the Ronetix PEEDI, the `peedi.same70xpld.cfg` or `peedi.samv71xult.cfg` file should be used to setup and configure the hardware to an appropriate state to load programs. These files only perform basic initialization by default, leaving application code to initialize PLLs and other clocks. However, these files also contain an alternate initialization section that will initialize the clocks and SDRAM from JTAG.

The configuration files also contains an option to define whether hardware or software breakpoints are used by default, using the `CORE0_BREAKMODE` directive in the `[PLATFORM_CortexM3]` section (NOTE: The PEEDI firmware identifies not just M3 CPUs with the `CortexM3` tag). Edit this file if you wish to use hardware break points, and remember to restart the PEEDI to make the changes take effect. However, hardware breakpoints only work below address 0x20000000, so should only be used for applications stored in flash.

On the PEEDI, debugging can be performed either via the telnet interface or using **arm-eabi-gdb** and the GDB interface. In the case of the latter, **arm-eabi-gdb** needs to connect to TCP port 2000 on the PEEDI's IP address. For example:

```
(gdb) target remote 111.222.333.444:2000
```

By default when the PEEDI is powered up, the target will always run the initialization section of the configuration file, and halts the target. This behaviour is repeated with the PEEDI **reset** command.

If the board is reset (either with the '**reset**', or by pressing the reset button) and the '**go**' command is then given, then the board will boot as normal and run from the contents of the flash.

The JTAG, JTAGEXT, ROM and ROMEXT startup types default to output of all diagnostics information via USART1. The default communications parameters are 115200 baud, no parity, 1 stop bit. It is recommended that USART1 be accessed via the EDBG port.

It is possible to arrange for diagnostics to be output via the JTAG connection and appear on the gdb console. This requires the configuration option `CYGFUN_HAL_GDB_FILEIO` in the common HAL package to be enabled. This has two sub-options, `CYGSEM_HAL_DIAG_TO_GDBFILEIO_CHAN` and `CYGSEM_HAL_DIAG_VIA_GDB_FILEIO_IMMEDIATE`, that are enabled by default when `CYGFUN_HAL_GDB_FILEIO` is enabled and both should remain enabled. In this case, when **arm-eabi-gdb** is attached to the PEEDI, the following gdb command must be issued:

```
(gdb) set hwdebug on
```

Eclipse users can do this by creating a GDB command file with the contents:

```
define preload
  set hwdebug on
end
```

This will be referenced from their Eclipse debug launch configuration. Using GDB command files is described in more detail in the "Eclipse/CDT for eCos application development" manual.

Consult the PEEDI documentation for information on other features.

Name

Configuration — Platform-specific Configuration Options

Overview

The SAMX70-EK motherboard platform HAL package is loaded automatically when eCos is configured for a suitable target, e.g. `samv71_ek` or `same70_ek`. It should never be necessary to load this package explicitly. Unloading the package should only happen as a side effect of switching target hardware.

Startup

The SAMX70_EK board platform HAL package supports four separate startup types:

JTAG

> This is the default startup type. It is used to build applications that are loaded via a JTAG interface into the on-chip SRAM. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x20400000 and entered at 0x20400408. eCos startup code will perform all necessary hardware initialization.

JTAGEXT

> This startup type is used to build applications that are loaded via a JTAG interface, or a boot loader, into the off-chip SDRAM. The application will be self-contained with no dependencies on services provided by other software. The program expects to be loaded from 0x70000000 and entered at 0x70000008. eCos startup code will perform all necessary hardware initialization other than the SDRAM controller, since that is initialised via the H/W (JTAG/SWD) debugger or a flash based boot loader.

ROM

> This startup type can be used for finished applications which will be programmed into internal flash at location 0x00400000 using the on-chip SRAM as the main application RAM area. Data and BSS will be put into SRAM starting from 0x20400000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. To make ROM code run from reset, it is necessary to set the GPNVM1 bit to 1; this can be done via the Atmel SAM-BA utility.

ROMEXT

> This startup type can be used for finished applications which will be programmed into internal flash at location 0x00400000 using the off-chip SDRAM as the main application RAM area. Data and BSS will be put into SDRAM starting from 0x70000000. The application will be self-contained with no dependencies on services provided by other software. eCos startup code will perform all necessary hardware initialization. To make ROM code run from reset, it is necessary to set the GPNVM1 bit to 1; this can be done via the Atmel SAM-BA utility.

The naming of the STARTUP types is for backwards compability with earlier releases that did not support the off-chip SDRAM.

UART Serial Driver

The SAMX70_EK board uses the SAM's internal UART serial support. The HAL diagnostic interface, used for both polled diagnostic output and GDB stub communication, is only expected to be available to be used on the UART0 (DBGU) port. This is because only UART0 is actually routed to an external RS232 connector.

As well as the polled HAL diagnostic interface, there is also a `CYGPKG_IO_SERIAL_ARM_AT91` package which contains all the code necessary to support interrupt-driven operation with greater functionality.

It is not recommended to use the interrupt-driven serial driver with a port at the same time as using that port for HAL diagnostic I/O.

This driver is not active until the CYGPKG_IO_SERIAL_DEVICES configuration option within the generic serial driver support package CYGPKG_IO_SERIAL is enabled in the configuration. By default this will only enable support in the driver for the UART0 port (the same as the HAL diagnostic interface), but the default configuration can be modified to enable support for other serial ports.

SPI Driver

An SPI bus driver is available in the package "Atmel AT91 SPI device driver" (CYGPKG_DEVS_SPI_ARM_AT91).

The only SPI device instantiated by default is for an external AT25DF321A NOR flash used for testing.

Consult the generic SPI driver API documentation in the eCosPro Reference Manual for further details on SPI support in eCosPro, along with the configuration options in the AT91 SPI device driver.

I²C Driver

Support for SAM I²C (TWI) busses is provided by the "Atmel TWI (I2C) device driver" package (CYGPKG_DEVS_I2C_ATMEL_TWI). The SAM variant HAL causes the two buses to be instantiated. These have been tested using external I²C devices.

CAN Driver

The SAMX70-EK has dual MCAN devices for CAN and CAN-FD support. Device support is via the Atmel MCAN CAN Driver (CYGPKG_DEVS_CAN_MCAN) package.

The SAMV71XULT board has an on-board CAN transceiver which is connected to MCAN1 and to CANH and CANL pins on the board. The SAME70XPLD board has no on-board transceiver and the CANTX and CANRX pins for both MCAN0 and MCAN1 are available on the Arduino connectors.

Consult the generic Chapter 90, *CAN Support* documentation for further details on use of the CAN API, CAN configuration and device drivers.

Flash Driver

The on-chip Flash may be programmed and managed using the Flash driver located in the "FLASH memory support for Atmel AT91 IAP" (CYGPKG_DEVS_FLASH_AT91IAP) package. This driver is enabled automatically if the generic "Flash device drivers" (CYGPKG_IO_FLASH) package is included in the eCos configuration. The driver will configure itself automatically for the size and parameters of the specific SAM variant present on the SAMX70-EK board.

Consult the driver and Part XVIII, “NOR Flash Support” documentation for more details.

ADC Driver

ADC support is provided by the Atmel AFEC ADC Driver (CYGPKG_DEVS_ADC_ATMEL_AFEC) package. Some ADC lines are available on the EXT1 and EXT2 headers.

Name

HAL Port — Implementation Details

Overview

This documentation explains how the eCos HAL specification has been mapped onto the SAMX70-EK board hardware, and should be read in conjunction with that specification. The SAMX70-EK platform HAL package complements the Cortex-M architectural HAL and the SAM variant HAL. It provides functionality which is specific to the target board.

Startup

For ROM and JTAG startup, the HAL will perform initialization, programming the various internal registers including the PLL, peripheral clocks and pin multiplexing. The details of the early hardware startup may be found in the `src/samx70_ek_misc.c` in both `hal_system_init()` and `hal_platform_init()`.

Memory Map

The platform HAL package provides the memory layout information needed to generate the linker script. The key memory areas are as follows:

Internal SRAM

> This is located at address 0x20400000 of the memory space, and is 384KiB in size. The eCos VSR table occupies the bottom 256 bytes, with the virtual vector table starting at 0x20000200 and extending to 0x20000300. The top of SRAM is reserved for the MCAN message buffer memory, whose size depends on the MCAN configuration, and below those `CYGNUM_HAL_COMMON_INTERRUPTS_STACK_SIZE` bytes are reserved for the interrupt stack. The remainder of internal RAM is available for use by applications.

Internal FLASH

> This is located at address 0x004000000 of the memory space. This region is 2048KiB in size. ROM applications are by default configured to run from this memory.

On-Chip Peripherals

> These are accessible at locations 0x40000000 and 0xE0000000 upwards. Descriptions of the contents can be found in the SAMX70 User Manual.

Linker Scripts

The platform linker scripts define the following symbols:

hal_vsr_table

> This defines the location of the VSR table. This is set to 0x20000000 for all startup types, and space for 128 entries is reserved.

hal_virtual_vector_table

> This defines the location of the virtual vector table used to communicate between a ROM monitor and an eCos application. This is allocated right after the VSR table, at 0x20400200.

hal_mcan_ram1

> This defines the location of the message RAM for MCAN1. It is allocated at the top of SRAM, and its size is specified by the MCAN package if present, or will be zero if it is not.

hal_mcan_ram0

> This defines the location of the message RAM for MCAN0. It is allocated just before the RAM for MCAN1, and its size is specified by the MCAN package if present, or will be zero if it is not.

hal_interrupt_stack — This defines the location of the interrupt stack. For all startup types this is allocated to the top of internal SRAM just before the MCAN message RAM.

hal_startup_stack — This defines the location of the startup stack. For all startup types it is initially allocated at the half-way point of the interrupt stack.

Real-time characterization

The tm_basic kernel test gives statistics gathered about the real-time characterization and performance of the kernel. The sample output is shown here for information. The test was built for JTAG startup on a SAMV71-XULT board.

Example 295.1. samv71-XULT Real-time characterization

```
Configured
Testing parameters:
   Clock samples:            32
   Threads:                  19
   Thread switches:         128
   Mutexes:                 873
   Mailboxes:               254
   Semaphores:             1528
   Scheduler operations:    128
   Counters:                509

            All done, main thrd : stack used   796 size  1536
            All done : Idlethread stack used   164 size  1280

Timing complete - 27860 ms total

PASS:<Basic timing OK>
EXIT:<done>
```

Chapter 296. STM32 Variant HAL

Name

CYGPKG_HAL_CORTEXM_STM32 — eCos Support for the STM32 Microprocessor Family

Description
